Infants between ages 2 and 6 months are more active, which makes them easier to evaluate. They spend more time awake, they begin to smile and make eye contact, and they recognize parents or caregivers. Healthy infants in this age group will have a strong sucking reflex, active extremity movement, and a vigorous cry. They may follow a bright light or toy with their eyes or turn their heads toward a loud sound or a familiar voice.

During this stage the infant has an increased awareness of what is going on around him or her and will use both hands to examine objects and explore the world. About 70% of infants will sleep through the night by 6 months. At this point in development, infants will begin to roll over.

As with younger infants, persistent crying and irritability can be an indicator of serious illness. A lack of eye contact in a sick infant can also be a sign of significant illness, depressed mental status, or a delay in development.

6 to 12 months

During this stage, infants begin to babble and by their first year, infants can say their first word. These infants also sit without support, progress to crawling, and finally begin to walk. This form of locomotion predisposes this age group to increased exposure to physical dangers. At this age, infants are teething and prone to explore their world by picking things up and placing them in their mouths. This behavior increases the risk for choking and poisonings from toxic substances.

At 6 to 12 months, infants may begin to cry if separated from their parents or caregivers. This behavior is called separation anxiety, which is common among this age group **Figure 34-2**. One way you can limit the infant's agitation is to let the parent or caregiver hold the infant as you start your physical assessment. As with the younger infants, persistent crying or irritability can be a symptom of serious illness.

Assessment

Begin your assessment by observing the infant from a distance, preferably in a parent's or caregiver's arms—this will avoid separation anxiety and often make the assessment of the infant easier. Provide as much sensory comfort as you can: warm your hands and the end of the stethoscope and offer a pacifier if the parent or caregiver allows it. If possible, have a parent or caregiver hold the infant during all procedures or allow them to stay close to the infant. If possible, plan to do any painful or uncomfortable procedures at the end of the assessment process, so that the infant does not become agitated while you are trying to perform a physical examination. Complete each procedure efficiently and avoid interruptions. Explain each procedure to the parent or caregiver before you perform it, because the procedure and the infant's reaction to it may be upsetting.

Figure 34-2 Infants are usually not afraid of strangers, but as they reach 6 months to 1 year, they may become irritable or cry if separated from their parents or caregivers.

The Toddler

After infancy, until about age 3 years, a child is called a **toddler**. Toddlers experience rapid changes in growth and development.

12 to 18 Months

During this period, toddlers begin to walk and to explore their environment. They are able to open doors, drawers, boxes, and bottles. Because they are explorers by nature and are not afraid, injuries in this age group increase. At 12 to 18 months, toddlers begin to imitate the behaviors of older children and parents and may express a desire to dress like their mommies or daddies. The toddler knows major body parts when you point to them and may speak 4 to 6 words. Because of a lack of molars, toddlers may not be able to fully chew their food before swallowing, leading to an increased risk of choking.

18 to 24 Months

The mind of the toddler develops rapidly. At the beginning of this stage, the toddler may have a vocabulary of 10 to 15 words. By age 2 years, a toddler should be able to pronounce approximately 100 words. When you point to a common object, toddlers should be able to name it. At this stage, toddlers begin to understand cause and effect with such activities as playing with pop-up toys (jack-in-the-box) and turning on and off a light switch. The toddler's balance and gait also improve rapidly during this period. Running and climbing are two skills that develop. At this stage, toddlers tend to cling to their parents or caregivers and often have a special object such as a blanket or teddy bear that comforts them when they are separated. Be sure to use any comforting objects when available to help calm the toddler.

Assessment

Stranger anxiety may still develop early in this period. Toddlers may resist separation from parents or caregivers and be afraid to let others come near them. Allow the toddler to hold any special object that brings the toddler comfort ("Would you like to hold your blankie while I listen to your tummy?"). When possible, demonstrate the assessment on a doll or stuffed animal first, which may limit the toddler's anxiety and make it easier to perform the assessment. Because of their newfound independence, they may also be very unhappy about being restrained or held for procedures **Figure 34-3**. Two-year-olds in particular have a well-deserved reputation for having their own ideas about almost everything, which is why these years are often called the "terrible twos."

Toddlers have trouble describing or localizing pain because they do not have the verbal ability to be precise. Pain in the abdomen may be expressed as, "My tummy hurts," and the physical examination may reveal tenderness throughout the body. With this in mind, the use of visual clues and the Wong-Baker FACES pain scale, discussed later in this chapter, can be helpful with this age group.

Toddlers can be curious and adventuresome, so you may be able to distract them **Figure 34-4**. For example, you might allow the toddler to play with a tongue depressor while you assess his or her vital signs. Restrain the toddler for as short a time as possible, and allow him or her to be comforted by the parent or caregiver immediately after a painful procedure. Whenever possible, begin your assessment at the feet or far from the location of any pain to keep from upsetting the toddler.

Figure 34-3 Because of their newfound independence, toddlers may be unhappy about being restrained or held for procedures.

Figure 34-4 Allow a toddler to sit on the parent's or caregiver's lap during your assessment, and use a toy to distract him or her.

Like infants, persistent crying or irritability in a toddler can be a symptom of serious illness or injury. Painful procedures make a lasting impression at this stage. Older toddlers may remember negative experiences with physicians or nurses, such as vaccinations or stitches, and fear treatment. Remember to involve the parent or caregiver in any procedures. This not only provides you with an extra set of hands, but the presence of the parent or caregiver will comfort the toddler. If a parent or caregiver is unavailable, reassure the toddler using simple words and a calm, soothing voice.

The Preschool-Age Child

Preschool-age children (ages 3 to 6 years) are able to use simple language effectively. The most rapid increase in language occurs during this stage of development. These children can walk and run well and begin throwing, catching, and kicking during play. Toilet training is mastered at this stage.

Preschool-age children have a rich imagination, which can make them particularly fearful about pain and change involving their bodies **Figure 34-5**. At this age, they often believe that their thoughts or wishes can cause injury or harm to themselves or to others. They may believe that an injury is the result of a bad deed they did earlier in the day.

They are also learning which behaviors are appropriate and which behaviors will lead to a "time out." Tantrums may occur when preschool-age children feel they cannot control a situation or its outcomes.

The risk of foreign body airway obstruction continues to be high at this age.

Figure 34-5 Preschool-age children have a vivid imagination, so much of the history must still be obtained from the parent or caregiver.

Assessment

Preschool-age children can understand directions, be more specific in describing their sensations, and identify painful areas when questioned. Despite the increased ability to communicate, much of the child's history will still be obtained from parents or caregivers. Remember to communicate simply and directly. Tell the child what you are going to do immediately before you do it; this way, the child has no time to develop frightening fantasies. Also keep in mind that the preschool-age child can be very literal. Asking if you may "take" his or her blood pressure may lead the child to believe that you will not give it back. Use plain language and provide plenty of reassurance.

At this age, preschool-age children are easily distracted with counting games, small toys, or conversation **Figure 34-6**. Appealing to the preschool-age child's imaginative thinking may allow treatment to go a bit smoother. For example, have the child pretend to be a superhero inhaling special powers while breathing in oxygen. Be sure to adjust the level of the game to the developmental level of the child; do not assume that preschool-age children understand more than they actually do.

While caring for this age group and others within the pediatric population, never lie to the patient. Once you have lost your pediatric patient's trust, it will be a challenge to regain it.

Begin your assessment with the feet and move toward the head, similar to assessing a toddler. Use adhesive bandages to cover the site of an injection or other small wound, because the preschool-age child might be worried about keeping his or her body together in one piece. Keep in mind that modesty is developing at this age, so keep the child covered when possible.

Figure 34-6 A preschool-age child can be easily distracted by games or conversation.

School-Age Years

School-age children (ages 6 to 12 years) begin to act more like adults. They can think in concrete terms, respond sensibly to direct questions, and help take care of themselves. School is important at this stage and concerns about popularity and peer pressure occupy a great deal of time and energy. Children with chronic illness or disabilities can become self-conscious because of concerns about fitting in with their peers. At this stage, children begin to understand that death is final, but their understanding of what death is and why it occurs is still unrealistic. This may increase their anxieties about illness or injury.

Assessment

Your assessment begins to be more like an adult assessment; talk to the child, not just the parent or caregiver, while taking the medical history **Figure 34-7**. This will help you gain the patient's trust. At this stage, the child is usually familiar with the process of physical examination through check-ups and immunizations. This may make your job easier or more difficult, depending on whether the child's prior health care experiences have been positive or negative. Begin your assessment at the head and move toward the feet, similar to assessing an adult.

Whenever possible, give the school-age child simple, appropriate choices, such as "Would you like to sit up or lie down?" or "Would you like to take off your clothes yourself?" Only ask the type of questions that let you control the answer and do not bargain or debate with the patient. For example, ask the child if you may find out the blood pressure on the child's right or left arm. Presenting a choice allows you to obtain assessment information and gives the child some control in a frightening situation. Encourage cooperation by allowing the child to listen to his or her own heartbeat through the stethoscope. Ensure the patient's modesty during the examination.

Figure 34-7 School-age children are more like adults in that they can answer your questions and can help to take care of themselves.

Preschool-age children can understand the difference between emotional and physical pain and have concerns about what pain means. Give them simple explanations about what is causing their pain and what will be done about it. Games and conversation may distract them. Ask them to describe their favorite place, pets, school activities, or toys. Ask the parent's or caregiver's advice in choosing the right distraction. Rewarding the child after a procedure can be very helpful in his or her future cooperation and recovery. Often, kind words and a smile make a good reward when toys or books are unavailable.

Adolescents

Most **adolescents** (ages 12 to 18 years) are able to think abstractly and can participate in decision making. This is also the stage when personal morals begin to develop. Adolescents are able to discriminate between what is right and wrong. They are now able to incorporate their own values and beliefs into their daily decision-making process. Even though this age group is physically similar to adults, adolescents are still children on an emotional level. They gradually shift from relying on family to relying on friends for emotional psychologic support, social development, and acceptance from their peers (especially the opposite sex). Interest in romantic relationships begins.

Adolescence is when puberty begins. Primary and secondary sex characteristics develop (sex organs, facial/axillary hair). This period of change makes the adolescent very concerned about his or her appearance. Simple injuries or illnesses can be exaggerated or understated due to anxiety about body image or fear of disfigurement. The adolescent may dislike being observed during procedures and may have strong feelings about privacy.

Adolescence is a time of experimentation and risk-taking behaviors. Adolescents often feel that they are free from danger, and that they are "indestructible." Adolescents struggle with independence, loss of control, body image, sexuality, and peer pressure. They may have mood swings or depression and when ill or injured, may act younger than their age.

Assessment

Remember that adolescents can often understand complex concepts and treatment options; provide them with information when they request it **Figure 34-8**. When the adolescent's condition is stable, discuss the situation and allow the adolescent to be involved in his or her care. Provide the adolescent with choices regarding his or her health, while also lending guidance if needed. You will find adolescents to be more helpful and understanding of necessary procedures than younger patients.

If the adolescent's condition requires him or her to be exposed or partially exposed to be assessed, take every measure to respect the patient's modesty and privacy. If an EMT of the same gender is available to perform the physical examination, it may lessen the stress of the event. Adolescents undergo numerous body changes during puberty, and some adolescents may have a negative or altered body image (an unrealistic sense of what their bodies look like, how it should look, or how society expects them to look). An injury that could result in a scar from a laceration or burn will be challenging for you to address. The best practice is to be honest, tactful, and to reassure the adolescent that you are doing everything within your training to help in this situation. Allow the adolescent to speak openly about any thoughts and concerns.

Figure 34-8 Respect the adolescent's privacy at all times; give the patient whatever information he or she requests.

Because the adolescent is under the influence of hormonal changes, peer pressure, and emotional highs and lows, risk-taking behaviors are common. Some of the risks that the adolescent takes can ultimately facilitate development and judgment and help to shape his or her identity as an adult. However, some risks can result in unintentional trauma, drug and/or alcohol abuse, unprotected sex, and teen pregnancy.

Be aware that female adolescents may be pregnant, so ask, "Is there a chance you could be pregnant?" Communicate her answer to the receiving facility and note it on your patient care report. The adolescent might not want this information known to her parents or caregivers and may fear the consequences of her actions. If you suspect that the patient might want to tell you something, but is silent in front of a parent or caregiver, try to interview the adolescent without the parent or caregiver present.

Adolescents have a clear understanding of the purpose and meaning of pain. Whenever possible, explain any necessary procedures well in advance. Assess their level of pain by observing facial and body expression as well as by asking questions; adolescents can be very reserved and may not request pain relief even when they need it. To distract them, find out some of their interests, such as sports or movies, and get them talking.

Anatomy and Physiology

There is no other time in a person's life that his or her body is growing and changing as fast as during childhood. Newborns quickly adapt to the world outside the mother's body (uterus). Toddlers learn to walk and talk. Adolescents transition into sexual maturity. To effectively assess and treat a pediatric patient, you must understand the physical differences between children and adults and alter your patient care accordingly.

The Respiratory System

To manage the pediatric airway effectively, you must understand the anatomic differences between the adult and pediatric airway. To start with, the pediatric airway is smaller in diameter and shorter in length, the lungs are smaller, and the heart is higher in a child's chest. The glottic opening (vocal cords) is higher and positioned more anteriorly (toward the front), and the neck appears to be nonexistent. As the child develops, the neck gets proportionally longer as the vocal cords and epiglottis achieve their anatomically correct adult position.

The anatomy of a pediatric airway and other important structures differs from that of an adult's in the following ways **Figure 34-9**:

- A larger, rounder occiput, or back of the head, which requires more careful positioning of the airway.
- A proportionately larger tongue relative to the size of the mouth and a more anterior location in the mouth. The child's tongue is also larger relative to the small mandible and can easily block the airway.

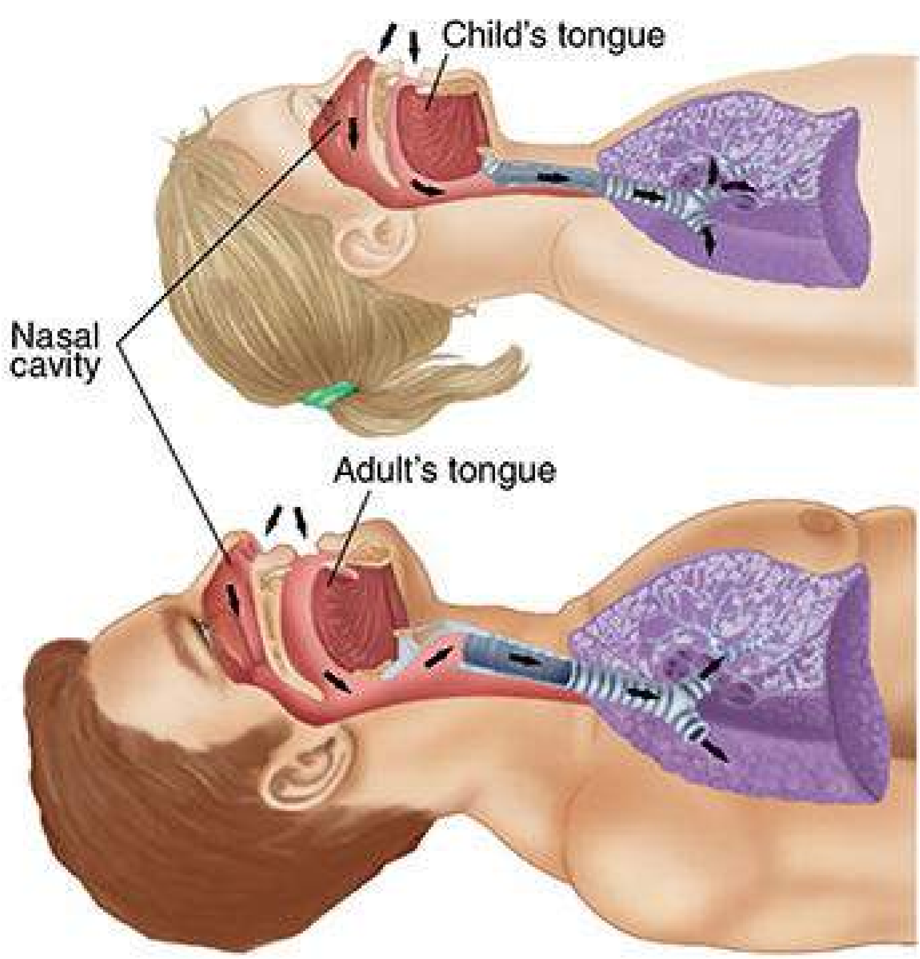

Figure 34-9 The anatomy of a child's airway differs from that of an adult's in several ways. The back of the head is larger in a child. The tongue is proportionately larger and is located more anterior in the mouth. The trachea is smaller in diameter and more flexible. The airway itself is lower and narrower (funnel-shaped).

- A long, floppy, U-shaped epiglottis in infants and toddlers is larger than an adult's, relative to the size of the airway that extends at a 45-degree angle into the airway.
- Less developed rings of cartilage in the trachea that may easily collapse if the neck is flexed or hyperextended.
- A narrowing funnel-shaped (wide to narrow) upper airway compared to that of a cylinder-shaped (same width) lower airway.

These differences will influence the treatment decisions that you make about pediatric patients, including whether or not intervention is needed and, if so, what procedure to use.

Words of Wisdom

To assist you with the assessment of a child, it is wise to utilize reference materials such as field guides or mobile device apps on these topics. Many EMS agencies also maintain copies of specialized pediatric protocols in their system. Refer to these resources during your care, and remember to make notes about your specific observations and treatment decisions. This “information-intensive” approach to pediatric care helps ensure good care and thorough documentation, and can reduce any anxiety you may feel about assessing children.

Because of the smaller diameter of the trachea in infants, which is about the same diameter as a drinking straw, their airway is easily obstructed by secretions, blood, or swelling. Infants are obligate nose breathers, which may require diligent suctioning or reassessment and management to maintain a clear airway.

An infant needs to breathe faster than an older child Table 34-1. Children’s lungs grow and develop increased abilities to handle the exchange of oxygen as they age. A respiratory rate of 30 to 60 breaths/min is normal for the newborn, whereas the adolescent is expected to have rates closer to the adult range (12 to 20 breaths/min). Children not only have a higher metabolic rate, but also a higher oxygen demand that is twice that of an adult. This in part is related to the actual size of the lung tissues and the volume that can be exchanged. Smaller lungs mean that the oxygen reserves are smaller. This higher oxygen demand combined with a smaller oxygen reserve increases the risk of hypoxia because of apnea or ineffective ventilation efforts.

Table 34-1 Pediatric Respiratory Rates

Age	Respirations (breaths/min)
Infant: 1 month to 1 year	30 to 60
Toddler: 1 to 3 years	24 to 40
Preschool-age: 4 to 5 years	22 to 34
School-age: 6 to 12 years	18 to 30
Adolescent: 13 to 18 years	12 to 16

Data From: Pediatric Advanced Life Support, 2012, the American Heart Association.

Safety Tips

In a pediatric patient, the lung tissues are prone to a simple or tension pneumothorax if excessive ventilatory pressures occur during assisted ventilations with a bag-valve mask (BVM). To prevent hypoxia and to avoid damaging the lung tissues, use the appropriate size mask and reservoir bag to avoid administering an excessively large tidal volume. Only use enough force to make the chest rise slightly. Focus your attention on the rise and fall of the chest wall, versus just simply squeezing the reservoir bag. Ventilate with the patient's underlying respiratory rate and be careful not to ventilate against the patient's efforts.

Breathing also requires the use of the chest muscles and diaphragm. Because intercostal muscles are not well developed in children, movement of the diaphragm, their major muscle of respiration, dictates the amount of air that they inspire. Young children also experience muscle fatigue much more quickly than older children. This can lead to respiratory failure if a child has to physically fight harder to breathe for long periods of time. Anything that places pressure on the abdomen of a young child can block the movement of the diaphragm and cause respiratory compromise. Gastric distention can also interfere with movement of the diaphragm and lead to hypoventilation. Use caution when applying straps to a spinal immobilization device because this may hinder full symmetrical chest wall expansion and thus limit tidal volume.

Breath sounds in children are easier to hear because of their thinner chest walls, but because less air is exchanged with each breath, detection of poor air movement or complete absence of breath sounds may be more difficult.

Table 34-2 Responsive Pediatric Pulse Rates

Age	Pulse Rate (beats/min)
Newborn to 3 months	85 to 205
3 months to 2 years	100 to 190
2 years to 10 years	60 to 140
>10 years	60 to 100

Data From: Pediatric Advanced Life Support, 2012, the American Heart Association.

The Circulatory System

It is important to know the normal pulse ranges when evaluating children Table 34-2. An infant's heart can beat as many as 160 times or more per minute if the body needs to compensate for injury or illness. This is the primary method the body uses to compensate for decreased perfusion.

Children are able to compensate for decreased perfusion by constricting the vessels in the skin. Constriction of the blood vessels can be so profound that blood flow to the extremities can be diminished. Signs of vasoconstriction include pallor (early sign), weak distal (eg, radial or pedal) pulses in the extremities, delayed capillary refill, and cool hands or feet.

The Nervous System

Compared with the adult nervous system, the pediatric nervous system is immature, underdeveloped, and not well protected. Recall that the head-to-body ratio of an infant and young child is disproportionately larger, making this population more prone to head injuries from falls or motor vehicle crashes. The occipital region of the head is larger, which increases the momentum of the head during a fall. The subarachnoid space is relatively smaller, leaving less cushioning for the brain. The brain tissue and the cerebral vasculature are fragile and prone to bleeding from shearing forces, such as during an incidence of shaken baby syndrome (discussed later in the chapter).

The pediatric brain requires a higher amount of cerebral blood flow, oxygen, and glucose than does adult brain tissue. Glucose stores are limited in the pediatric patient. These special needs mean that the pediatric brain is at risk for secondary brain damage from hypotension and hypoxic events.

Spinal cord injuries are less common in pediatric patients. According to studies conducted on the epidemiology of catastrophic spine injuries in high school, college, and professional sports, approximately 12,000 new spinal cord injuries are reported yearly in the United States. Roughly 10% of those spinal injuries occur in children under the age of 16. If a child's cervical spine is injured, it is most likely to be an injury to the ligaments as the result of a fall. If you suspect a neck injury, perform manual in-line stabilization or follow local protocols.

The Gastrointestinal System

The abdominal muscle structures are less developed in the pediatric patient, which results in less protection from blunt or penetrating trauma. The internal organs, such as the liver and the spleen, are proportionally larger and situated more anteriorly, so they are prone to bleeding and injury. Because the internal organs are positioned in a closer proximity to each other, there is a higher risk for multiple organ injury caused by minimal direct impact to this region, such as from a lap belt in a motor vehicle. The liver, spleen, and kidneys are more frequently injured in children than in adults.

The Musculoskeletal System

A child's bones are softer than an adult's. The skeletal system contains open growth plates at the ends of long bones, which enable these bones to grow during childhood. As a result of the active growth plates, children's bones are weaker and more flexible, making them prone to fracture with stress. The open growth plates are also weaker than ligaments and tendons, leading to length discrepancies if there is an injury to the growth plate. Because of these factors, immobilize extremities with suspected sprains or strains because they may actually be stress fractures.

The bones of the infant's head are flexible and soft, which allows the head to be delivered through the birth canal and for the growth of the brain during development. Located on the front (anterior) and back (posterior) portions of the head are soft spots known as **fontanelles**. Each will close at particular stages of development, 18 months for the anterior suture and 6 months for the posterior suture. It is important to note that some bulging is a normal assessment finding when the infant is either crying, coughing, or lying on the back or stomach. The fontanelles of an infant can be a useful assessment tool for such issues as increased cranial pressure (bulging with a noncrying infant) or dehydration (a sunken appearance).

The thoracic cage in children is highly elastic and flexible because it is primarily composed of cartilaginous connective tissue. The ribs and vital organs are less protected by muscle and fat. The highly flexible ribs mean that fractures in pediatric patients are rare, unless a high-energy impact to the chest wall is encountered, such as during a motor vehicle crash. However, underlying damage may still exist within the thoracic cavity without any exterior markings.

The Integumentary System

The integumentary system of the child differs from that of the adult in a few ways. The child's skin is thinner with less subcutaneous fat; it tends to burn more deeply and easily than an adult's, as in the case of a sunburn. Infants and children also have a larger body-surface-area-to-body-mass ratio, which can lead to significant fluid and heat losses.

Patient Assessment

Because a young child might not be able to speak, your assessment of his or her condition must be based in large part on what you can see and hear. Family members may be able to provide vital information about an incident or illness. Remember to include parents or caregivers as part of your team. Whenever possible, involve them in decisions and have them help comfort the infant or child during the assessment and any interventions.

Scene Size-up

The assessment begins at the time of initial dispatch. On the way to the scene, prepare mentally for approaching and treating an infant or child and interacting with the family. This means planning for a pediatric scene size-up, pediatric equipment, and the age-appropriate physical assessment. If possible, collect information from the dispatcher on the age and gender of the child, the location of the scene, the nature of illness (NOI), the mechanism of injury (MOI), and the chief complaint.

As with any EMS call, the scene size-up begins by ensuring that you and your partner have taken the appropriate safety precautions and standard precautions. As you enter the scene, note the position in which the child is found. Look for any possible safety threats to the child, parents or caregivers, bystanders, or EMS providers. Keep in mind that the child may be a safety threat if he or she has an infectious disease.

Next, do an environmental assessment. The environmental assessment will give important information on the chief complaint, number of patients, MOI or NOI, and ongoing health risks. Inspect the physical environment and observe the family–child and/ or caregiver–child interactions. Information from the parents or caregivers will be extremely important and may provide clues as to the patient's problem. As with the adult population, document dangerous scene conditions and obtain statements from parents, caregivers, or bystanders; this information will assist child protective services if the child is later determined to be a victim of an intentional injury. On the scene, be like a sponge; soak up as much useful information as possible to ensure scene safety and the delivery of timely care.

At a traumatic scene when the child is unresponsive or unable to communicate because of his or her developmental age, assume that the MOI was significant enough to cause head or neck injuries. Perform cervical spine immobilization if you suspect the MOI to be severe. Remember to pad under the child's head and/or shoulder to facilitate a neutral position for airway management. Always follow local protocols.

Primary Assessment

As with the adult population, the objective of the primary assessment is to identify and treat immediate or potential threats to life.

Pediatric Assessment Triangle

When you assess an infant or child, use the pediatric assessment triangle (PAT) to determine if the patient is sick or not sick. The **pediatric assessment triangle (PAT)** is a structured assessment tool that allows you to rapidly form a general impression of the child's condition without touching him or her. This "first glance" assessment, which can be performed in less than 30 seconds, will help you to identify the general category of the patient's physical problem and establish urgency for treatment and/or transport.

The PAT consists of three elements: appearance (muscle tone and mental status), **work of breathing**, and circulation to the skin Figure 34-10. The only equipment required for the PAT is your own eyes and ears.

As you evaluate the pediatric patient's appearance, note the level of consciousness or interactiveness and muscle tone—signs that will provide you with information about the adequacy of the pediatric patient's cerebral perfusion (mentation) and overall function of the central nervous system.

Much of the information regarding the pediatric patient's level of consciousness can be obtained by using the PAT. In addition, you can evaluate the pediatric patient's level of consciousness by using the AVPU scale, modified as necessary for his or her age Table 34-3.

An infant or child with a normal level of consciousness will act appropriately for his or her age, exhibiting good muscle tone and maintaining good eye contact Figure 34-11. An abnormal level of consciousness is characterized by age inappropriate behavior or interactiveness, poor muscle tone, or poor eye contact with the parent or caregiver or with you Figure 34-12.

YOU are the Provider — PART 2

You arrive at the scene, enter the residence, and find the child sitting on the couch next to her mother. She immediately makes eye contact with you, appears fearful of your presence, and starts clinging to her mother. You note that she is in obvious respiratory distress. As you approach the child, you make a visual assessment of her.

Recording Time: 0 Minutes	
Appearance	Obvious respiratory distress
Level of consciousness	Conscious; appears fearful
Airway	Open, no obvious obstructions
Breathing	Increased rate; moderate difficulty; nasal flaring; prominent supraclavicular retractions

Circulation	Skin pink and dry; no gross bleeding

3. Why did you not immediately perform a hands-on assessment of this child?
4. On the basis of your initial observations, is this child experiencing respiratory distress or respiratory failure?

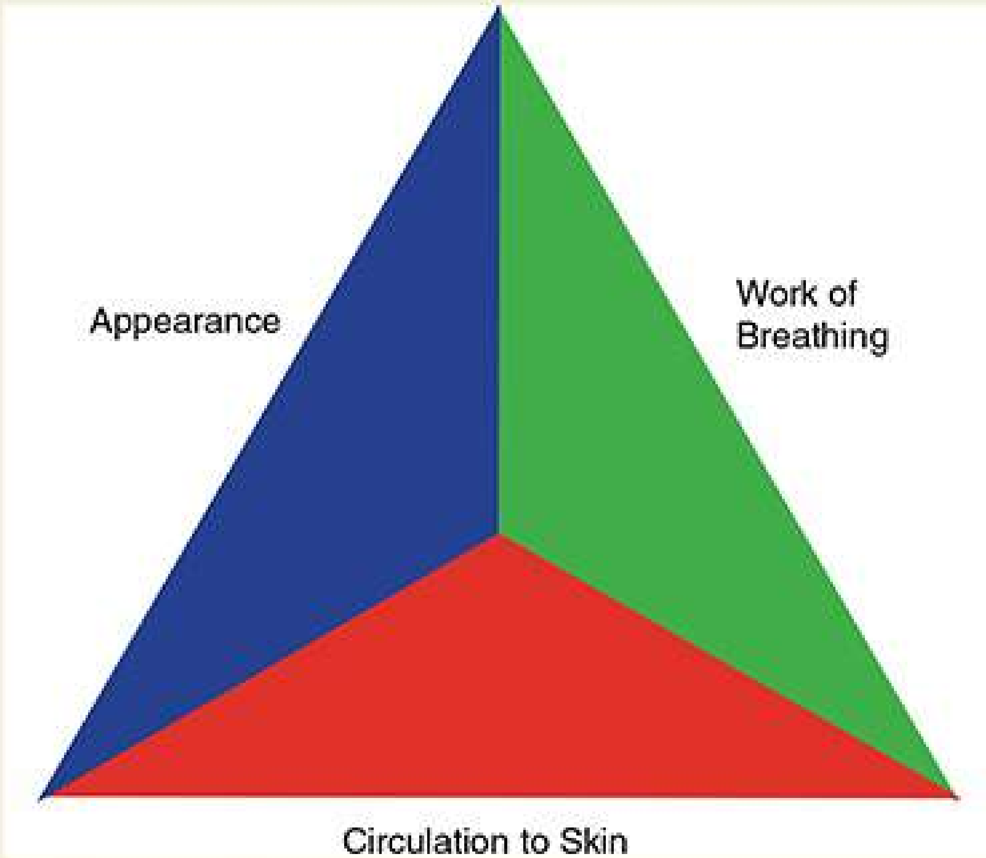

Figure 34-10 The three components of the pediatric assessment triangle (PAT) include appearance, work of breathing, and circulation to the skin.

Table 34-3 The AVPU Scale

Awake and Alert	Patient is awake; the eyes visually track people and objects
Responsive to Verbal Stimuli	Patient opens the eyes or moans, speaks, or moves in response to your voice
Responsive to Pain	Patient does not respond to verbal stimuli but moves or cries out in response to pain (eg, pinched ear lobe)
Unresponsive	No response to any stimulus

Figure 34-11 An infant or child making good eye contact is most likely not critically ill.

Figure 34-12 A limp child who is unable to maintain eye contact may be critically ill or injured.

Courtesy Health Resources and Services Administration, Maternal and Child Health Bureau, Emergency Medical Services for Children Program.

The mnemonic TICLS (or tickles) can also help to determine if the pediatric patient is sick or not sick. TICLS includes Tone, Interactiveness, Consolability, Look or gaze, and Speech or cry Table 34-4.

A pediatric patient's work of breathing increases as the body attempts to compensate for abnormalities in oxygenation and ventilation. Increased work of breathing often manifests as follows:

- **Abnormal airway noise:** (grunting or wheezing)
- **Accessory muscle use:** Contractions of the muscles above the clavicles (supraclavicular)
- **Retractions:** Drawing in of the muscles between the ribs (intercostal retractions) or of the sternum (substernal retractions) during inspiration Figure 34-13
- **Head bobbing:** The head lifts and tilts back during inspiration, then moves forward during expiration
- **Nasal flaring:** The nares (the external openings of the nose) widen; usually seen during inspiration

Table 34-4 Characteristics of Appearance: The TICLS Mnemonic

Characteristic	Features to Look For
Tone	Is the child moving or resisting examination vigorously? Does the child have good muscle tone? Or is the child limp, listless, or flaccid?
Interactiveness	How alert is the child? How readily does a person, object, or sound distract the child or draw the child's attention? Will the child reach for, grasp, and play with a toy or examination instrument, like a penlight or tongue blade? Or is the child uninterested in playing or interacting with the parent or caregiver or with the EMT?
Consolability	Can the child be consoled or comforted by the parent or caregiver or by the EMT? Or is the child's crying or agitation unrelieved by gentle reassurance?
Look or gaze	Does the child fix his or her gaze on a face, or is there a "nobody home," glassy-eyed stare?
Speech or cry	Is the child's cry strong and spontaneous or weak or high-pitched? Is the content of speech age-appropriate or confused or garbled?

Figure 34-13 Retractions of the intercostal muscles or sternum indicate increased work of breathing.

Courtesy of Health Resources and Services Administration, Maternal and Child Health Bureau, Emergency Medical Service for Children Program.

- **Tachypnea**: Increased respiratory rate
- **Tripod position**: In older children, this position will maximize the effectiveness of the airway **Figure 34-14**

As discussed previously, an important sign of perfusion is circulation to the skin. When cardiac output falls, the body, through vasoconstriction, shunts blood from areas of lesser need (such as the skin) to areas of greater need (such as the brain, heart, and kidneys). The PAT is a valuable tool in the field when you are confronted with various etiologies, such as respiratory distress or failure, cardiovascular shock leading to cardiopulmonary failure or arrest, isolated head injury, ingestion of a toxic substance, neurologic injuries—or even as an approach to a stable pediatric patient.

Figure 34-14 A patient in the tripod position will sit leaning forward on outstretched arms with the head and chin thrust slightly forward.

Pallor of the skin and mucous membranes may be seen in compensated shock; it may also be a sign of anemia or hypoxia. Mottling is caused by constriction of peripheral blood vessels and is another sign of poor perfusion **Figure 34-15**.

Cyanosis, a blue discoloration of the skin and mucous membranes, reflects a decreased level of oxygen in the blood.

Cyanosis is a late sign of respiratory failure or shock; absence of discoloration, however, does not rule out these conditions. Never wait for the development of cyanosis before administering oxygen!

On the basis of the findings of the PAT triangle, you will decide if the pediatric patient is in stable condition or requires urgent care. If the pediatric patient is in unstable condition, assess the ABCs, treat any life threats, and transport immediately to an appropriate facility. In pediatric patients with obvious life-threatening external hemorrhage, assess and address the CABs first, including applying tourniquets for arterial hemorrhage from extremities. See Chapter 25, *Bleeding,* for more information.

If the pediatric patient is in stable condition, then you have time to continue with the remainder of the patient assessment process, perform necessary interventions, and discuss transport options with the parents or caregivers.

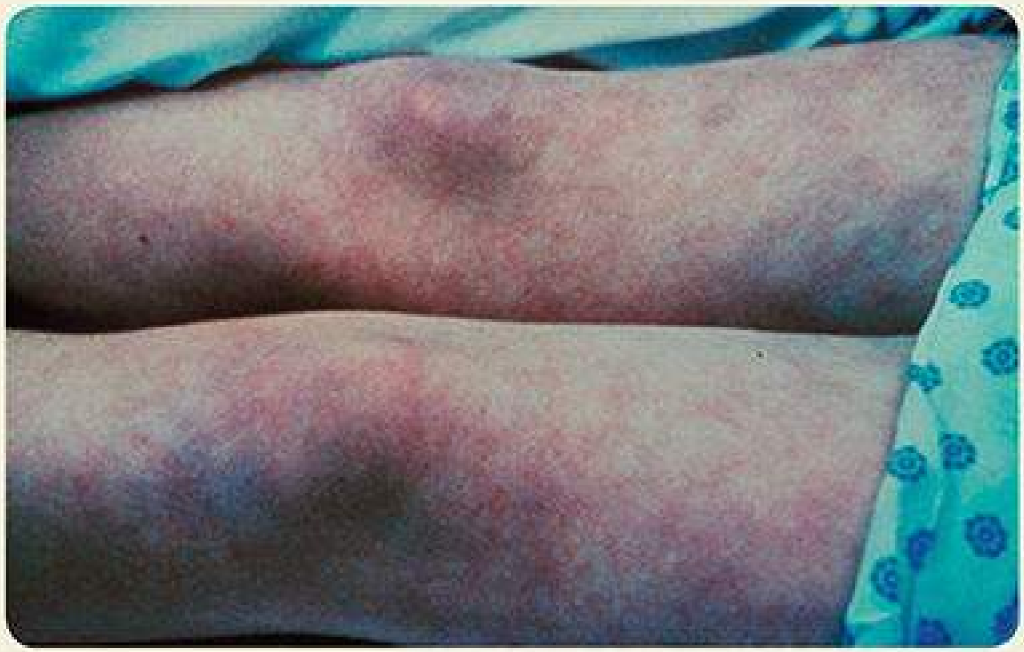

Figure 34-15 Mottling of the skin indicates poor perfusion and is the result of constriction of peripheral blood vessels.

Hands-on ABCs

For the pediatric patient, you will now perform a hands-on ABCs assessment. Assess and treat any life threats as you identify them by following the ABCDE format:

- **A**irway
- **B**reathing
- **C**irculation
- **D**isability
- **E**xposure

If the pediatric patient's airway is open and the patient can adequately keep it open (as is often the case in conscious pediatric patients), assess respiratory adequacy. However, if the pediatric patient is unresponsive or has difficulty keeping the airway clear, you must ensure that the airway is properly positioned and that it is clear of mucus, vomitus, blood, and foreign bodies.

If trauma has been ruled out, open the pediatric patient's airway with the head tilt–chin lift maneuver **Figure 34-16**. If spinal trauma is suspected, use the jaw-thrust maneuver to open the airway **Figure 34-17**.

Positioning the airway correctly is critical in pediatric emergency care. Always position the airway in a neutral **sniffing**

position. This accomplishes two goals at once, keeping the trachea from kinking and maintaining the proper alignment should you have to immobilize the spine.

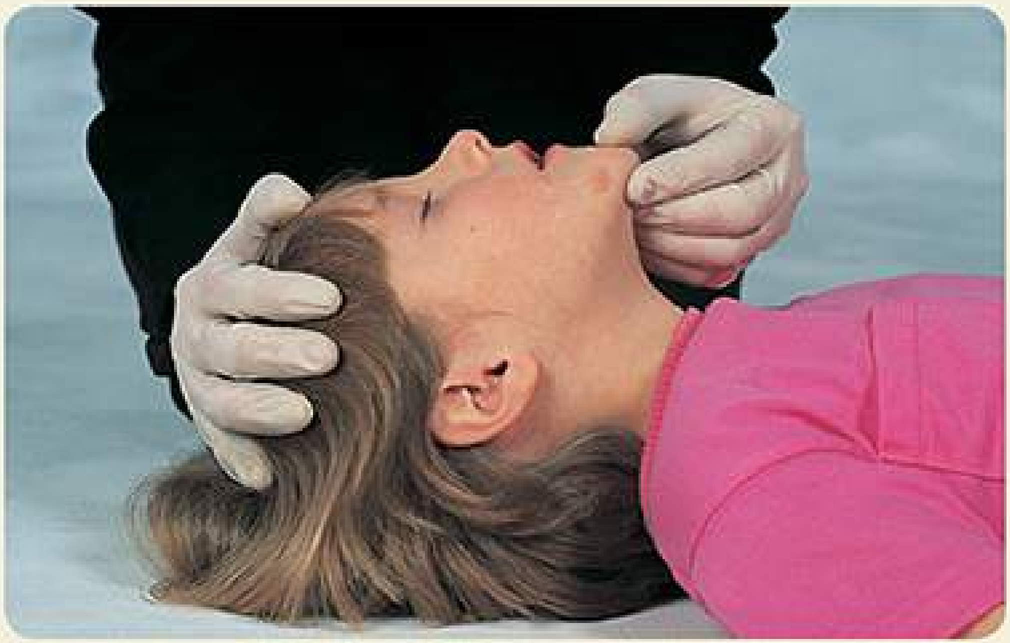

Figure 34-16 Use the head tilt–chin lift maneuver to open the airway of a pediatric patient without trauma.

Figure 34-17 Use the jaw-thrust maneuver to open the airway of a pediatric patient with possible spinal injury.

Follow these steps to position the airway in a pediatric patient without trauma **Skill Drill 34-1**:

1. Place the pediatric patient on a firm surface such as a short backboard or pediatric immobilization device **Step 1**.
2. Fold a small towel and place it under the pediatric patient's shoulders and back **Step 2**.
3. Stabilize the pediatric patient's forehead to limit rolling of the head during transport. Use the head tilt–chin lift maneuver to open the airway **Step 3**.

After the pediatric patient's airway has been opened, make sure that it is clear of potential obstructions such as mucus, blood, or foreign bodies. Next, establish whether the pediatric patient can maintain his or her own airway spontaneously (without the use of airway adjuncts) or whether adjuncts will be necessary to maintain airway patency. Techniques for airway management, and how to identify appropriately sized equipment for the pediatric patient, will be discussed later in this chapter.

Skill Drill 34-1 Positioning the Airway in a Pediatric Patient

Step 1

Position the pediatric patient on a firm surface.

Step 2

Place a folded towel about 1 inch (2.5 cm) thick under the shoulders and back.

Step 3

Stabilize the forehead to limit movement and use the head tilt–chin lift maneuver to open the airway.

Carefully assess the pediatric patient's breathing while at the same time feeling for a pulse. Note the degree of air movement at the nose and mouth and determine whether the chest is rising adequately and symmetrically. Assess the respiratory rate and effort with which the pediatric patient is breathing as well.

When you assess a pediatric patient, place both hands on the pediatric patient's chest to feel for the rise and fall of the chest wall. You will be able to count the actual respiratory rate and assess for symmetry. This assessment maneuver is especially helpful when your pediatric patient requires assisted ventilations with a BVM. In infants, belly breathing is considered adequate because of the soft pliable bones of the chest and the strong muscular diaphragm.

If the pediatric patient is conscious and not in need of immediate intervention (such as suctioning or assisted ventilation), it is usually easier to assess respirations with the pediatric patient sitting on the parent's or caregiver's lap. Listen for abnormal breath sounds **Table 34-5**, and note any signs of increased respiratory effort (work of breathing).

As the pediatric patient begins to tire, retractions often become weak and ineffective and the accessory muscles become less prominent during breathing. **Bradypnea**, a decrease in the respiratory rate, is an ominous sign and indicates impending respiratory arrest. Do not mistake bradypnea for a sign of improvement; it usually indicates that the pediatric patient's condition has deteriorated. Therefore, be prepared to begin ventilatory assistance.

When you assess circulation, you must determine if the pediatric patient has a pulse, is bleeding, or is in shock. Remember, infants and children can tolerate only small amounts of blood loss before circulatory compromise occurs. Assess and control any active bleeding early in your assessment.

A pulse may be difficult to palpate if it is weak, very fast, or very slow. In infants, palpate the brachial pulse or femoral pulse. In children older than 1 year, palpate the carotid pulse **Figure 34-18**. Note the rate and quality of the pulse: Is it weak or strong? Is it normal, slow, or fast? Strong **central pulses** usually indicate that the child is not hypotensive; however, this does not rule out the possibility of compensated shock. Weak or absent peripheral pulses indicate decreased perfusion. The absence of a central pulse (that is, brachial or femoral in infants, carotid in older children) indicates the need for cardiopulmonary resuscitation (CPR).

Tachycardia may be an early sign of hypoxia or shock, but it may also reflect less serious conditions such as fever, anxiety, pain, and excitement. Like the respiratory rate and effort, the pulse rate should be interpreted within the context of the overall history, PAT, and the entire primary assessment.

A trend of an increasing or decreasing pulse rate may be quite useful and may suggest worsening hypoxia or shock or improvement after treatment. When hypoxia or shock becomes critical, bradycardia occurs. Bradycardia is a condition in which the heart rate is less than 80 beats/min in children or less than 100 beats/min in newborns. As with slowing respirations, bradycardia in a pediatric patient is an ominous sign and often indicates impending cardiopulmonary arrest.

Table 34-5 Abnormal Breath Sounds

Crackles	A crackling or bubbling sound typically heard on inspiration; indicates inflammation or infection (such as in pneumonia)
Stridor	High-pitched inspiratory sound; indicates a partial upper airway obstruction (such as in croup or from a foreign body)
Wheezing	High- or low-pitched sound heard usually during expiration; indicates a partial lower airway obstruction (such as in asthma or bronchiolitis)
Grunting	An "uh" sound heard during exhalation; reflects the pediatric patient's attempt to keep the alveoli open by increasing pressure in the chest cavity; indicates inadequate oxygenation (such as in pneumonia)
Absent breath sounds (silent chest)	Combined with increased work of breathing, absent breath sounds indicate a complete upper or lower airway obstruction (such as from a foreign body, severe asthma, or pneumothorax); an ominous sign of impending respiratory failure that must be quickly addressed

Figure 34-18 **A.** Palpate the brachial pulse in infants. **B.** Palpate the femoral pulse as a second choice. **C.** In children older than 1 year, palpate the carotid pulse.

Feel the skin for temperature and moisture at the same time you assess the patient's pulse. Is the skin warm and dry, or cold and clammy? Estimate the capillary refill time by squeezing the end of a finger or toe for several seconds until the nail bed **blanches** and then observing the return of blood to the area **Figure 34-19**. Color should return within 2 seconds after you let go. The capillary refill time is used to assess end-organ perfusion. It is most reliable in children younger than 6 years; however, factors such as cold temperatures may affect the capillary refill time.

Figure 34-19 Estimate the capillary refill time by squeezing the end of a finger or toe for several seconds until the nail bed blanches. Normal color should return within 2 seconds after you let go.

Assess the pediatric patient's level of consciousness using the AVPU scale or the Pediatric Glasgow Coma Scale **Table 34-6**.

Check the responses of each pupil to a direct beam of light. A normal pupil constricts after a light stimulus. Pupillary response may be abnormal in the presence of drugs, ongoing seizures, hypoxia, or brain injury. Note if the pupils are dilated, constricted, reactive, or fixed.

Words of Wisdom

Helpful mnemonics to remember:

B	Blood pressure
L	Level of consciousness
S	Skin: color, temperature, moisture
C	Capillary refill time
P	Pulse: rate, rhythm, strength
R	Respiratory rate, effort, pattern

Next, look for symmetric movement of the extremities and note any neurologic motor deficit such as the inability to move the upper or lower extremities, an inability to communicate, weakness, or difficulty walking (gait).

Table 34-6 Pediatric Glasgow Coma Scale (GCS)

Activity	Score	Infant	Score	Child
Eye opening	4	Open spontaneously	4	Open spontaneously
	3	Open to speech or sound	3	Open to speech
	2	Open to painful stimuli	2	Open to painful stimuli
	1	No response	1	No response
Verbal	5	Coos, babbles	5	Oriented conversation
	4	Irritable cry	4	Confused conversation
	3	Cries to pain	3	Cries
	2	Moans to pain	2	Inappropriate words
	1	No response	1	Moans
				Incomprehensible words/sounds
				No response
Motor	6	Normal spontaneous movement	6	Obeys verbal commands
	5	Localizes pain	5	Localizes pain
	4	Withdraws to pain	4	Withdraws to pain
	3	Abnormal flexion (decorticate)	3	Abnormal flexion (decorticate)
	2	Abnormal extension (decerebrate)	2	Abnormal extension (decerebrate)
	1	No response (flaccid)	1	No response (flaccid)

Data Adapted From: Pediatric Advanced Life Support, 2012, the American Heart Association.

Pain is present with most types of injury and many illnesses. Inadequate treatment of pain has many adverse effects on the pediatric patient and the family. Pain causes significant morbidity and misery for pediatric patients and caregivers and interferes with assessment.

When you assess the severity of pain, consider the developmental age of the patient. The ability to recognize pain will improve as patients become older. For example, crying and agitation in an infant may be the result of hunger or a wet diaper. Meanwhile, a 3-year-old child can say, "My tummy really hurts." In children ages 3 and older, pain scales using pictures of facial expressions (Wong-Baker FACES Scale) may be helpful in assessing the level of pain **Figure 34-20**.

Proper exposure of the pediatric patient is necessary to complete the hands-on ABCs. The PAT requires that the parent or caregiver remove part of the pediatric patient's clothing to allow careful observation of the face, chest wall, and skin. Further exposure may be needed to fully evaluate physiologic functions, anatomic abnormalities, and unsuspected injuries or rashes. Be careful to avoid heat loss, especially in infants, by covering the patient as soon as possible.

The thermoregulatory system in the pediatric body is immature. Paired with thinner skin and a lack of subcutaneous fat, this makes the pediatric population more prone to hypothermia. Infants younger than 6 months lack the ability to shiver in response to a cold stimulus and therefore cannot generate body heat from this protective mechanism. Newborns and infants less than 1 month are the most susceptible to hypothermia.

Figure 34-20 The Wong-Baker FACES Scale.

Words of Wisdom

Remember that infants and children are prone to hypothermia because of poor thermoregulation and a larger surface-area-to-mass ratio than adults. You must ensure that a pediatric patient stays warm, especially when he or she is compromised due to illness or trauma.

Keep infants and young children warm (but not overly hot) during transport or when the patient is exposed to assess or reassess an injury. Cover the head in particular, because up to 50% of heat loss can occur with a head that is larger in proportion to the rest of the body. Without recognition and treatment of hypothermia, the pediatric patient may become unconscious and lapse into convulsive seizure activity.

Transport Decision

After you have completed the primary assessment using hands-on ABCs and initiated any treatment, you must decide when, how, and where to transport the patient. First, determine whether rapid transport to the hospital is indicated. If the pediatric patient is in stable condition, obtain a patient history, perform a secondary assessment at the scene, transport, and provide additional treatment as needed.

Rapid transport is indicated if the scene is unsafe for the pediatric patient or if any of the following conditions exist:

- A significant MOI—same MOIs as adults (Chapter 24, *Trauma Overview*), with the addition of:
  - Any fall from a height equal to or greater than a pediatric patient's height, especially with a headfirst landing
  - Bicycle crash (when not wearing a helmet)
- A history compatible with a serious illness
- A physical abnormality noted during the primary assessment
- A potentially serious anatomic abnormality
- Significant pain
- Abnormal level of consciousness, altered mental status, and/or any signs or symptoms of shock

In addition to the preceding factors, consider the following when making a transport decision:

- The type of clinical problem (injury versus illness)
- The expected benefits of advanced life support (ALS) treatment in the field

- Local EMS system treatment and transport protocols
- Your comfort level
- Transport time to the hospital

If the pediatric patient's condition is urgent, then initiate rapid transport to the closest appropriate facility. Specialty facilities such as trauma centers or children's hospitals have the training, staff, and equipment to provide complete care for all levels of pediatric patients. However, the most appropriate facility is not always the closest facility. To help you determine where to transport a pediatric patient, ask yourself this crucial question: *Can I deliver the pediatric patient to the most appropriate facility without risk or delay to the pediatric patient?* If you cannot, or if the illness or injury is so extensive that you cannot provide the care that the pediatric patient needs, then transport the pediatric patient to the closest facility. Additional assessment and treatment should occur en route to the hospital.

Pediatric patients weighing less than 40 pounds (18 kg) who do not require spinal immobilization should be transported in a car seat if the situation allows. Many types of car seats are available. A car seat should be chosen to fit the appropriate weight of the pediatric patient and should meet the current applicable standards set by your governing agency. There are only a few locations to place a car seat in an ambulance. Car seats are designed to be either forward-facing or rear-facing; they cannot be mounted sideways on a bench seat. Car seats should not be mounted in the front of an ambulance, especially if the ambulance is equipped with air bags. To mount a car seat to the stretcher, place the head of the stretcher in an upright position. Place the seat so it is against the back of the stretcher. Secure one of the stretcher straps from the upper portion of the stretcher through the seat belt positions on the seat and strap it tightly to the stretcher. Repeat on the lower portion of the stretcher. Push the car seat into the stretcher tightly and retighten the straps.

To secure a car seat to the captain's chair, follow the seat manufacturer's instructions. Remember that pediatric patients younger than 2 years must be transported in a rear-facing position because of the lack of mature neck muscles.

For pediatric patients who require spinal immobilization, it is no longer considered appropriate to secure a pediatric patient in a car seat. Immobilize the pediatric patient on a long backboard or other suitable spinal immobilization device. If the patient's condition is unstable and requires airway or ventilatory support, he or she should be positioned to maximize the ability to manage the airway and ventilatory requirements. Pediatric patients in cardiopulmonary arrest should likewise not be placed in a car seat but instead on a device that can be secured to the stretcher. Follow local protocols.

Do not use the pediatric patient's own car seat when the pediatric patient is in stable condition. Instead, transfer the pediatric patient to the ambulance's car seat or suitable restraining device. The goal is to secure and protect the pediatric patient for transport in the ambulance. The pediatric patient should be protected just as if he or she were in any other vehicle on the road.

Words of Wisdom

Depending on the age or developmental level of the pediatric patient, he or she may be unable to provide the necessary information for a thorough and complete patient history. Always include parents and primary caregivers in the history taking process. This is especially true when a child has a chronic, critical, or unique illness; the parents and caregivers will often have more experience and knowledge about the illness and the necessary care than you. Take advantage of their knowledge and their ability to assist you on scene, which will benefit the child's care.

History Taking

Your approach to the history will depend on the age of the pediatric patient. Historical information for an infant, toddler, or preschool-age child will need to be obtained from the parent or caregiver. When dealing with an adolescent, you will usually be able to obtain most of the immediate information from the patient; however, consult the parent or caregiver for a complete history.

Information about sexual activity, the possibility of pregnancy, or the use of illicit drugs or alcohol should be obtained from an adolescent patient in private. Adolescents will be reluctant to provide this information in the presence of their parents or caregivers. When asking sensitive questions, assure the adolescent that this information is important and is needed to provide the most appropriate care.

Question the parent or child about the immediate illness or injury based on the child's chief complaint. Together with an evaluation of the child's medical history, this may provide clues to the underlying illness or injury and other conditions that may exist.

When you interview the parent or caregiver or older child about the chief complaint, obtain the following pertinent information:

- The NOI or MOI
- How long the pediatric patient has been sick or injured
- The key events leading to the injury or illness: Were there any witnesses to the injury? From what height did the pediatric patient fall? What surface did the pediatric patient land on (soft or hard)?
- Presence of fever
- Effects of the illness or injury on the pediatric patient's behavior
- Pediatric patient's activity level
- Recent eating, drinking, and urine output
- Change in bowel or bladder habits
- Presence of vomiting, diarrhea, abdominal pain
- Presence of rashes

If the parent or caregiver is unable to accompany you to the hospital, obtain a name and phone number so a staff person can call if there are questions. This might be the case when you respond to a day care facility or babysitter's location. Most day care facilities require emergency contact information, past medical history, and/or a list of current prescribed medications taken by the child in case of an emergency. Care may be delayed if this information is not discovered early; however, you must never delay care of a critical patient.

Obtaining a SAMPLE history for a pediatric patient is the same as obtaining an adult's. However, the questions should be based on the pediatric patient's age and developmental stage of life Table 34-7.

Recall from Chapter 9, *Patient Assessment,* that the OPQRST format can help you gather additional information about a patient's history of present illness and current symptoms. The process for obtaining OPQRST is the same for children and adults. As with the SAMPLE history, the questions should be based on the pediatric patient's age and developmental stage Table 34-8.

Special Populations

A lower extremity injury should be suspected in any child who refuses to bear weight. Do not allow a patient with a suspected lower extremity injury to walk—question parents, bystanders, or even the child to determine the MOI and symptoms.

Secondary Assessment

In some instances, such as a critically ill or injured pediatric patient or a short transport time, you may not have time to conduct a secondary assessment. Perform a secondary assessment of the entire body when pediatric patients have the potential for hidden illnesses or injuries; for example, unresponsive medical patients or trauma patients with a significant MOI. This type of examination may help to identify problems such as a distended abdomen or possible fractures that were not as obvious during the primary assessment, but over time, the presenting signs and symptoms become more apparent.

Table 34-7 Pediatric SAMPLE Components

Component	Explanation
Signs and symptoms	Onset and nature of symptoms of pain or fever Age-appropriate signs of distress (see OPQRST listed below)
Allergies	Known drug reactions or other allergies
Medications	Exact names and doses of ongoing drugs (including over-the-counter, prescribed, herbal, and recreational drugs) Timing and amount of last dose Time and dose of analgesics or antipyretics
Pertinent past medical history	Previous illness or injuries Immunizations Complications surrounding pregnancy, labor, or delivery, including the route of delivery (infants and toddlers)
Last oral intake	Timing of the child's last food or drink, including bottle or breastfeeding
Events leading up to the illness or injury	Key events leading up to the current incident Fever history

Table 34-8 Pediatric OPQRST Components

Component	Explanation
Onset	How long has the patient been experiencing this event? What was the patient doing when the symptoms began?
Provocation/palliation	Does anything make the pain or discomfort better or worse? In what position is the patient most comfortable?
Quality	What does the pain feel like? "Dull," "sharp," or "cramping" are common descriptions. Does it come in waves?
Region/radiation	Where does the patient feel the symptoms?
Severity	Observe nonverbal cues (such as wincing or posture). Ask the pediatric patient to rate his or her symptoms using the Wong-Baker FACES pain scale (see) Figure 34-20.
Timing	When did symptoms begin? Have the symptoms been constant or do they come and go?

Use the DCAP-BTLS mnemonic (Deformities, Contusions, Abrasions, Punctures/Penetrations, Burns, Tenderness, Lacerations, and Swelling) to remind you what to assess for on a pediatric patient involved in a traumatic event.

After a physical examination of the whole body has been completed, perform a focused assessment on pediatric patients without life-threatening illnesses or injuries. Focus your physical examination on the area(s) of the body affected by the illness or injury as well as on the chief complaint, MOI or NOI, and on the findings of the primary assessment.

Words of Wisdom

Remember that DCAP-BTLS is *only* used for the trauma patient. For the medical patient, use SAMPLE and OPQRST and perform a full-body scan that focuses on the systems of the body.

Words of Wisdom

Young children are often afraid of authority figures in general, so you must earn their trust quickly in order to gain their cooperation. For example, demonstrate how you will perform the assessment using a stuffed animal or even an older sibling; this will show children that the assessment will not hurt them and establish a sense of trust. In addition, always remain calm and confident. Pediatric patients can sense fear and may not be willing to let you render care.

Infants, toddlers, and preschool-age children who do not have apparent life-threatening illness or injuries should be assessed starting at the feet and ending at the head; school-age children and adolescents can be assessed using the head-to-toe approach, as with adults. The extent of the physical examination will depend on the situation and may include the following:

- **Head.** The younger the infant or child, the larger the head is in proportion to the rest of the body, increasing the risk for head injury with deceleration (such as in falls or motor vehicle crashes). Look for bruising, swelling, and hematomas. Significant blood loss can occur between the skull and scalp of a small infant. A tense or bulging fontanelle in an upright, noncrying infant suggests elevated intracranial pressure caused by meningitis, encephalitis, or intracranial bleeding. A sunken fontanelle suggests dehydration.
- **Nose.** Young infants are obligate nose breathers, so nasal congestion with mucus can cause respiratory distress. Gentle bulb or catheter suction of the nostrils may bring relief.
- **Ears.** Look for any drainage from the ear canals. Leaking blood suggests a skull fracture. Check for bruises behind the ear or Battle sign, a late sign of skull fracture. The presence of pus may indicate an ear infection or perforation of the ear drum.
- **Mouth.** In the trauma patient, look for active bleeding and loose teeth. Note the smell of the breath. Some ingestions are associated with identifiable odors, such as hydrocarbons (eg, gasoline). Acidosis, as in diabetic ketoacidosis, may impart a fruity odor to the breath.
- **Neck.** Examine the area near the trachea for swelling or bruising. Note if the pediatric patient cannot move his or her neck and has a high fever. This may indicate that the pediatric patient has bacterial or viral meningitis.
- **Chest.** Examine the chest for penetrating injuries, lacerations, bruises, or rashes. If the pediatric patient is injured, feel the clavicles and every rib for tenderness and/or deformity.
- **Back.** Inspect the back for lacerations, penetrating injuries, bruises, or rashes.
- **Abdomen.** Inspect the abdomen for distention. Gently palpate the abdomen and watch closely for guarding or tensing of the abdominal muscles, which may suggest infection, obstruction, or intra-abdominal injury. Note any tenderness or masses. Look for any seat belt abrasions or bruising.
- **Extremities.** Assess for symmetry. Compare both sides for color, warmth, size of joints, swelling, and tenderness. Put each joint through full range of motion while watching the eyes of the pediatric patient for signs of pain, unless there is obvious deformity of the extremity suggesting a fracture.

Words of Wisdom

Because of the frequency of serious internal injuries in pediatric patients who show no external signs, it is especially important to investigate and thoroughly document the MOI. Do not let the rush at the scene distract you from determining the MOI, or at least direct another reliable responder to do so. Hospital care providers need this information.

Some of the guidelines used to assess adult circulatory status—heart rate and blood pressure—have important limitations in pediatric patients. First, normal heart rates vary with age in pediatric patients. Second, blood pressure is usually not assessed in pediatric patients younger than 3 years; it offers little information about the pediatric patient's circulatory status and is often difficult to obtain. In these pediatric patients, assessment of the skin is a better indication of their circulatory status.

It is important to use appropriately sized equipment when you assess a pediatric patient's vital signs. To obtain an accurate reading of a pediatric patient's blood pressure, use a cuff that covers two-thirds of the pediatric patient's upper arm. A blood pressure cuff that is too small may give you a falsely high reading, whereas a cuff that is too large may give you a falsely low reading. A useful tool to determine blood pressure in children ages 1 to 10 years (lower limits) is:

$$70 + (2 \times \text{child's age in years}) = \text{Systolic Blood Pressure}$$

Respiratory rates may be difficult to interpret. Rapid respiratory rates may simply reflect high fever, anxiety, pain, or excitement. Normal rates, on the other hand, may occur in a child who has been breathing rapidly with increased work of breathing for some time and is now becoming tired. Count the respirations for 30 seconds and then double that number. If the patient yawns, sighs, coughs, or talks during the 30-second period, wait a few seconds and begin again. In infants and children younger than 3 years, evaluate respirations by assessing the rise and fall of the abdomen. Assess the pulse rate by counting at least 1 minute, noting its quality and regularity.

Note that normal vital signs in pediatric patients vary with age **Table 34-9**. Remember that your approach to taking vital signs also varies with the age of the pediatric patient. Be gentle, talk to the pediatric patient, assess respirations and then pulse, and assess blood pressure last. Warm your stethoscope on your hands or a cloth before placing it on the skin. You may also want to let the pediatric patient hold the equipment first; this may help to reduce his or her anxiety.

Evaluate pupils in the child using a small pen-light. The response of pupils is a good indication of how well the brain is functioning, particularly when trauma has occurred. Be sure to compare the size of the pupils against each other.

A pulse oximeter is a valuable tool to measure the oxygen saturation in a pediatric patient with respiratory issues **Figure 34-21**.

YOU are the Provider — PART 3

Your partner hands the child's mother a pediatric nonrebreathing mask with the oxygen flow rate set at 12 L/min, and he asks her to hold the mask near the child's face. Although the child becomes somewhat agitated by the oxygen, she does not push the mask away. After your partner talks to the child and explains what he is going to do, he assesses her vital signs. You gather additional information from the child's parents.

Recording Time: 5 Minutes	
Respirations	34 breaths/min; labored
Pulse	124 beats/min; strong and regular
Skin	Pink, warm, and dry; capillary refill time, 1 second
Blood pressure	86/56 mm Hg
Oxygen saturation (Spo_2)	95% (on oxygen)

The child's mother tells you that her daughter has had a cold for the past 2 days, and has slowly developed a low-grade fever and high-pitched cough, which she describes as a "barking seal" sound. She was going to take her to the doctor tomorrow, but called 9-1-1 when the child began experiencing trouble breathing. Further assessment of the child reveals that her breath sounds are clear and equal bilaterally and she has prominent intercostal retractions.

5. What is the most likely cause of this child's respiratory distress?

6. Should you separate this child from her parents to provide further treatment? Why or why not?

Table 34-9 Pediatric Blood Pressure Ranges

Age	Systolic Blood Pressure (mm Hg)
Neonate: 1 day to 4 days	60 to 76
Neonate: 4 days to 1 month	67 to 84
Infant: 1 month to 3 months	73 to 94
Infant: 3 months to 6 months	78 to 103
Infant: 6 months to 1 year	82 to 105
Child: 1 year to 2 years	85 to 104
Child: 2 years to 7 years	88 to 106
Child: 7 years to 15 years	96 to 115
Adolescent: 15 years to 18 years	110 to 131

Data Adapted From: Pediatric Advanced Life Support, 2012, the American Heart Association.

Reassessment

Reassess the pediatric patient's condition as necessary—a general rule is to obtain vital signs and temperature every 15 minutes for a child in stable condition and at least every 5 minutes for a child in unstable condition. Infants and children can decompensate with alarming unpredictability; therefore, continually monitor respiratory effort, skin color and condition, and level of consciousness or interactiveness. Repeat the primary assessment and adjust your treatment accordingly.

When you provide interventions for a pediatric patient, remember that parents and caregivers may be able to assist you by calming and reassuring their child and are often well educated about their child's medical conditions. They are also able to assist with administering oxygen or medications via a nebulizer. Together you can build a trusting environment for the pediatric patient, who is already in a state of stress.

Communicate with the hospital on your findings and the interventions you used to improve the pediatric patient's condition. Be sure that all of this information is documented and given to emergency department (ED) personnel.

Figure 34-21 Pulse oximetry, which measures the pediatric patient's oxygen saturation, can be used to monitor the pediatric patient's status. **A.** Pulse oximeter probes can wrap around or clip onto fingers, toes, or ear lobes. **B.** A pulse oximeter being applied to an infant's foot.

Respiratory Emergencies and Management

Respiratory problems are the leading cause of cardiopulmonary arrest in the pediatric population. Failure to recognize and treat declining respiratory status will lead to death. A pediatric patient in respiratory distress still has the compensatory mechanisms and the ability to exchange oxygen and carbon dioxide. During respiratory distress, the pediatric patient is working harder to breathe and will eventually go into respiratory failure if left untreated. Respiratory failure occurs when the pediatric patient has exhausted all compensatory mechanisms and waste products begin to collect. If this is not treated, a total shutdown of the respiratory system will occur—respiratory arrest.

In the early stages of respiratory distress, you may note changes in the pediatric patient's behavior, such as combativeness, restlessness, and anxiety. As the body attempts to maximize the amount of air going into the lungs, the work of breathing increases. As discussed previously, the signs and symptoms of increased work of breathing include nasal flaring, abnormal breath sounds, accessory muscle use, and the tripod position.

As the pediatric patient progresses to possible respiratory failure, efforts to breathe decrease; the chest rises less with inspiration. The body has used up its available energy stores and cannot continue to support the extra work of breathing under these conditions. At this point, without care, cyanosis may develop (a late sign). Be aware not all pediatric patients develop cyanosis. You should be just as concerned about a pediatric patient with pale skin as one with blue skin.

Changes in behavior will also occur until the pediatric patient demonstrates an altered level of consciousness. The pediatric patient may experience periods of apnea (absence of breathing). As the lack of oxygen becomes more serious, the heart muscle itself becomes hypoxic and slows down. This leads to bradycardia—almost always an ominous sign in pediatric patients. If the heart rate is fast, you need to investigate the cause. However, if the heart rate is slow (less than 60 beats/min) or absent, especially in an unconscious infant or child, you must begin CPR immediately. Without aggressive airway management, bradycardia may quickly progress to cardiopulmonary arrest.

Of course, respiratory failure does not always indicate airway obstruction. It may indicate trauma, nervous system problems, dehydration (often caused by vomiting and diarrhea), or metabolic disturbances. For example, a pediatric patient with diabetes might have a blood glucose level that is too high or too low, or a pediatric patient might have a pH imbalance, as can happen with some rare pediatric diseases. Regardless of the cause, your first step is always to ensure adequate oxygenation and ventilation.

Never forget that a pediatric patient's condition can progress from respiratory distress to respiratory failure at any time. For this reason, you must reassess the pediatric patient frequently.

A child or infant in respiratory distress needs supplemental oxygen. Anxiety, agitation, or crying may increase the effort or work of breathing, so use whichever method seems least upsetting to the pediatric patient—mask, blow-by, or nasal cannula. You may need to get creative by distracting the pediatric patient with games, a toy, or conversation. Assist ventilation with a BVM and 100% oxygen for infants and children who are in possible respiratory failure.

Allow the pediatric patient to remain in a comfortable position. For a small child, this may mean sitting on the parent's or caregiver's lap. Give nothing by mouth, in case the patient's condition deteriorates suddenly. If the patient's condition progresses to respiratory failure, begin assisted ventilation immediately and continue to provide supplemental oxygen.

Airway Obstruction

Children, especially those younger than 5 years, can (and do) obstruct their airway with any object that they can fit into their mouth, such as hot dogs, balloons, grapes, or coins **Figure 34-22**. In cases of trauma, a child's teeth may have been dislodged into the airway. Blood, vomitus, or other secretions can also cause mild or severe airway obstruction.

As discussed in Chapter 15, *Respiratory Emergencies,* airway obstructions can also be caused by infections, including pneumonia, croup, epiglottitis, and bacterial **tracheitis** **Figure 34-23**. Consider infection as a possible cause of airway obstruction if a pediatric patient has congestion, fever, drooling, and cold symptoms.

Special Populations

Pediatric patients who have a tracheostomy tube to assist in breathing are at risk of tracheostomy dysfunction. This is an airway obstruction that results from an accumulation of thick mucus at the opening of the tracheostomy tube. These pediatric patients require urgent care and transport.

Obstruction by a foreign object may involve the upper or the lower airway, and may be partial or complete. Signs and symptoms that are frequently associated with a partial upper airway obstruction include decreased or absent breath sounds and stridor. Stridor is usually caused by swelling of the area surrounding the vocal cords or upper airway obstruction. Infants or children with a complete airway obstruction will have absent breath sounds and become rapidly cyanotic.

Figure 34-22 Any number of objects can obstruct a child's airway, including batteries, coins, toys, buttons, and candy.

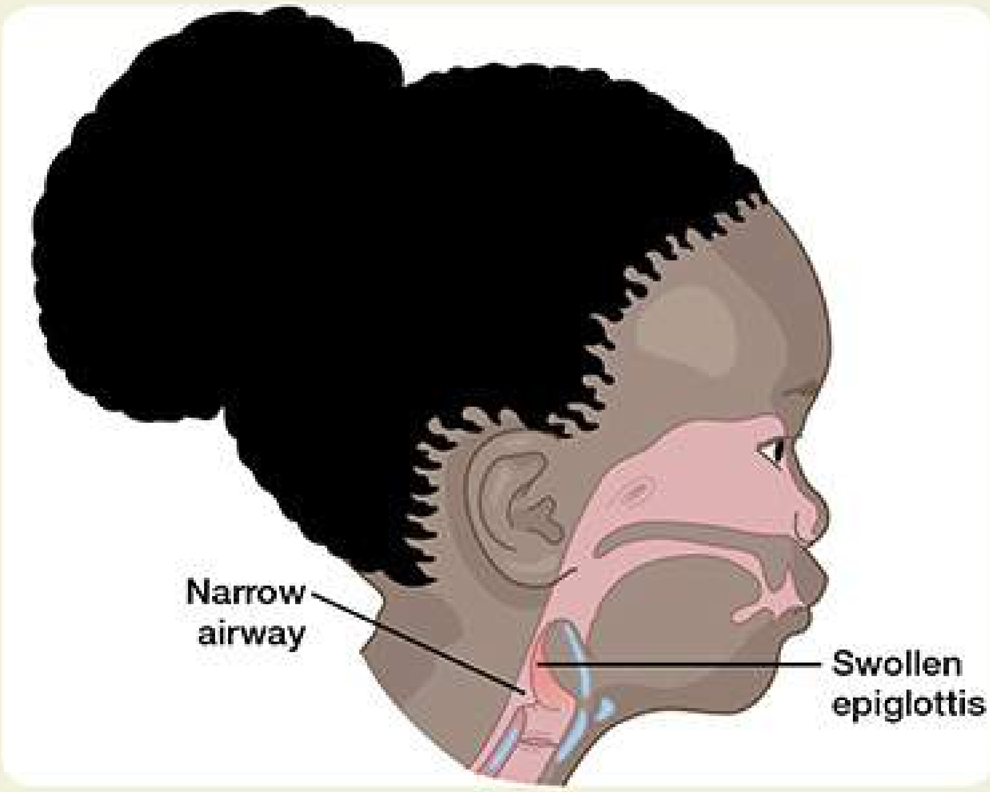

Figure 34-23 Epiglottitis is an infection that can cause airway obstruction in pediatric patients.

Signs and symptoms of a lower airway obstruction include wheezing and/or crackles. The best way to auscultate breath sounds in a pediatric patient is to listen on both sides of the chest at the level of the armpit **Figure 34-24**.

Immediately begin treatment of the pediatric patient with an airway obstruction. If the patient is conscious and coughing forcefully and you know for sure that there is a foreign body in the airway—that is, if someone actually saw the object go into the child's mouth—encourage the child to cough to clear the airway. If the material in the airway does not completely block the flow of air, the pediatric patient may be able to breathe adequately on his or her own without any intervention. In such cases, do not intervene except to provide supplemental oxygen **Figure 34-25**. Allow the pediatric patient to remain in whatever position is most comfortable, and monitor his or her condition during transport.

Figure 34-24 The best way to auscultate breath sounds in pediatric patients is to listen on both sides of the chest at the level of the armpit.

Figure 34-25 If a pediatric patient has a partial airway obstruction, do not intervene except to give supplemental oxygen. Allow the child to remain in whatever position is most comfortable during transport.

If you see signs of a severe airway obstruction, however, you must attempt to clear the airway immediately. The signs include the following:

- Ineffective cough (no sound)
- Inability to speak or cry
- Increasing respiratory difficulty, with stridor
- Cyanosis
- Loss of consciousness

If an infant is conscious with a complete airway obstruction, perform up to five back blows followed by five chest thrusts. First, position the infant facedown on your forearm. Support the infant's jaw and head with your hand. Next, use the heel of your other hand to slap the back forcefully five times (between the shoulder blades). If the airway does not clear, flip the infant onto his or her back, using your hand to support the head. Perform up to five chest thrusts in the same manner you would provide chest compressions for CPR. Repeat the process until the obstruction clears or until the infant becomes unconscious.

If a child (older than 1 year) is conscious with a complete airway obstruction, perform abdominal thrusts (Heimlich maneuver). Continue until the obstruction clears or until the child becomes unconscious.

If there is reason to believe that an unconscious child has a foreign body obstruction and there are no suspected spinal injuries, open the airway using the head tilt–chin lift maneuver and look inside the mouth to see whether the obstructing object is visible **Figure 34-26**. If the object is visible, try to remove it using a finger sweep motion. Never use finger sweeps if you cannot see the object because you may push it further into the airway.

Chest compressions are recommended to relieve a severe airway obstruction in an unconscious pediatric patient. Chest compressions increase the pressure in the chest, creating an artificial cough that may force a foreign body from the airway. Chapter 13, *BLS Resuscitation*, covers clearing a foreign body obstruction in an infant and child in detail.

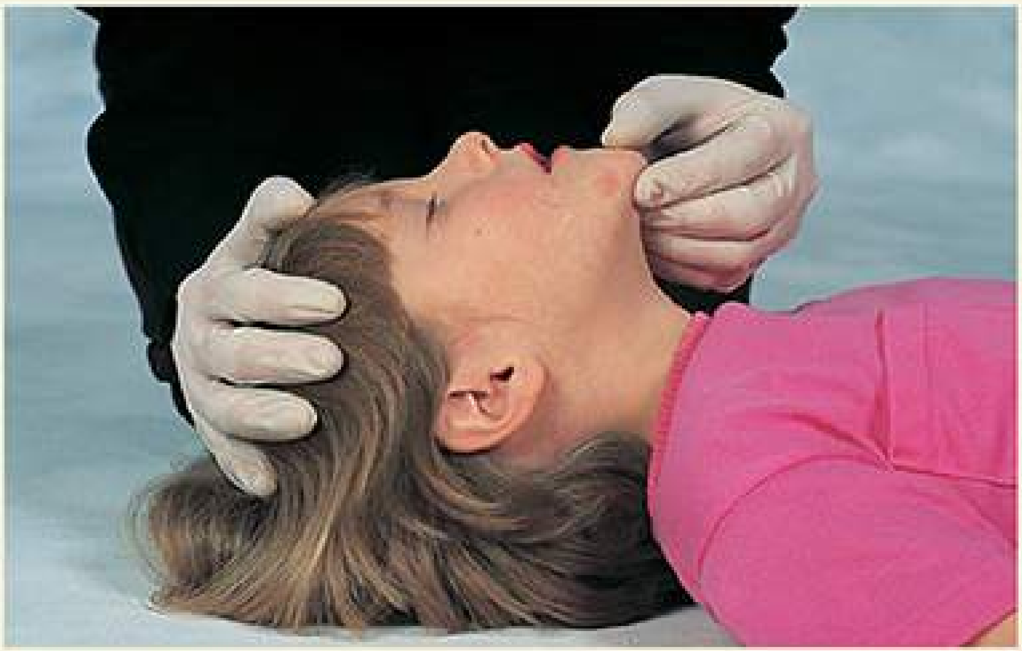

Figure 34-26 Open the airway and look inside the mouth of an unconscious pediatric patient with a possible airway obstruction.

Asthma

Asthma is a condition in which the smaller air passages (bronchioles) become inflamed, swell, and produce excessive mucus, which leads to difficulty breathing. Asthma is a true medical emergency if not promptly identified and treated. According to the Centers for Disease Control and Prevention (CDC), 10% of children in the United States have asthma and in 2007 alone, 185 children died of asthma. Common causes (triggers) for an asthma episode include upper respiratory infection, exercise, exposure to cold air or smoke, and emotional stress. Asthma is rare in children younger than 1 year.

Children with asthma will wheeze as they attempt to exhale through partially obstructed lower air passages; you may be able to hear loud wheezing without a stethoscope. In other cases, the airways are completely blocked and no air movement is heard. In severe cases, cyanosis and/or respiratory arrest may quickly develop. Asthma patients in respiratory distress will typically assume a position of comfort, such as the tripod position, to allow for maximum respiratory effort.

If possible, allow the pediatric patient to assume a position of comfort in the parent's or caregiver's lap. Avoid overexciting the pediatric patient because this may worsen the condition. Administer supplemental oxygen via a route that is tolerated by the child. Allow the parent or caregiver to assist the team by gathering any medications, calming the pediatric patient, or holding blow-by oxygen or a nonrebreathing mask.

A bronchodilator (albuterol, a beta-2 agonist) via a metered-dose inhaler (MDI) with a spacer-mask device may be administered based on local agency protocols. Often the parents or caregivers have attempted multiple dosages of albuterol via the MDI or nebulizer. In this case, ALS providers should be dispatched immediately to meet you en route for additional medication administration and advanced care.

If you must assist ventilations in a pediatric patient who is having an asthma attack, use slow, gentle breaths. Remember, the problem in asthma is getting the air out of the lungs, not into them. Resist the temptation to squeeze the reservoir bag hard and fast.

A prolonged asthma attack that is unrelieved may progress into a condition known as status asthmaticus. The pediatric patient is likely to be frightened, frantically trying to breathe, and using all the accessory muscles. Status asthmaticus is a true emergency. Administer oxygen and provide rapid transport to the ED.

The effort to breathe during an asthma attack is very tiring, and the pediatric patient may be exhausted by the time you arrive. An exhausted pediatric patient may have stopped feeling anxious or even struggling to breathe. It may look as if this patient is recovering; however, he or she is at a very critical stage and is likely to stop breathing. Aggressive airway management, oxygen administration, and prompt transport are essential in this situation. Consider calling for ALS backup. Follow local protocol.

Pneumonia

According to the World Health Organization, pneumonia is the leading cause of death for over 2 million children worldwide annually. Pneumonia is a general term that refers to an infection of the lungs. Pneumonia is often a secondary infection; it occurs during or after treatment for a pre-existing infection such as a cold. It can also be caused by direct lung injuries, such as from an accidental ingestion of a chemical or a submersion incident. Children with diseases causing immunodeficiency are at increased risk for pneumonia developing. You will notice that the incidence of this type of virus is greatest during the fall and winter months, affecting a large number of the pediatric population.

Often pediatric patients will present with unusually rapid breathing, or will breathe with grunting or wheezing sounds. Additional signs and symptoms include nasal flaring, tachypnea, and hypothermia or fever. The patient may also exhibit unilateral diminished breath sounds or crackles over the infected lung segments. Assess the work of breathing by observing for signs of accessory muscle usage. Pneumonia is particularly serious in infants because they have an increased oxygen demand and less respiratory reserve than older children or adults. For a pediatric patient with suspected pneumonia, your primary treatment will be supportive. Monitor the patient's airway and breathing status, and administer supplemental oxygen if required. If the child is wheezing, administer a bronchodilator if permitted in your EMS system. A diagnosis of pneumonia must be confirmed in the hospital setting with a chest x-ray, followed by the administration of antibiotics as the primary treatment.

Croup

Croup (laryngotracheobronchitis) is an infection of the airway below the level of the vocal cords, usually caused by a virus. This disease is typically seen in children between ages 6 months and 3 years. It is easily passed between children. The disease starts with a cold, cough, and a low-grade fever that develops over 2 days. The hallmark signs of croup are stridor and a seal-bark cough, which is a signal of significant narrowing of the air passage of the trachea that may progress to significant obstruction. Peak seasonal outbreaks of this disease occur in the late fall and during the winter. Croup often responds well to the administration of humidified oxygen. Bronchodilators are *not* indicated for croup and can make the child worse.

Epiglottitis

Epiglottitis (supraglottitis) is an infection of the soft tissue in the area above the vocal cords. Bacterial infection is the most common cause. Infants and children are the most common age groups diagnosed with epiglottitis, but it occurs in patients of all ages. Since the development of a vaccine against one organism that causes epiglottitis, the incidence of this disease has dramatically decreased. In preschool- and school-aged children especially, the epiglottis can swell to two to three times its normal size. This puts the airway at risk of complete obstruction. Patients with epiglottitis typically look very sick. The condition usually develops in otherwise healthy children, and symptoms are relatively sudden in onset. Children with this infection look ill, report a very sore throat, and have a high fever. They will often be found in the tripod position and drooling.

Bronchiolitis

Bronchiolitis is a specific viral illness of newborns and toddlers, often caused by respiratory syncytial virus (RSV) that causes inflammation of the bronchioles. RSV is highly contagious and spread through droplets when the pediatric patient coughs or sneezes. RSV is more common in premature infants and results in copious secretions that may require suctioning. The virus can also survive on surfaces, including hands and clothing. The infection tends to spread rapidly through schools and in child care centers.

Bronchiolitis occurs during the first 2 years of life and is more common in boys. These infections are most widespread in the winter and early spring. Bronchioles become inflamed, swell, and fill with mucus. The airways of infants and young children can become easily blocked.

When assessing a pediatric patient, look for signs of dehydration—infants with RSV often refuse liquids. If the RSV has progressed to bronchiolitis, shortness of breath and fever may be present.

Approach the pediatric patient with a calm demeanor and allow for a position of comfort. Treat airway and breathing problems as appropriate. Humidified oxygen is helpful if available. Consider calling for ALS backup and transport to the appropriate hospital.

Pertussis

Pertussis, also known as whooping cough, is a communicable disease caused by a bacterium that is spread through respiratory droplets. As the result of vaccinations, this potentially deadly disease is less common in the United States. The typical signs and symptoms are similar to a common cold: coughing, sneezing, and a runny nose. As the disease progresses, the coughing becomes more severe and is characterized by the distinctive whoop sound heard during inspiration. Infants infected with pertussis may develop pneumonia or respiratory failure. To treat pediatric patients, keep the airway patent (open) and transport. Because pertussis is contagious, follow standard precautions, including wearing a mask and eye protection.

Airway Adjuncts

In children with inadequate ventilation, use an airway adjunct to maintain an open airway. Airway adjuncts are devices that help to maintain the airway or assist in providing artificial ventilation, including oropharyngeal and nasopharyngeal airways, bite blocks, and BVMs. Placing the adjuncts correctly starts with choosing the appropriately sized equipment Table 34-10.

Oropharyngeal Airway

An oropharyngeal (oral) airway is designed to keep the tongue from blocking the airway, and it makes suctioning the airway, if necessary, easier. An oropharyngeal airway should be used for pediatric patients who are unconscious and in respiratory failure. This adjunct should not be used in either conscious pediatric patients or those who have a gag reflex. Pediatric patients with a gag reflex do not tolerate an oropharyngeal airway. In addition, this adjunct should not be used in children who may have ingested a caustic or petroleum-based product because it may induce vomiting.

Skill Drill 34-2 shows the steps for inserting an oropharyngeal airway in a child:

1. Determine the appropriately sized airway by placing the airway next to the face with the flange at the level of the central incisors and the bite block segment parallel to the hard palate. The tip of the airway should reach the angle of the jaw Step 1. Or, use length-based resuscitation tape to determine the appropriately sized airway.

YOU are the Provider — PART 4

The child's father carries her to the ambulance, where you appropriately secure her to the stretcher. You reassess her condition prior to transport and note that it has changed. On appearance, you note that her retractions have markedly weakened, she has a blank stare, and she is listless. Your partner quickly secures the child's mother in the front seat of the ambulance and begins rapid transport.

Recording Time: 10 Minutes	
Level of consciousness	Decreased activity; blank stare; listless
Respirations	18 breaths/min; weak retractions
Pulse	90 beats/min; weak and regular
Skin	Perioral cyanosis; cool and dry; capillary refill time, 3 seconds
Blood pressure	76/56 mm Hg
Spo_2	85% (on oxygen)

7. How has this child's condition changed? What should you do next?
8. How could an ALS intercept benefit this child?

Table 34-10 Pediatric Equipment: Getting the Size Right

The best way to identify the appropriately sized equipment for a pediatric patient is to use **length-based resuscitation tape** (Broselow tape). This color-coded tool can estimate weight as well as height in pediatric patients weighing up to 75 lb (34 kg) **Figure 34-27**. The proper sequence for using the tape is the following:

1. Place the pediatric patient supine on a flat surface.
2. Lay the tape next to the pediatric patient with the multicolored side facing up.
3. Place the red end of the tape at the top of the pediatric patient's head (red to head).
4. Place one hand with its side down at the top of the pediatric patient's head, covering the red box at the end of the tape.
5. Starting from the pediatric patient's head, run the side of your free hand down the tape.
6. Stretch the tape out the full length of the child, stopping at the heel. If the child is longer than the tape, stop here and use the appropriate adult equipment.
7. Place your free hand, side down, at the bottom of the child's heel.
8. Note the color or letter block and weight range on the edge of the tape where your hand is. Say the color or letter out loud.
9. Select the appropriately sized equipment by matching the color or letter on the tape to the color or letter on the equipment.

Figure 34-27 Length-based resuscitation tape is the best way to estimate the correct size for airway adjuncts in children.

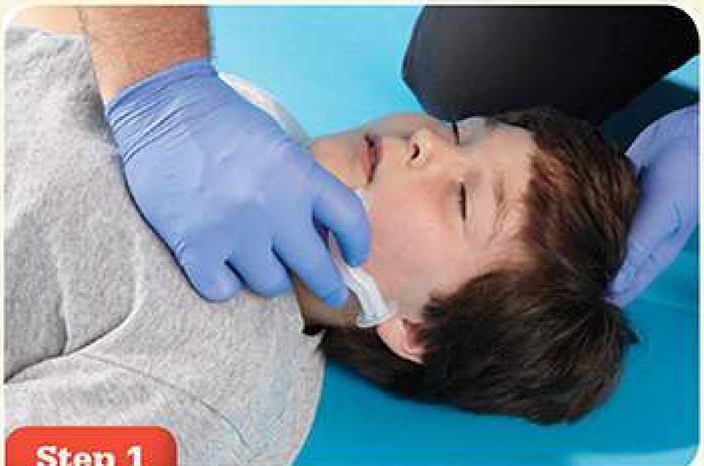
2. Position the pediatric patient's airway. If the emergency is medical, use the head tilt–chin lift maneuver. Avoid hyperextension; you may place a towel under the pediatric patient's shoulders. If the pediatric patient has a traumatic injury, use the jaw-thrust maneuver and provide manual in-line stabilization **Step 2**.
3. Open the mouth by applying pressure on the chin with your thumb.
4. Insert the airway by depressing the tongue with a tongue blade applied to the base of the tongue and inserting the airway directly over the tongue blade **Step 3**. If a tongue blade is unavailable, point the airway tip toward the roof of the mouth to depress the tongue. Gently rotate the airway into position as it passes through the mouth toward the curve of the tongue. Insert the airway until the flange rests against the lips.
5. Reassess the airway after insertion. Take care to avoid injuring the hard palate as you insert the airway. Rough insertion can cause bleeding, which can aggravate airway problems and may even cause vomiting. Note also that if the pediatric patient's airway is too small, the tongue may be pushed back into the pharynx, obstructing the airway. If the airway is too large, it may obstruct the larynx.

Nasopharyngeal Airway

A nasopharyngeal (nasal) airway is usually well tolerated and is not as likely as the oropharyngeal airway to cause vomiting. Unlike the oropharyngeal airway, the nasopharyngeal airway is used for pediatric patients who are responsive. In pediatric patients, the nasopharyngeal airway is typically used in association with possible respiratory failure. It is rarely used in infants younger than 1 year.

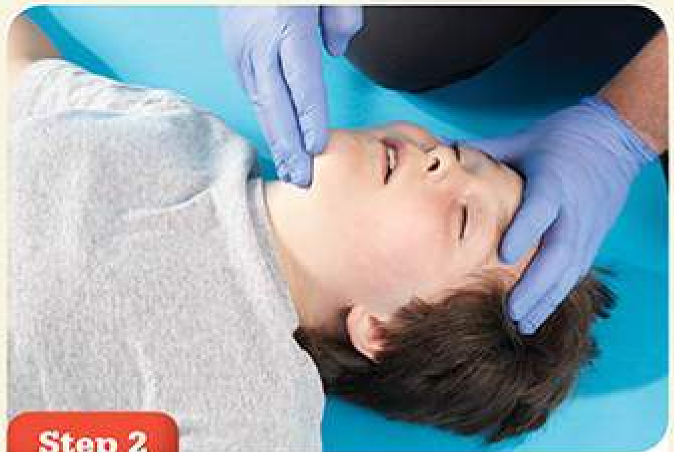
A nasopharyngeal airway should not be used in pediatric patients with nasal obstruction or head trauma (possible basilar skull fracture) or in pediatric patients with moderate to severe head trauma because this adjunct could increase intracranial pressure.

Skill Drill 34-2 Inserting an Oropharyngeal Airway in a Pediatric Patient



Step 1

Determine the appropriately sized airway. Confirm the correct size visually, by placing it next to the pediatric patient's face.



Step 2

Position the pediatric patient's airway with the appropriate method.

Step 3

Open the mouth. Insert the airway until the flange rests against the lips. Reassess the airway.

Follow the steps in **Skill Drill 34-3** to insert a nasopharyngeal airway in a pediatric patient:

1. Determine the appropriately sized airway. The external diameter of the airway should not be larger than the diameter of the nares, and there should be no blanching of the nares after insertion.
2. Place the airway next to the pediatric patient's face to make sure the length is correct. The airway should extend from the tip of the nose to the tragus of the ear. The tragus is the small cartilaginous projection in front of the opening of the ear.

3. Position the pediatric patient's airway, using the techniques described above for the oropharyngeal airway **Step 1**.
4. Lubricate the airway with a water-soluble lubricant.
5. Insert the tip into the right naris (nostril opening) with the bevel pointing toward the septum, or central divider in the nose **Step 2**. The right naris is commonly larger than the left naris in most patients.
6. Carefully move the tip forward, following the roof of the mouth, until the flange rests against the outside of the nostril **Step 3**. If you are inserting the airway on the left side, insert the tip into the left naris upside down, with the bevel pointing toward the septum. Move the airway forward slowly about 1 inch (2.5 cm) until you feel a slight resistance, and then rotate the airway 180 degrees.

Skill Drill 34-3 Inserting a Nasopharyngeal Airway in a Pediatric Patient

Step 1

Determine the correct airway size by comparing its diameter to the opening of the nostril (nare). Place the airway next to the pediatric patient's face to confirm correct length. Position the airway.

Step 2

Lubricate the airway. Insert the tip into the right naris with the bevel pointing toward the septum.

Step 3

Carefully move the tip forward until the flange rests against the outside of the nostril. Reassess the airway.

7. Reassess the airway after insertion.

As with the oropharyngeal airway, there can be problems with the nasopharyngeal airway. An airway with a small diameter may easily become obstructed by mucus, blood, vomitus, or the soft tissues of the pharynx. If the airway is too long, it may stimulate the vagus nerve and slow the heart rate or enter the esophagus, causing gastric distention. Inserting the airway in responsive patients may cause a spasm of the larynx and result in vomiting. Nasopharyngeal airways should not be used when pediatric patients have facial trauma because the airway may tear soft tissues and cause bleeding into the airway.

Oxygen Delivery Devices

When treating infants and children who require more than the usual 21% oxygen found in room air, you have several options:

- Blow-by technique at 6 L/min provides more than 21% oxygen concentration.
- Nasal cannula at 1 to 6 L/min provides 24% to 44% oxygen concentration.
- Nonrebreathing mask at 10 to 15 L/min provides up to 95% oxygen concentration (unassisted ventilations).
- BVM (with oxygen reservoir) at 15 L/min provides nearly 100% oxygen concentration (assisted ventilations).

Pediatric patients need enough air to be delivered for adequate gas exchange in the lungs. Therefore, use of a nonrebreathing mask, a nasal cannula, or a simple face mask is indicated only for pediatric patients who have adequate respirations and/or tidal volumes. The tidal volume is the amount of air that is delivered to the lungs and airways in one inhalation. Children with respirations of less than 12 breaths/ min or more than 60 breaths/min, an altered level of consciousness, and/or an inadequate tidal volume should receive assisted ventilation with a BVM.

Blow-by oxygen is not as effective as a face mask or nasal cannula for delivering oxygen. In the blow-by technique, an oxygen tube is held near the infant or child's nose and mouth. It is often used after childbirth to deliver a small amount of oxygen to the neonate. On rare occasions when other adjuncts cannot be used or the pediatric patient will not tolerate any other adjunct, this technique may be necessary. The blow-by technique does not provide a high concentration of oxygen but is better than no oxygen. To administer blow-by oxygen:

Figure 34-28 The blow-by technique may be less frightening to a child than an oxygen mask. Make a small hole in an 8-oz (237-mL) cup, or use a funnel inserted into the end of the oxygen tubing. Connect tubing to an oxygen source, and hold the cup about 1 to 2 inches (2 to 5 cm) from the child's face.

1. Place oxygen tubing through a small hole in the bottom of an 8-oz (237-mL) cup **Figure 34-28**. A cup is a familiar object that is less likely to frighten young children than is an oxygen mask.
2. Connect tubing to an oxygen source set at 6 L/min.
3. Hold the cup approximately 1 to 2 inches (2 to 5 cm) away from the child's nose and mouth.

Nasal Cannula

Some pediatric patients prefer the nasal cannula whereas others find it uncomfortable. To apply a nasal cannula:

1. Choose the appropriately sized pediatric nasal cannula. The prongs should not fill the nares entirely **Figure 34-29**. If the nares blanch, select a smaller cannula.
2. Connect the tubing to an oxygen source set at 1 to 6 L/min.

Figure 34-29 The prongs of a pediatric nasal cannula should not fill the nares entirely.

Nonrebreathing Mask

A nonrebreathing mask delivers up to 90% oxygen to the pediatric patient and allows the pediatric patient to exhale all carbon dioxide without rebreathing it **Figure 34-30**. To apply a nonrebreathing mask:

1. Select the appropriately sized pediatric nonrebreathing mask. The mask should extend from the bridge of the nose to the cleft of the chin.
2. Connect the tubing to an oxygen source set at 10 to 15 L/min.
3. Adjust oxygen flow as needed to match the pediatric patient's respiratory rate and depth. The reservoir bag should neither deflate completely nor fill to bulging during the respiratory cycle.

Bag-Valve Mask

Assisting ventilations with a BVM is indicated for pediatric patients who have respirations that are either too slow or too fast to provide an adequate volume of inhaled oxygen, who are unresponsive, or who do not respond in a purposeful way to painful stimuli.

Figure 34-30 A pediatric nonrebreathing mask delivers up to 95% oxygen and allows the patient to exhale carbon dioxide without rebreathing it.

Assist ventilation of an infant or child using a BVM in the following way:

1. Ensure that you have the appropriately sized equipment. The proper size mask will extend from the bridge of the nose to the cleft of the chin, avoiding compression of the eyes **Figure 34-31**. The mask is transparent, so you can watch for cyanosis and vomiting. In addition, mask volume should be small to decrease dead space and avoid rebreathing; however, the bag should contain at least 450 mL of air. Use an infant bag, not a neonatal bag, for infants younger than 1 year; use a pediatric bag for children older than 1 year. Older children and adolescents may need an adult bag. Make sure that there is no popoff valve on the bag; if the bag has a pop-off valve, make sure that you can hold it shut as necessary to achieve chest rise. Proper mask size for BVM ventilation is critical.
2. Maintain a good seal with the mask on the face.

Figure 34-31 Proper mask size for BVM ventilation is critical. The mask should extend from the bridge of the nose to the cleft of the chin, avoiding compression of the eyes.

3. Ventilate at the appropriate rate and volume using a slow, gentle squeeze, not a sharp, quick one. Stop squeezing and begin to release the bag as soon as the chest wall begins to rise, indicating that the lungs are filled to capacity. To keep from ventilating too rapidly, use the phrase "Squeeze, release, release." Say "Squeeze" as you squeeze the bag; when you see the chest start to rise, release pressure on the bag and slowly say "Release, release."

Words of Wisdom

Remember that one-person BVM ventilation is difficult; the ILCOR guidelines do not recommend this method. Errors in technique—such as providing too much volume with each breath, squeezing the bag too forcefully, or ventilating at a rate that is too fast—can result in gastric distention or overinflation of the lung, resulting in a pneumothorax. An inadequate mask seal or improper head position can lead to hypoventilation or hypoxia.

Special Populations

One of the problems associated with abdominal injuries in children is the presence of air in the stomach. Pediatric patients, especially those who have had a traumatic injury, tend to swallow air. Air in the stomach can cause distention and interfere with your assessment. Air can also accumulate in the stomach with artificial ventilation, making it less effective.

One-Person Bag-Valve-Mask Ventilation on a Pediatric Patient

Perform one-person BVM-ventilation according to these steps **Skill Drill 34-4**:

1. Open the airway, and insert the appropriate airway adjunct **Step 1**.
2. Hold the mask on the pediatric patient's face with a one-handed head tilt–chin lift maneuver (EC clamp technique). Form a *C* with the thumb and index finger along the mask while the other three fingers form an *E* along the mandible.

With infants and toddlers, support the jaw with only your third fingertip. Be careful not to compress the area under the chin because you may push the tongue into the back of the mouth and block the airway. Keep fingers on the mandible.

3. Make sure the mask forms an airtight seal on the face. Maintain the seal while checking that the airway is open **Step 2**.
4. Squeeze the bag using the correct ventilation rate of 1 breath every 3 to 5 seconds, or 12 to 20 breaths/min.
5. Each ventilation (squeeze of the bag) should last 1 second. Allow adequate time for exhalation **Step 3**.
6. Assess the effectiveness of ventilation by watching for adequate bilateral rise and fall of the chest **Step 4**.

Skill Drill 34-4 One-Person Bag-Valve Mask Ventilation on a Pediatric Patient

Step 1

Open the airway and insert the appropriate airway adjunct.

Step 2

Hold the mask on the pediatric patient's face with a one-handed head tilt–chin lift maneuver (EC clamp method). Ensure a good mask–face seal while maintaining the airway.

Step 3

Squeeze the bag using the correct ventilation rate of 1 breath every 3 to 5 seconds, or 12 to 20 breaths/min. Allow adequate time for exhalation.

Step 4

Assess the effectiveness of ventilation by watching bilateral rise and fall of the chest.

Two-Person Bag-Valve-Mask Ventilation on a Pediatric Patient

This procedure is similar to one-person ventilation except that it requires two EMTs—one to hold the mask to the pediatric patient's face and maintain the pediatric patient's head position, the other to ventilate the pediatric patient. This technique is usually more effective in maintaining a tight seal, as it provides an open airway due to proper body position.

Cardiopulmonary Arrest

As previously discussed, cardiac arrest in infants and children is most often associated with respiratory failure and respiratory arrest. Compared with adults, children are affected differently when it comes to decreasing oxygen concentrations. An adult becomes hypoxic and the heart develops a dysrhythmia that leads to sudden cardiac death. This is often in the form of ventricular fibrillation and is the reason that an automated external defibrillator (AED) is the treatment of choice. Children, on the other hand, become hypoxic and their hearts slow down, becoming more and more bradycardic. The heart will beat slower and more weakly until no pulse is felt. The overall survival rate from cardiac arrest in the prehospital setting in children is about approximately 8% according to the *2010 Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care* published by the American Heart Association. The survival rate from respiratory arrest is only 70%. Any child who is breathing very poorly with a slowing heart rate must be ventilated with high concentrations of oxygen early to try to oxygenate the heart before cardiac arrest occurs. Chapter 13, *BLS Resuscitation*, covers providing CPR to pediatric patients in detail.

Circulation Emergencies and Management

The pediatric cardiovascular system is not all that different than an adult's. Although pediatric patients have a larger proportional amount of circulating blood volume than adults, they are more dependent on the actual cardiac output of the heart (amount of blood being pumped out of the heart in 1 minute). A pediatric patient actually may be in a state of shock while displaying a normal blood pressure. Infants and children have less blood circulating in their bodies than adults do, so the loss of even a small volume of fluid or blood may lead to shock.

Shock

As discussed in Chapter 12, *Shock*, shock is a condition that develops when the circulatory system is unable to deliver a sufficient amount of blood to the organs of the body. This results in organ failure and eventually cardiopulmonary arrest. The early stage of shock, while the body can still compensate for blood loss, is called compensated shock. The late stage, when blood pressure is falling, is called decompensated shock.

YOU are the Provider — PART 5

The closest ALS ambulance is 8 miles across town in heavy traffic and your estimated transport time is about 5 minutes, so you make the decision to continue transport. Your partner notifies the hospital and informs them of your impending arrival. Following additional treatment, you reassess the child's condition.

Recording Time: 18 Minutes	
Level of consciousness	Eyes are open; still appears listless
Respirations	20 breaths/min and shallow (baseline); assisted ventilations
Pulse	110 beats/min; stronger
Skin	Cyanosis is resolving; capillary refill time, 2 seconds
Blood pressure	84/54 mm Hg
Spo_2	96% (on oxygen)

9. Are you providing adequate ventilations? How can you tell?
10. Why is it especially important to avoid hyperventilating infants and children?

In pediatric patients, the most common causes include:

- Traumatic injury with blood loss (especially abdominal)
- Dehydration from diarrhea and vomiting
- Severe infection
- Neurologic injury, such as severe head trauma
- A severe allergic reaction to an allergen (anaphylaxis), such as an insect bite or food allergy
- Diseases of the heart

- A collapsed lung (tension pneumothorax)
- Blood or fluid around the heart (cardiac tamponade or pericarditis)

Pediatric patients respond differently than adults to fluid loss. They may respond by increasing their heart rate, increasing respirations, and showing signs of pale skin (pallor) or blue skin (cyanosis).

Signs of shock in infants and children are as follows:

- Tachycardia
- Poor capillary refill (>2 seconds)
- Mental status changes

Begin treating shock by assessing the ABCs, intervening immediately as required; do not wait until you have performed the complete assessment to take action. If there is an obvious life-threatening external hemorrhage, the order becomes CAB, because bleeding control is the most critical step. If cardiac arrest is suspected, the order also becomes CAB because chest compressions are essential. Pediatric patients in shock often have increased respirations but do not demonstrate a fall in blood pressure until shock is severe.

When you assess circulation, pay particular attention to the following:

- **Pulse.** Assess both the rate and the quality of the pulse. A weak, "thready" pulse is a sign that there is a problem. The appropriate rate depends on age; generally, except in the case of a newborn, anything over 160 beats/min suggests shock.
- **Skin signs.** Assess the temperature and moisture of the hands and feet. How does this compare with the temperature of the skin on the trunk of the body? Is the skin dry and warm, or cold and clammy?
- **Capillary refill time.** Squeeze a finger or toe for several seconds until the skin blanches, and then release it. Does the fingertip return to its normal color within 2 seconds, or is it delayed?
- **Color.** Assess the patient's skin color. Is it pink, pale, ashen, or blue?
- **Changes.** Changes in pulse rate, color, skin signs, and capillary refill time are all important clues suggesting shock.

Blood pressure is the most difficult vital sign to measure in pediatric patients. The cuff must be the proper size—two-thirds the length of the upper arm. The value for normal blood pressure is also age-specific. Remember that blood pressure may be normal with compensated shock. Low blood pressure is a sign of decompensated shock, requiring care from an ALS team and rapid transport.

Part of your assessment should also include talking with the parents or caregivers to determine when the signs and symptoms first appeared and whether any of the following has occurred:

- Decrease in urine output (with infants, are there fewer than 6 to 10 wet diapers?)
- Absence of tears, even when the child is crying
- A sunken or depressed fontanelle (infant patient)
- Changes in level of consciousness and behavior

Limit your management to these simple interventions. Do not waste time performing field procedures. Ensure that the airway is open; prepare for artificial ventilation; control bleeding; and give supplemental oxygen by mask or blow-by method as tolerated. Continue to monitor airway and breathing. Place the pediatric patient in a position of comfort. Keep the pediatric patient warm with blankets and by turning up the heat in the patient compartment. Provide rapid transport to the nearest appropriate facility and continue monitoring vital signs en route. Call for ALS backup as needed. Allow a parent or caregiver to accompany the pediatric patient whenever possible.

Anaphylaxis

Anaphylaxis, also called anaphylactic shock, is a life-threatening allergic reaction that involves a generalized, multisystem response to an antigen (foreign substance). Anaphylaxis is characterized by airway swelling and the dilation of blood vessels. Common causes include insect bites or stings, medications, and food.

A pediatric patient in anaphylactic shock will have hypoperfusion as well as additional signs such as stridor and/or wheezing, with increased work of breathing. The pediatric patient will also have an altered appearance with restlessness, agitation, and sometimes a sense of impending doom. Hives, an intensely itchy skin rash, are usually present.

Maintain the airway and administer oxygen via a route that is tolerated. If the pediatric patient is in stable condition, allow the parent or caregiver to assist in the positioning of the patient, oxygen delivery, and keeping the patient calm. Increased agitation and crying, combined with an increased work of breathing, may lead to increased bronchoconstriction. Based on local protocol, assist the parent or caregiver with administering a prescribed epinephrine auto-injector, if available. As discussed in Chapter 20, *Immunologic Emergencies*, the administration of epinephrine is the highest priority in infants and children with signs and symptoms of anaphylaxis. The pediatric epinephrine auto-injector (EpiPen Jr) is supplied in a dose of 0.15 mg and is given intramuscularly in the lateral thigh. Provide rapid transport to the hospital.

Bleeding Disorders

Hemophilia is a congenital condition in which the patient lacks one or more of the normal clotting factors of blood. There are several forms of hemophilia, most of which are hereditary and some of which are severe. Hemophilia is predominantly found in the male population. Sometimes bleeding may occur spontaneously. Because the pediatric patient's blood does not clot, all injuries, no matter how minor, are potentially serious. Transport a pediatric patient with hemophilia immediately and do not delay tourniquet application for life-threatening hemorrhage.

Neurologic Emergencies and Management

There are several causes of altered mental status in the pediatric population. Some of the most common causes are hypoglycemia, hypoxia, seizure, and drug or alcohol ingestion. The parent or caregiver is an important resource for you when you are gathering information regarding the baseline neurologic status of the pediatric patient. A pediatric patient with altered mental status may appear sleepy, lethargic, combative, or even unresponsive to tactile stimulus. Be diligent about assessing and managing the airway because pediatric patients may be prone to airway obstructions from their large tongues.

Altered Mental Status

An altered mental status is an abnormal neurologic state in which the pediatric patient is less alert and interactive than is age appropriate. Sometimes, the concern of the parent or caregiver is vague, stating that the child is "not acting right." Therefore, it is key that you understand normal developmental or age-related changes in behavior, and listen carefully to the parent's or caregiver's opinion about a pediatric patient's baseline behavior. For instance, a 4-month-old infant should be active, have the ability to track a toy or light with his or her eyes, smile, and make eye contact. As discussed at the beginning of this chapter, if the pediatric patient is not behaving in a developmentally appropriate manner, then this could indicate an altered mental status.

The mnemonic AEIOU-TIPS reflects the major causes of altered mental status **Table 34-11**.

The signs and symptoms of altered mental status vary widely from simple confusion to coma. Management of altered mental status focuses on the ABCs and transport. If the pediatric patient's level of consciousness is low, then the pediatric patient may not be able to protect his or her airway. Ensure a patent airway and adequate breathing through a nonrebreathing mask or a BVM. Pediatric patients with an altered level of consciousness may have inadequate breathing despite spontaneous respiratory effort, based on an inadequate respiratory rate or inadequate tidal volume. Transport to the hospital.

Seizures

A seizure is the result of disorganized electrical activity in the brain, causes of which are listed in **Table 34-12**. It can be very frightening to witness a seizure in a pediatric patient. Therefore, it is important to reassure the family and to approach assessment and management in a calm, step-by-step manner.

Table 34-11 Mnemonic to Assess Causes of Altered Mental Status

A	Alcohol
E	Epilepsy, endocrine, electrolytes
I	Insulin
O	Opiates and other drugs
U	Uremia (kidney failure)
T	Trauma, temperature
I	Infection
P	Poisoning, psychogenic causes
S	Shock, stroke, seizure, syncope, space-occupying lesion, subarachnoid hemorrhage

Table 34-12 Common Causes of Seizures

- Child abuse
- Electrolyte imbalance
- Fever
- Hypoglycemia (low blood glucose level)
- Infection
- Ingestion
- Lack of oxygen
- Medications
- Poisoning
- Seizure disorder
- Recreational drug use
- Head trauma
- No cause can be found

Seizures in children may manifest in a wide variety of ways, depending on the age of the child. Seizures in infants can be subtle, consisting only of an abnormal gaze, sucking motions, or “bicycling” motions. In older children, seizures are more obvious and typically consist of repetitive muscle contractions and unresponsiveness. Once a seizure has stopped, the patient’s muscles relax, becoming almost flaccid (floppy), and the breathing becomes labored (fast and deep). This is the postictal state. The longer and more intense a seizure is, the longer it will take for the imbalance to correct itself. Likewise, longer and more severe seizures will result in longer postictal unresponsiveness and confusion. Once the pediatric patient regains a normal level of consciousness, the postictal state is over.

Seizures that continue every few minutes without regaining consciousness or last longer than 30 minutes are referred to as status epilepticus. Recurring or prolonged seizures should be considered potentially life-threatening situations in which pediatric patients need emergency medical care. If the pediatric patient does not regain consciousness or continues to seize, protect the pediatric patient from harming himself or herself and call for ALS backup. These pediatric patients need advanced airway management and medication to stop the seizure.

Securing and protecting the airway are your priorities. Position the head to open the airway. Clear the mouth with suction. Consider placing the pediatric patient in the recovery position if the pediatric patient is actively vomiting and suction is inadequate to control the airway Figure 34-32. Provide 100% oxygen by nonrebreathing mask or blow-by method. If there are no signs of improvement, begin BVM-ventilation with appropriately sized equipment with supplemental oxygen. Some parents or caregivers will have given the child a rectal dose of diazepam (Diastat) to stop the seizure prior to your arrival. Monitor breathing and level of consciousness carefully in these patients. Transport the pediatric patient to the appropriate facility.

Figure 34-32 Position the head to open the airway and clear the airway with suction. If suction is inadequate or the patient is vomiting, consider placing the patient in the recovery position.

Pediatric seizures caused by fever (febrile seizures) are discussed later in the chapter.

Meningitis

Meningitis is an inflammation of the tissues called the meninges, that cover the spinal cord and brain. It is caused by an infection by bacteria, viruses, fungi, or parasites. If left untreated, meningitis can lead to permanent brain damage or death. You must be able to recognize a pediatric patient who may have meningitis.

Meningitis can occur in both children and adults, but some pediatric patients are at greater risk than others, as follows:

- Males
- Newborn infants
- Children with compromised immune systems (such as HIV/AIDS or cancer)
- Children who have any history of brain, spinal cord, or back surgery
- Children who have had head trauma
- Children with shunts, pins, or other foreign bodies within their brain or spinal cord

At especially high risk are children with a ventriculoperitoneal (VP) shunt. VP shunts drain excess fluids from around the brain into the abdomen. These children with special needs have tubing that can usually be seen and felt just under the scalp.

The signs and symptoms of meningitis vary, depending on the age of the patient. Fever and altered level of consciousness are common symptoms of meningitis in patients of all ages. Changes in the level of consciousness can range from a mild or severe headache to confusion, lethargy, and/or an inability to understand commands or interact appropriately. The child may also experience a seizure, which may be the first sign of meningitis. Infants younger than 2 to 3 months can have apnea, cyanosis, fever, a distinct high-pitched cry, or hypothermia.

In describing children with meningitis, physicians often use “meningeal irritation” or “meningeal signs” to describe pain that accompanies movement. Bending the neck forward or back increases the tension within the spinal canal and stretches the meninges, causing a great deal of pain. This results in the characteristic stiff neck of children with meningitis, who will often refuse to move their neck, lift their legs, or curl into a *C* position, even if coached to do so. One sign of meningitis in an infant is increasing irritability, especially when being handled. Another sign is a bulging fontanelle without crying.

One form of meningitis deserves special attention. Neisseria meningitidis is a bacterium that causes a rapid onset of meningitis symptoms, often leading to shock and death. Children with *N meningitidis* typically have small, pinpoint, cherry-red spots or a larger purple or black rash **Figure 34-33**. This rash may be on part of the face or body. These children are at serious risk of sepsis, shock, and death.

Figure 34-33 Children with *Neisseria meningitidis* typically have small, pinpoint, cherry-red spots or a larger purple or black rash.

All pediatric patients with possible meningitis should be considered contagious. Therefore, follow standard precautions whenever you suspect meningitis and follow up with the hospital to learn the patient's final diagnosis. If you have been exposed to saliva and respiratory secretions from a child with *N meningitidis*, you should receive antibiotics to protect yourself and others from the bacteria. This is particularly true if you managed the pediatric patient's airway. If you were not in close contact with the pediatric patient or his or her respiratory secretions, you do not need treatment.

Provide these pediatric patients with supplemental oxygen and assist with ventilations if needed. Reassess the pediatric patient's vital signs frequently as you transport the patient to the highest level of service available.

Gastrointestinal Emergencies and Management

As with any injury or complaint in the abdominal region, the signs and symptoms may be vague in nature. The abdominal wall muscles are not as developed, which leaves this region more prone to injury. Pediatric patients may not be able to pinpoint the exact site where the pain or discomfort originates, but will have complaints of diffuse tenderness. Never take a complaint of abdominal pain and discomfort lightly because a large amount of bleeding may occur within the abdominal cavity without any outward signs of shock. Remember that liver and splenic injuries are common among this age group and may result in life-threatening emergencies. The pediatric patient needs to be monitored for signs and symptoms of shock, which include an altered mental status; pale, cool skin; tachypnea; tachycardia; and bradycardia (late sign).

Complaints of gastrointestinal origin are common in the pediatric population. A common source of gastrointestinal upset is the ingestion of certain foods or unknown substances, such as milk or ice cream (lactose intolerance). In most cases, you will be faced with a pediatric patient who is experiencing abdominal discomfort with nausea, vomiting, and/or diarrhea. This can become a concern because both vomiting and diarrhea can cause dehydration in children.

Appendicitis is also common in pediatric patients and, if untreated, can lead to peritonitis (inflammation of the peritoneum, which lines the abdominal cavity) or shock. Appendicitis will typically present with a fever and pain on palpation of the right lower abdominal quadrant. Rebound tenderness is a common sign associated with appendicitis. Remember that constipation also can be a cause of abdominal pain in children. If you suspect appendicitis, promptly transport the pediatric patient to the hospital for further evaluation.

Because children are sensitive to fluid loss, obtain a thorough history from the parent or primary caregiver. In particular, ask questions such as:

- How many wet diapers has your child had today?
- Is your child tolerating liquids and is he or she able to keep them down?
- How many times has your child had diarrhea and for how long?
- Are tears present when your child cries?

These questions can help to determine how dehydrated the pediatric patient may be. If the pediatric patient is dehydrated, transport to the hospital for further care.

Poisoning Emergencies and Management

Poisoning is common among children, and the common sources of poisoning in children are listed in **Table 34-13**. It can occur by ingesting, inhaling, injecting, or absorbing a toxic substance.

The signs and symptoms of poisoning vary widely, depending on the substance and the age and weight of the pediatric patient. The pediatric patient may appear normal at first, even in serious cases, or he or she may be confused, sleepy, or unconscious. With some substances, one pill may be enough to cause death in a small child.

Infants may be poisoned as a result of being fed a harmful substance by a sibling, parent, or caregiver, or as a result of child abuse. Infants can be exposed to drugs and poisons left on floors and carpeting. They can also be exposed in a setting in which harmful drugs are being smoked. Toddlers are curious and often ingest poisons when they find them in the home or garage **Figure 34-34**. For example, some people store petroleum products in soda bottles. Toddlers may believe the substance to be soda. Adolescents are more likely to have ingested alcohol and street drugs while partying or during a suicide attempt.

Table 34-13 Common Sources of Poisoning in Children

- Alcohol
- Aspirin and acetaminophen
- Cosmetics
- Household cleaning products (such as bleach and furniture polish)
- Houseplants
- Iron
- Prescription medications
- Illicit (street) drugs (such as crack, cocaine, or PCP)
- Vitamins

After you have completed your primary assessment, ask the parent or caregiver the following questions:

- What is the substance(s) involved?
- Approximately how much of the substance was ingested or involved in the exposure (eg, number of pills, amount of liquid)?
- What time did the incident occur?
- Are there any changes in behavior or level of consciousness?
- Was there any choking or coughing after the exposure? (These can be signs of airway involvement.)

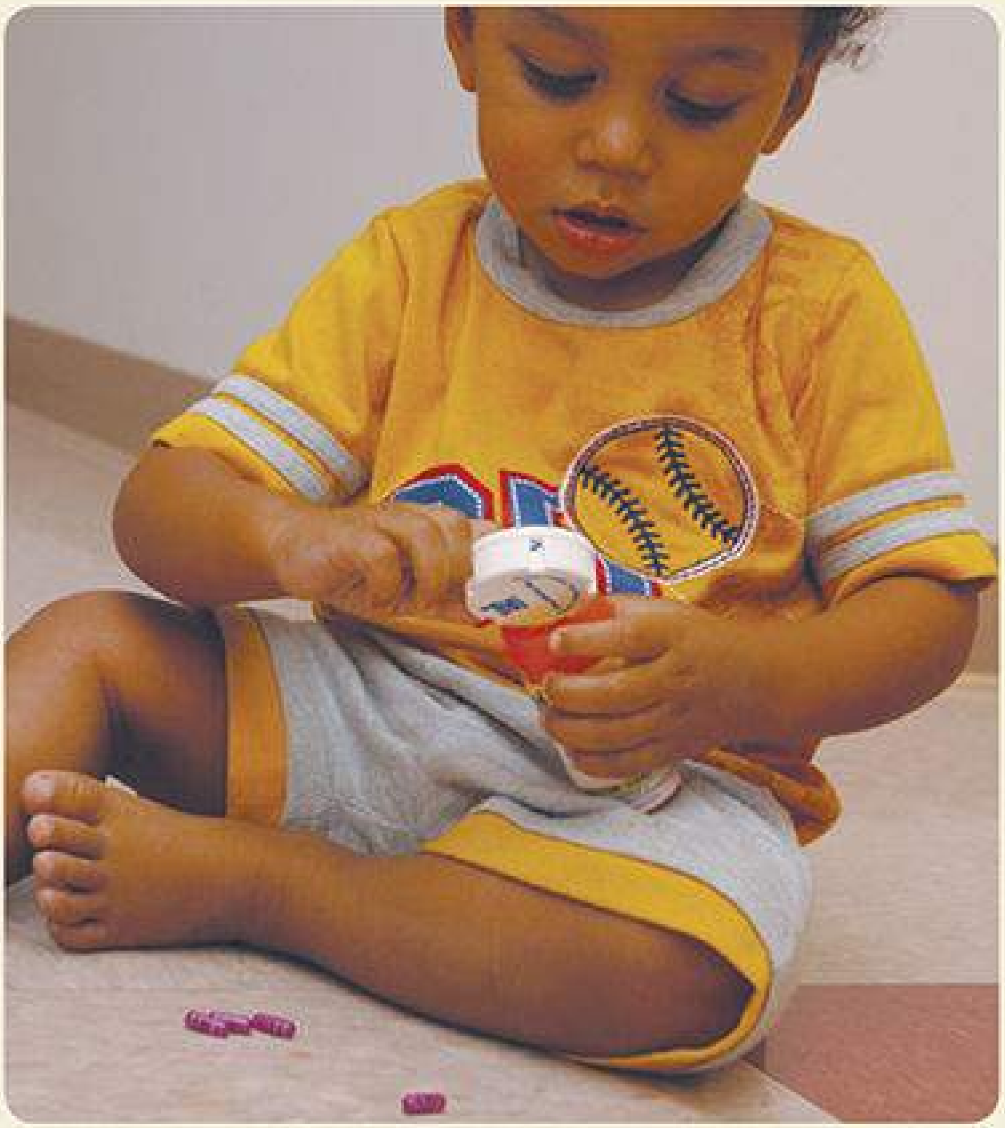


Figure 34-34 A curious child will try to taste or swallow almost any substance. A common victim of accidental ingestion of dangerous compounds is the unwatched toddler.

Contact the national Poison Control hotline for assistance in identifying poisons at 1-800-222-1222. This free service is available 24 hours a day, 7 days a week.

To treat a pediatric patient exposed to a poisonous substance, first perform an external decontamination. Remove tablets or fragments from the patient's mouth, and wash or brush poison from the skin. Treatment is supportive: assess and maintain the pediatric patient's ABCs and monitor breathing. Provide oxygen and perform ventilations if necessary. If the patient demonstrates signs and symptoms of shock, position the child supine, keep the child warm, and transport promptly to the nearest appropriate hospital.

In some cases, you will give activated charcoal to pediatric patients who have ingested poison, if approved by medical control or local protocol. Activated charcoal is not indicated for pediatric patients who have ingested an acid, an alkali, or a petroleum product; who have a decreased level of consciousness and cannot protect their airway; or who are unable to swallow. If local protocol permits, you will likely carry plastic bottles of premixed suspension, each containing up to 50 g of activated charcoal. Some common trade names for the suspension form are InstaChar, Actidose, and LiquiChar. The usual dose for a child is 1 g of activated charcoal per kilogram of body weight. The usual pediatric dose is 12.5 to 25 g. Chapter 21, *Toxicology*, discusses the administration of activated charcoal in detail.

Words of Wisdom

When you respond to a poisoning, remember to remain calm and control the scene. Poisonings can be emotional for the parents or caregivers involved because of the potential for self-blame.

Dehydration Emergencies and Management

Dehydration occurs when fluid losses are greater than fluid intake. The most common cause of dehydration in pediatric patients is vomiting and diarrhea. If left untreated, dehydration can lead to shock and eventually death. Infants and children are at greater risk than adults for dehydration because their fluid reserves are smaller than those in adults. Life-threatening dehydration can overcome an infant in a matter of hours.

Dehydration can be mild, moderate, or severe. The severity of the dehydration can be gauged by looking at several clues Table 34-14. For example, an infant with mild dehydration may have dry lips and gums, decreased saliva, and fewer wet diapers throughout the day. As the dehydration grows more severe, the lips and gums may become very dry, the eyes may look sunken, and the infant may be sleepy and/or irritable, refusing bottles. The skin may be loose and have no elasticity; this is called poor skin turgor Figure 34-35. Also, infants may have sunken fontanelles.

Table 34-14 Vital Signs and Symptoms of Dehydration

	Mild Dehydration	Moderate Dehydration	Severe Dehydration
Pulse	Normal	Increased	Increased; >160 beats/min is sign of impending shock in pediatric patients except newborns
Level of activity	Normal or slowed	Slowed	Variable, weak to unresponsive
Urine output	Decreased	Decreased	No output
Skin	Normal	Cool, mottled; poor turgor	Cool, clammy; poor turgor; delayed capillary refill time
Mouth	Decreased saliva	Dry mucous membranes	Dry mucous membranes
Eyes	Normal	No tears	Sunken eyes
Anterior fontanelle	Normal to sunken	Sunken	Very sunken
Level of consciousness	Normal	Altered	Altered; lethargic
Blood pressure	Normal	Normal	Normal to low

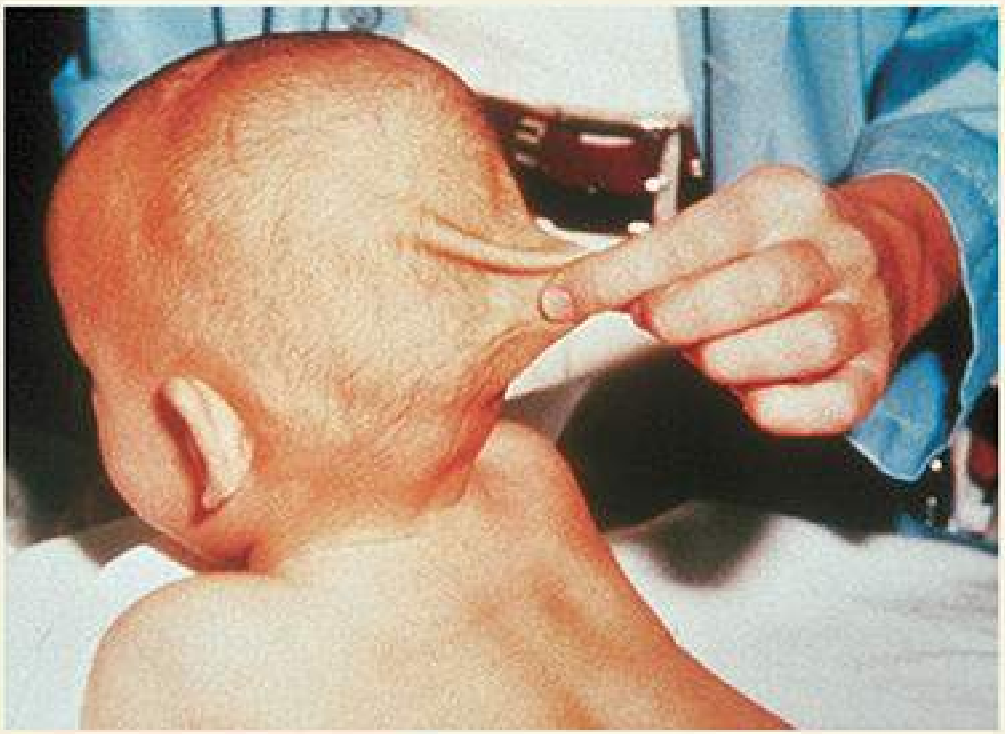

Figure 34-35 An infant with dehydration may exhibit "tenting" or poor skin turgor.

Courtesy of Ronald Dieckmann, MD.

Young children can compensate for fluid losses by decreasing blood flow to the extremities and directing blood flow to vital organs such as the brain and heart. Children who are moderately to severely dehydrated may have mottled, cool, clammy skin and delayed capillary response time. Respirations will usually be increased. Be aware blood pressure may remain within a normal range while the pediatric patient is in shock, because the compensatory mechanisms are still in place.

Emergency medical care should include assessing the ABCs and obtaining baseline vital signs. However, if the dehydration is severe, ALS backup may be necessary so that IV access can be obtained and rehydration can begin. All pediatric patients with signs and symptoms of moderate to severe dehydration should be transported to the ED for further evaluation and treatment.

Fever Emergencies and Management

Fever is a common reason why parents or caregivers call 9-1-1. Simply defined, a fever is an increase in body temperature, usually in response to an infection. Body temperatures of 100.4°F (38°C) or higher are considered to be abnormal. A fever may have many causes and is rarely life threatening. However, do not underestimate the potential seriousness of a fever that occurs in conjunction with a rash, which is a sign of serious illness, such as meningitis. Common causes of a fever in pediatric patients include the following:

- Infection, such as pneumonia, meningitis, or urinary tract infection
- Status epilepticus
- Cancer
- Drug ingestion (aspirin)
- Arthritis and systemic lupus erythematosus (rash across nose)
- High environmental temperature

Fever is the result of an internal body mechanism in which heat generation is increased and heat loss is decreased. Note that there are other conditions in which the core body temperature also increases. Hyperthermia differs from fever in that it is an increase in body temperature caused by an inability of the body to cool itself. Hyperthermia is typically seen in warm environments, such as a closed vehicle on a hot day.

An accurate body temperature is an important vital sign for pediatric patients. A rectal temperature is the most accurate for infants to toddlers. Older children will be able to follow directions if placing a thermometer under the tongue or under the arm.

A fever can have several causes, such as a viral or a bacterial infection. Depending on the source of infection, the pediatric patient may have additional signs of respiratory distress, shock, a stiff neck, a rash, skin that is hot to the touch, flushed cheeks, seizures, and bulging fontanelles in an infant. Assess the patient for other signs and symptoms such as nausea, vomiting, diarrhea, decreased feedings, and headache. A fever that is accompanied by a stiff neck, sensitivity to light, and a rash may be an indication that the patient has either bacterial or viral meningitis.

A pediatric patient with a fever may require only minimal interventions in the field. Provide rapid transport and manage the patient's ABCs. Follow standard precautions if you suspect that the patient may have a communicable disease such as meningitis.

Febrile Seizures

Febrile seizures are common in children between the ages of 6 months and 6 years. Most pediatric seizures are the result of fever alone, which is why they are called febrile seizures.

These seizures typically occur on the first day of a febrile illness, are characterized by **generalized tonic-clonic seizure** activity, and last less than 15 minutes with a short postictal phase or none at all. They may be a sign of a more serious problem, such as meningitis. Obtain a history from the parent or caregiver because these pediatric patients may have had a febrile seizure in the past.

If you are called to care for a pediatric patient who has had a febrile seizure, you often will find that the pediatric patient is awake, alert, and fully interactive when you arrive. Keep in mind that a persistent fever can lead to another seizure. Carefully assess the ABCs, begin cooling measures with tepid (not cold) water, and provide prompt transport. All pediatric patients with febrile seizures need to be seen in the hospital setting.

Drowning Emergencies and Management

In drowning emergencies, you must always ensure your own safety when rescuing the patient from the water. Do not become a victim yourself!

According to the CDC, drowning is the second most common cause of unintentional death among children aged 1 to 4 years in the United States. At this age, children often fall into swimming pools and lakes, but many drown in bathtubs and even puddles or buckets of water. Older adolescents drown when swimming or boating; alcohol is frequently a factor.

As discussed in *Chapter 32, Environmental Emergencies*, the principal condition that results from drowning is lack of oxygen. Even a few minutes (or less) without oxygen affects the heart, lungs, and brain, causing life-threatening problems such as cardiac arrest, respiratory failure, and coma. Submersion in icy water can lead to hypothermia. Although it is possible for victims of submersion hypothermia to survive long periods in cardiac arrest, most people in this situation die. Diving into the water, of course, increases the risk of neck and spinal cord injuries.

Signs and symptoms of a drowning patient will vary based on the type and length of submersion. A pediatric patient involved in a drowning emergency may have with coughing; choking; airway obstruction; difficulty breathing; altered mental status; seizure activity; unresponsiveness; fast, slow, or no pulse noted; pale, cyanotic skin; and abdominal distention from ingestion of fluids.

Once the pediatric patient is successfully removed from the water, assess and manage the ABCs, and call for ALS backup to intervene if needed. Administer oxygen at 100% via a nonrebreathing mask or BVM if assisted ventilations are required. Be prepared to suction as these patients often vomit. If trauma is suspected, apply a cervical collar and place the pediatric patient on a backboard. Pad all open spaces under the pediatric patient before securing the patient onto the backboard. If the pediatric patient is unresponsive and in cardiopulmonary arrest, perform CPR.

Words of Wisdom

Swimming pool and water hazards are major contributors to pediatric injury and death. Pool safety begins with educating children and parents or caregivers on the risks of playing around a pool. All swimming pools should be surrounded by a fence that is at least 6 feet (2 m) high, with slats no farther apart than 3 inches (8 cm). Additional precautions include pool covers and alarm systems. Children should also take water safety and swim lessons to help ensure their safety around pools and other bodies of water.

Words of Wisdom

Before using an AED on a pulseless drowning patient, ensure that the pediatric patient is dried off. Use caution when operating an AED in this situation.

Pediatric Trauma Emergencies and Management

According to the CDC, unintentional injuries are the number one killer of children in the United States. As an EMT, you will frequently treat injured children; therefore, you must have a thorough understanding of how trauma affects them. The quality of care in the first few minutes after a child has been injured can have an enormous impact on that child's chances for complete recovery.

The muscles and bones of children continue to grow well into adolescence. For this reason, coupled with their risk-taking approach to activities, adolescents are prone to fractures of the extremities. The younger the child, the more flexible the bone structures are to trauma. If a pediatric patient is unable to place weight on an extremity or favors an extremity, suspect injury until proven otherwise. Sprains are uncommon in this age group because the ligaments are more developed than the larger long bones.

A fracture of the femur is rare in pediatric patients, but when it does occur, it is a source of major blood loss. Older children and adolescents are prone to long bone fractures (femur and humerus) because they tend to take more risks during physical activities. The goal for care and treatment in this circumstance is to immobilize the injured extremity and to provide pain relief once ALS has arrived on the scene.

Physical Differences

As discussed, children are smaller than adults; therefore, when they are hurt in the same type of crash as an adult, the location of their injuries may differ from those in an adult. For example, the bumper of a motor vehicle will strike an adult pedestrian in the lower leg, whereas that same bumper will strike a child in the pelvis. In a crash involving sudden deceleration, an adult might injure a ligament in the knee; in that same crash, a child might injure the bones in the leg.

Children's bones and soft tissues are less well developed than those of adults; therefore, the force of an injury affects these structures somewhat differently than it does in an adult. Because a child's head is proportionately larger than an adult's, it exerts greater stress on the neck structures during a deceleration injury. Because of these anatomic differences, always carefully assess children for head and neck injuries.

Psychologic Differences

Children are also less mature psychologically than adults; therefore, they are often injured because of their undeveloped judgment and their lack of experience. For example, children are more likely than adults to cross the street without looking for oncoming traffic. As a result, children are more likely than adults to be struck by motor vehicles. Children and adolescents are also more likely to sustain injuries from diving into shallow water because they forget to check the depth of the water before they dive. In such situations, always assume that the child has serious head and neck injuries.

Injury Patterns

Although you are not responsible for diagnosing injuries in children, your ability to recognize and report serious injuries will provide critical information to hospital staff. For this reason, it is important for you to understand the special physical and psychologic characteristics of children and what makes them more likely to have certain kinds of injuries.

Vehicle Collisions

Children playing or riding a bicycle can dart out in front of motor vehicles without looking. In such a situation, the driver may have very little time to slow down or stop to prevent hitting the child. The area of greatest injury varies, depending on the size of the child and the height of the bumper at the time of impact. When vehicles slow down at the moment of impact, the bumper dips slightly, causing the point of impact with the child to be lowered. The exact area that is struck depends on the child's height and the final position of the bumper at the time of impact. Children who are injured in these situations often sustain high-energy injuries to the head, spine, abdomen, pelvis, or legs. In addition to differences in size and anatomy, children will often turn toward an oncoming vehicle when they see it approaching and, therefore, sustain different injuries than an adult who turns away.

Sports Activities

Children, especially those who are older or adolescents, are often injured in organized sports activities. Head and neck injuries can occur after high-speed collisions in contact sports such as football, wrestling, ice hockey, field hockey, soccer, or lacrosse. Remember to immobilize the cervical spine when caring for children with sports-related injuries when indicated. Familiarize yourself with local protocols related to helmet removal, and/or follow the guidelines presented in Chapter 28, *Head and Spine Injuries*.

Injuries to Specific Body Systems

Head Injuries

Head injuries are common in children. This is because the size of a child's head, in relation to the body, is larger than that of an adult. An infant also has a softer, thinner skull, which may result in injury to the underlying brain tissues. The scalp and facial vessels can bleed easily and may cause significant blood loss if the bleeding is not controlled. The signs and symptoms of head injury in a child are similar to those in an adult, but there are some important differences. Nausea and vomiting are common signs and symptoms of head injury in children; however, it is easy to mistake these for an abdominal injury or illness. You should suspect a serious head injury in any child who experiences nausea and vomiting after a traumatic event. Pediatric patients are managed in the same manner as adults. Chapter 28, *Head and Spine Injuries,* discusses head injuries in detail.

Immobilization. Spinal immobilization is necessary for all children who have possible head or spinal injuries after a traumatic event. Follow these steps **Skill Drill 34-5**:

1. Maintain the child's head in a neutral position by placing a towel under the shoulders and torso **Step 1**.
2. Place an appropriately sized cervical collar on the pediatric patient **Step 2**.
3. Carefully log roll the child onto the short backboard or pediatric immobilization device **Step 3**.
4. Secure the pediatric patient's torso to the short backboard or pediatric immobilization device first **Step 4**.
5. Secure the child's head to the short backboard or pediatric immobilization device **Step 5**.
6. Complete immobilization by ensuring that the child is strapped in properly **Step 6**.

Skill Drill 34-5 Immobilizing a Pediatric Patient

Step 1

Use a towel under the back, from the shoulders to the hips, to maintain the head in a neutral position.

Step 2

Apply an appropriately sized cervical collar.

Step 3

Log roll the child onto the short backboard or pediatric immobilization device.

Step 4

Secure the torso first.

Step 5

Secure the head.

Step 6

Ensure that the child is strapped in properly.

Immobilization can be difficult to perform because of the child's body proportions. Young children require padding under the torso to maintain a neutral position. Beginning at ages 8 to 10 years, children no longer require padding underneath the torso to create a neutral position. Instead, they can simply lie supine on the backboard. However, another complication may occur if a child is immobilized on an adult-sized backboard. A child's body is narrower than an adult's; therefore, padding will be required along the sides of the adult-sized backboard so that the child can be properly secured.

Many infants and children will be in a car seat when you approach them. The patient must be removed to a short backboard or pediatric immobilization device prior to transport. Follow these steps to immobilize a patient in a car seat **Skill Drill 34-6**:

1. Carefully stabilize the patient's head in a neutral position **Step 1**.
2. Lay the seat down into a reclined position on a hard surface. Position a short backboard or pediatric immobilization device between the patient and the surface on which the patient is resting **Step 2**.
3. Carefully slide the patient into position on the short backboard or pediatric immobilization device **Step 3**.
4. Make sure the patient's head is in a neutral position by placing a towel under the back, from the shoulders to the hips **Step 4**.
5. Secure the torso first and place padding to fill any voids **Step 5**.
6. Secure the patient's head to the short backboard or pediatric immobilization device. **Step 6**.

Chest Injuries

Chest injuries in children are usually the result of blunt trauma rather than penetrating objects. Remember that children have soft, flexible ribs that can be significantly compressed without breaking. This chest wall flexibility can produce a flail chest. Keep this in mind as you assess a child who has sustained high-energy blunt trauma to the chest. Even though there may be no external sign of injury, such as broken ribs, contusions, or bleeding, there may be significant injuries within the chest **Figure 34-36**. Pediatric patients are managed in the same manner as adults. Chapter 29, *Chest Injuries*, discusses the treatment of chest injuries in detail.

Abdominal Injuries

Abdominal injuries are common in children. Remember, though, that children can compensate for significant blood loss better than adults without signs or symptoms of shock developing **Figure 34-37**. They can also have a serious injury without early external evidence of a problem. All children with abdominal injuries should be monitored for signs and symptoms of shock, including a weak, rapid pulse; cold, clammy skin; decreased capillary refill (an early sign); confusion; and decreased systolic blood pressure (a late sign). Even in the absence of signs and symptoms of shock, or with only very few signs and symptoms, you should remain cautious about the possibility of internal injuries.

Skill Drill 34-6 Immobilizing a Patient in a Car Seat

Step 1

Stabilize the head in neutral position.

Step 2

Place a short backboard or pediatric immobilization device between the patient and the surface he or she is resting on.

Step 3

Slide the patient onto the short backboard or pediatric immobilization device.

Step 4

Place a towel under the back, from the shoulders to the hips, to ensure neutral head position.

Step 5

Secure the torso first; pad any voids.

Step 6

Secure the head to the short backboard or pediatric immobilization device.

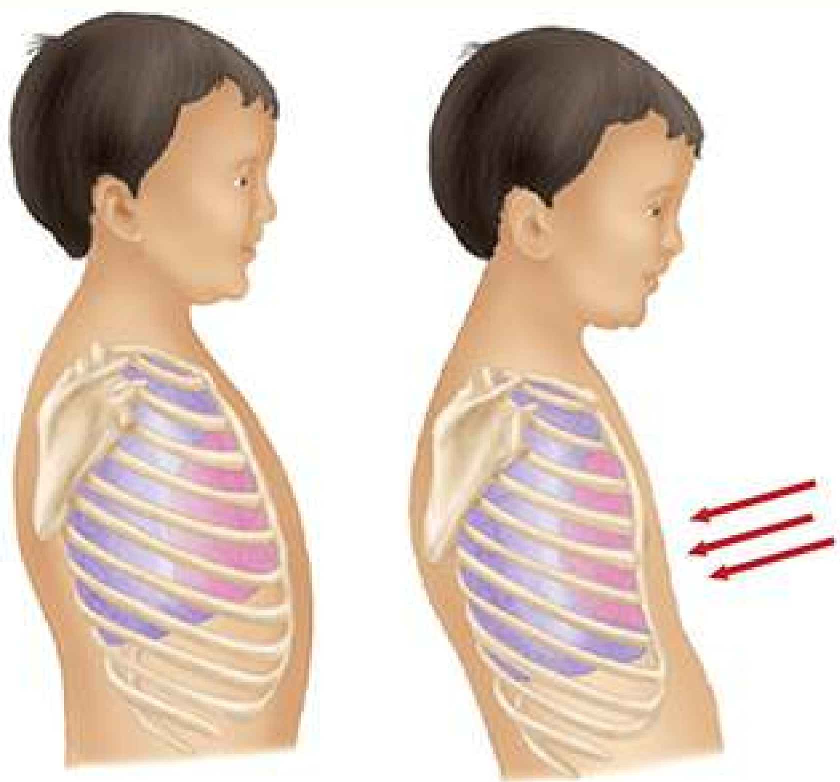

Figure 34-36 A child's ribs are softer and more flexible than an adult's. As a result, they may compress the lungs and heart if there is blunt trauma, causing serious injury with no obvious external damage.

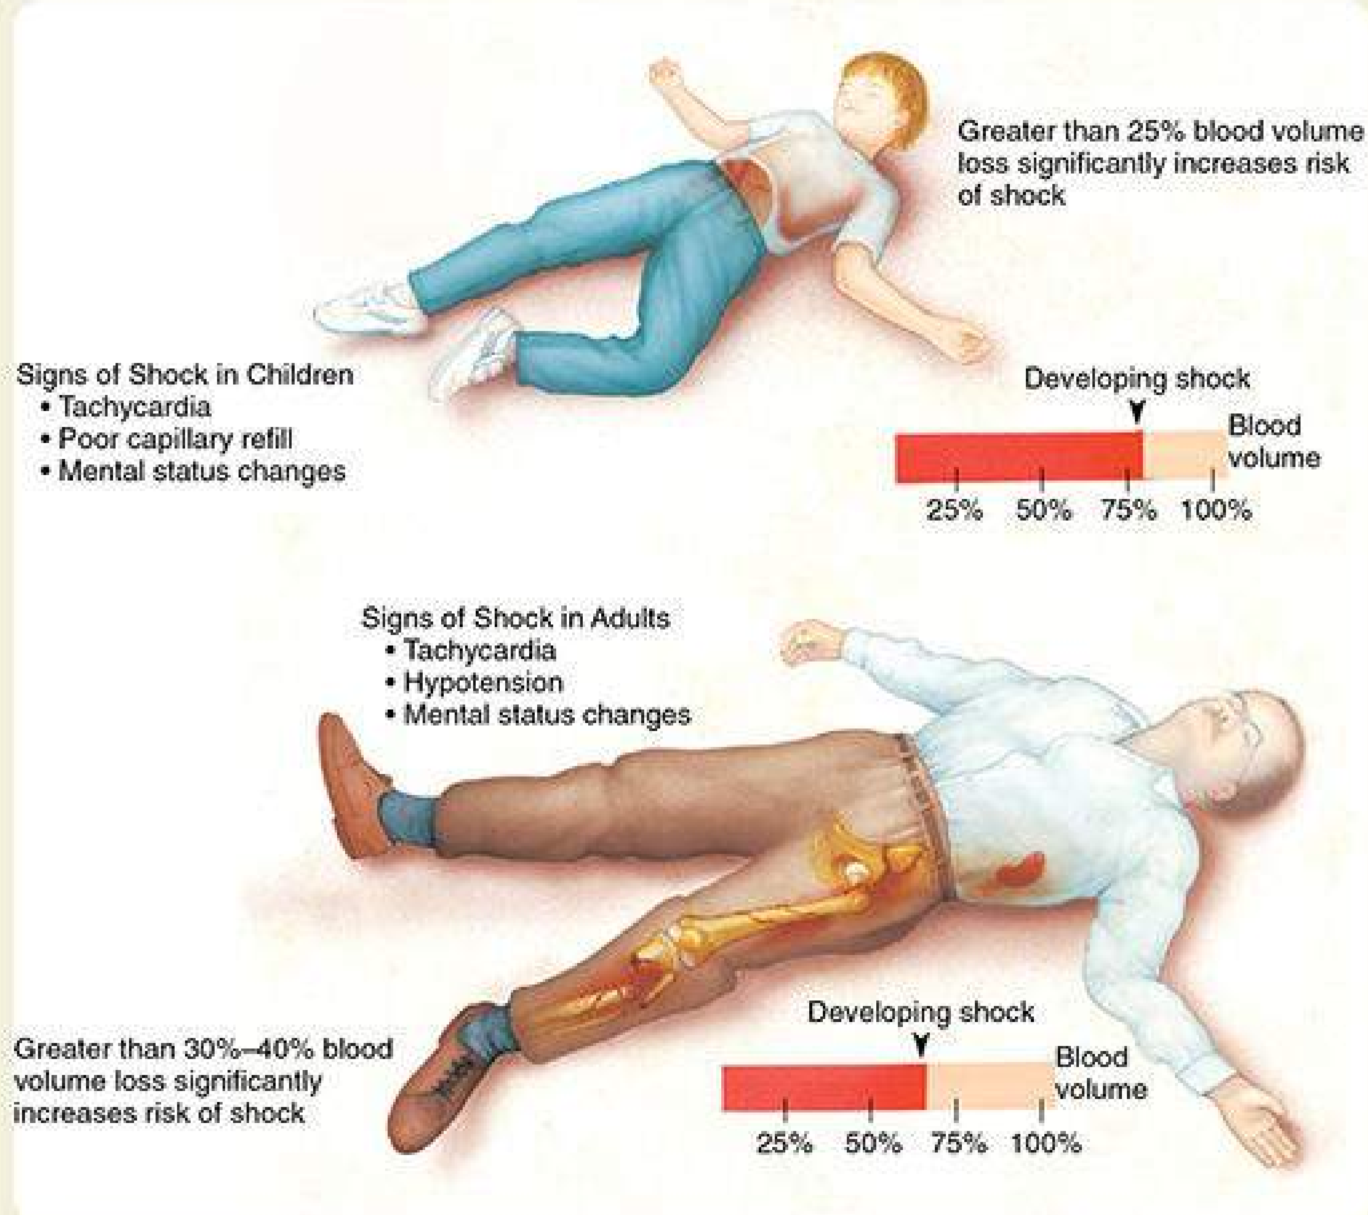

Figure 34-37 All children with abdominal injuries should be monitored closely for signs of shock. Although children may compensate for significant blood loss better than adults, shock develops in children after proportionally smaller blood losses.

Pediatric patients are managed in the same manner as adults. Chapter 30, *Abdominal and Genitourinary Injuries*, discusses abdominal injuries in detail. If the patient shows signs and symptoms of shock, prevent hypothermia by keeping the patient warm with blankets. If the patient has bradycardia, ventilate. Monitor the patient's condition during transport.

Burns

Burns to children are generally considered more serious than burns to adults. This is because infants and children have more surface area relative to total body mass, which means greater fluid and heat loss. In addition, children do not tolerate burns as well as adults do. Children are also more likely to go into shock, develop hypothermia, and experience airway problems because of the unique differences of their ages and anatomy.

Children can be burned in a variety of ways. The most common involve exposure to hot substances such as scalding water in a bathtub, hot items on a stove, or exposure to caustic substances such as cleaning solvents or paint thinners **Figure 34-38**.

According to the CDC, older children are more likely to be burned by flames from fire. You should suspect possible internal injuries from chemical ingestion when you see a child who has burns, particularly around the face and mouth.

One common problem following burn injuries in children is infection. Burned skin cannot resist infection as effectively as normal skin can. For this reason, sterile techniques should be used in handling the skin of children with burn wounds if possible.

Table 34-15 provides some general guidelines to follow in assessing a pediatric patient who has been burned. These guidelines may help you to determine which pediatric patients should be treated primarily at specialized burn centers. Also consider the possibility of child abuse in any burn situation. Make sure you report any information about your suspicions to the appropriate authorities.

Pediatric patients are managed in the same manner as adults. Chapter 26, *Soft-Tissue Injuries*, discusses burn care in detail. If the patient shows signs and symptoms of shock, prevent hypothermia by keeping the pediatric patient warm with blankets. If the pediatric patient has bradycardia, ventilate. Monitor the pediatric patient's condition during transport.

Figure 34-38 Some burns in children involve exposure to hot surfaces. This child's buttocks were placed against a hot heating grate.

Table 34-15 Severity of Burns in Pediatric Patients

Severity of Burn	Body Area Involved
Minor	Partial-thickness burns involving less than 10% of the body surface
Moderate	Partial-thickness burns involving 10% to 20% of the body surface
Severe	Any full-thickness burn Any partial-thickness burn involving more than 20% of the body surface Any burn involving the hands, feet, face, airway, or genitalia

Injuries of the Extremities

Children have immature bones with active growth centers. Growth of long bones occurs from the ends at specialized growth plates. These growth plates are potential weak spots in the bone and are often injured as a result of trauma. In general, children's bones bend more easily than adults' bones. As a result, greenstick (incomplete) fractures can occur.

Extremity injuries in pediatric patients are generally managed in the same manner as those in adults. Painful, deformed limbs with evidence of broken bones should be splinted. Specialized splinting equipment, such as a traction splint for fractures of the femur, should be used only if it fits the pediatric patient. Do not attempt to use adult immobilization devices on a pediatric patient unless the pediatric patient is large enough to properly fit in the device.

Pain Management

The first step in pain management is recognizing that the patient is in pain. Since some pediatric patients will be nonverbal or have a limited vocabulary, remember to look for visual clues and use the Wong-Baker FACES pain scale (see Figure 34-20).

When dealing with pediatric pain management issues, you are limited to the following interventions: positioning, ice packs, and extremity elevation. These interventions will decrease the pain and swelling to the site of an injury. However, additional interventions (medications) from an ALS provider may be necessary. Another important tool is simple kindness and providing emotional support to the patient and the parent or caregiver. This act alone can decrease pediatric patient anxiety and allow for a more soothing environment for all involved. Pediatric patients can sense fear and frustration from adults, so it is important to maintain a calm, professional, and trusting relationship with your patient and the family during the course of treatment.

Disaster Management

The JumpSTART triage system was developed for pediatric patients because the original START triage system did not take into account the developmental and physiologic differences in children **Figure 34-39**. This system is intended for pediatric patients younger than age 8 years or who appear to weigh less than 100 pounds (45 kg). Because infants and children may not be able to walk or follow commands (including children with special needs) during a disaster event, they must be considered for immediate delivery to the treatment area.

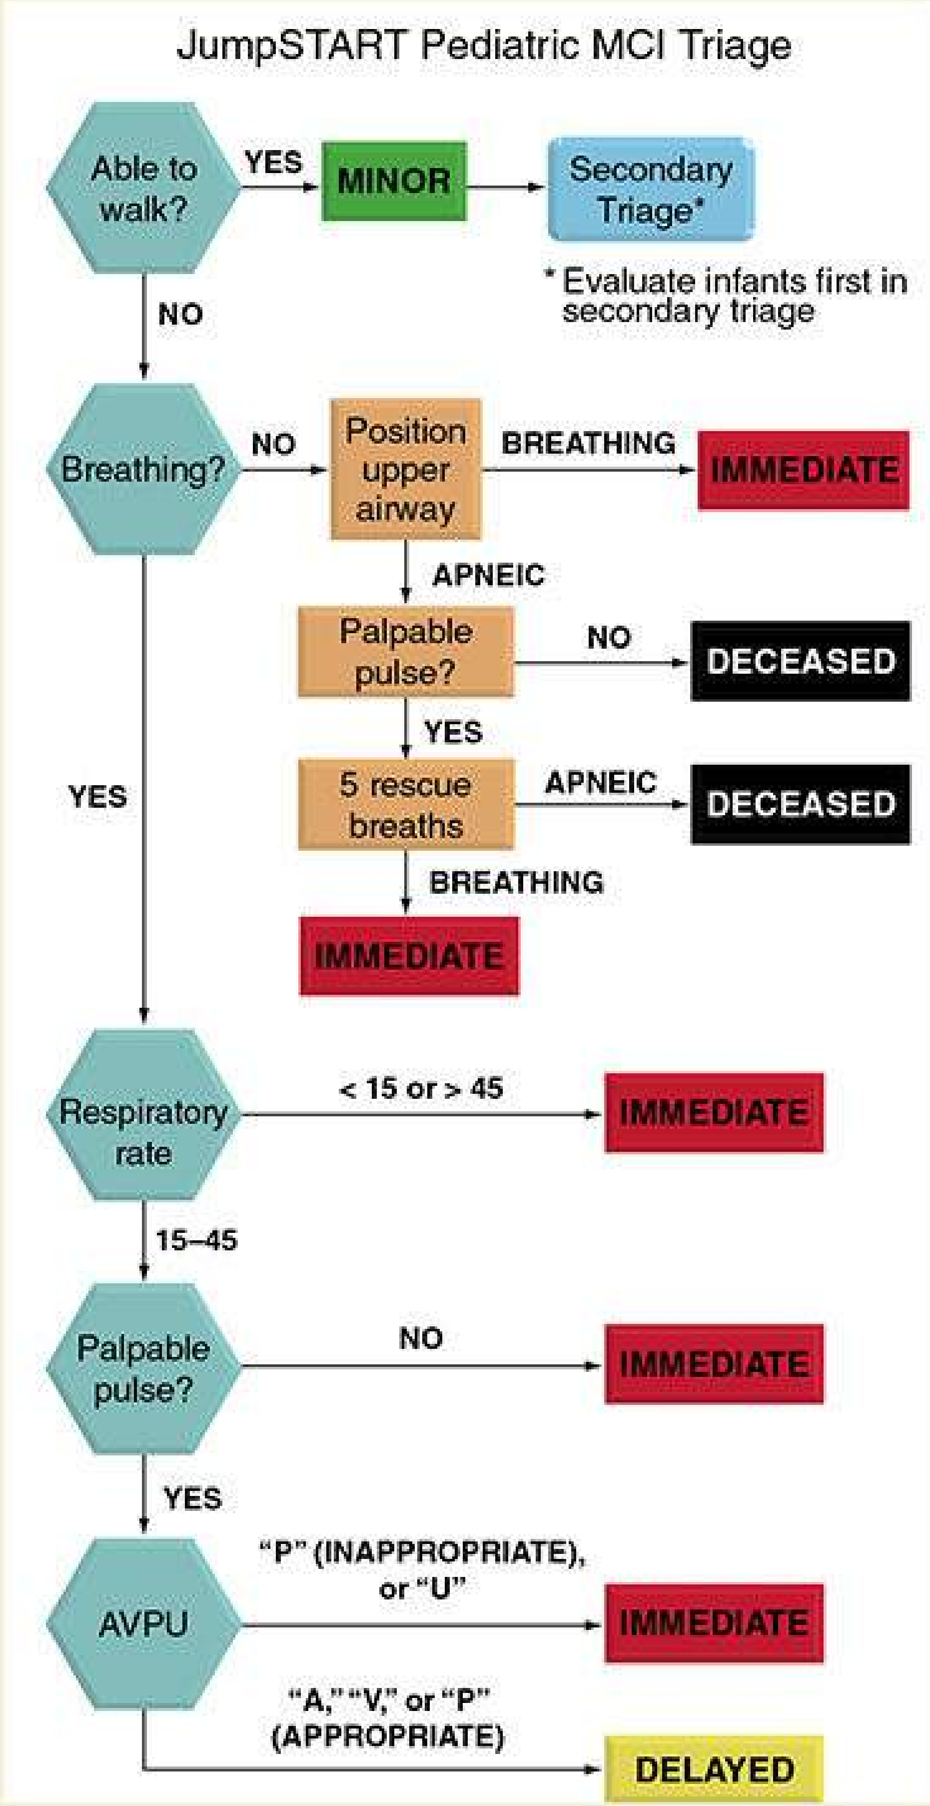

Figure 34-39 The JumpSTART triage system.

There are four triage categories in the JumpSTART system, designated by colors corresponding to different levels of urgency for treatment. Decision points include: ability to walk (except in infants); presence of spontaneous breathing; respirations of less than 15 or of greater than 45 breaths/min; palpable peripheral pulse; and appropriate response to painful stimuli on the AVPU scale.

Pediatric patients who are able to walk are designated as the third or minor priority (green tag), meaning they are not in immediate need of treatment. Patients who breathe spontaneously, have a peripheral pulse, and are appropriately responsive to painful stimuli are designated as the second priority (yellow tag). Their treatment and transport can be delayed. Pediatric patients who are breathing but pulseless, who are apneic and responsive to positioning or rescue breathing, or who are inappropriately responsive to painful stimuli are designated as the highest priority (red tag). These patients need immediate care and transport. Pediatric patients who are both apneic and pulseless, or who are apneic and unresponsive to rescue breathing, are considered deceased or expectant deceased (black tag). Triage is discussed in greater detail in Chapter 39, *Incident Management*.

Words of Wisdom

It is always difficult to deal with a situation of child abuse. When you assess a pediatric patient, you may find that the pattern of illness or injury, or the severity of the illness or injury, does not match the information that the child's parent or caregiver provides to you. Under no circumstances should you question the discrepancies. Remember that your sole focus is to ensure that the pediatric patient is transported to the hospital for an evaluation. If you offend or "tip off" the suspected abuser, he or she may deny transport of the pediatric patient and you may be forced to leave the pediatric patient on scene. Ensure that you are familiar with mandated reporting requirements per your local protocols. Privately inform the hospital staff of your findings.

Child Abuse and Neglect

The term **child abuse** means any improper or excessive action that injures or otherwise harms a child or infant; it includes physical abuse, sexual abuse, neglect, and emotional abuse. The intentional injury of a child, whether physical or emotional, unfortunately is not rare in our society. According to the report *Child Maltreatment 2012* from the US Department of Health & Human Services, over half a million children are victims of child abuse annually. Many of these children suffer life-threatening injuries, and some die. If suspected child abuse is not reported, the child is likely to be abused again and again, which can lead to permanent injury or death. Therefore, you must be aware of the signs of child abuse and neglect, and it is your responsibility to report suspected abuse to law enforcement or child protection agencies.

Signs of Abuse

As an EMT, you will be called to homes because of a reported injury to a child. Child abuse occurs in every socioeconomic status, so be aware of the patient's surroundings and document your findings objectively. EMTs are commonly called to testify in abuse cases, so it is essential to record all findings, including any statements made by parents or caregivers or others on the scene. If you suspect that physical or sexual abuse is involved, ask yourself the following questions:

- Is the injury typical for the developmental level of the child?
- Is the method of injury reported by the parent or caregiver consistent with the pediatric patient's injury?
- Is the parent or caregiver behaving appropriately (concerned about the child's well-being)?
- Is there evidence of drinking or drug use at the scene?
- Was there a delay in seeking care for the child?
- Is there a good relationship between the child and the parent or caregiver?
- Does the child have multiple injuries at different stages of healing?
- Does the child have any unusual marks or bruises that may have been caused by cigarettes, heating grates, or branding injuries?
- Does the child have several types of injuries, such as burns, fractures, and bruises?
- Does the child have any burns on the hands or feet that involve a glove distribution (marks that encircle a hand or foot in a pattern that looks like a glove)?
- Is there an unexplained decreased level of consciousness?
- Is the child clean and an appropriate weight for his or her age?
- Is there any rectal or vaginal bleeding?
- What does the home look like? Clean or dirty? Is it warm or cold? Is there adequate food?

Your assessment in the field will allow a better assessment by the medical staff later. An easy way to remember these points for the pediatric population is the mnemonic CHILD ABUSE, shown in Table 34-16.

As you assess the pediatric patient, look for and pay particular attention to the following signs Figure 34-40.

Bruises

Observe the color and location of any bruises. New bruises are pink or red. Over time, bruises turn blue, then green, then yellow-brown and faded. Note the location. Bruises to the back, buttocks, ears, or face are suspicious and are usually inflicted by a person.

Table 34-16 Mnemonic for Assessing Possible Child Abuse

C	Consistency of the injury with the child's developmental age
H	History inconsistent with injury
I	Inappropriate parental concerns
L	Lack of supervision
D	Delay in seeking care
A	Affect
B	Bruises of varying ages
U	Unusual injury patterns
S	Suspicious circumstances
E	Environmental clues

Words of Wisdom

In children, bumps and bruises are a common occurrence. You should be concerned when bruises are found in uncommon locations or in patterns. Elbow and knee bruising, or injuries that follow the patterns of falls or rough play, match the nature of a playing child, but bruises to the back, buttocks, or backs of the arms and legs are much less common. Also be mindful of bruises in various stages of healing, which can also be an indicator of abuse. If the bruises have a unique pattern, as if a child was struck with an object once or repeatedly, this may be a sign of abuse.

Burns

Burns to the penis, testicles, vagina, or buttocks are usually inflicted by someone else, as are burns that encircle a hand or foot to look like a glove. You should suspect abuse if the child has cigarette burns or grid pattern burns.

Fractures

Fractures of the humerus or femur do not normally occur without major trauma, such as a fall from a high place or a motor vehicle crash. Falls from a bed are not usually associated with fractures. Maintain some index of suspicion if an infant or young child sustains a femur fracture or a complete fracture of any bone. As discussed, children are more likely to experience greenstick (incomplete) fractures, as opposed to complete fractures, due to their soft and pliable bones.

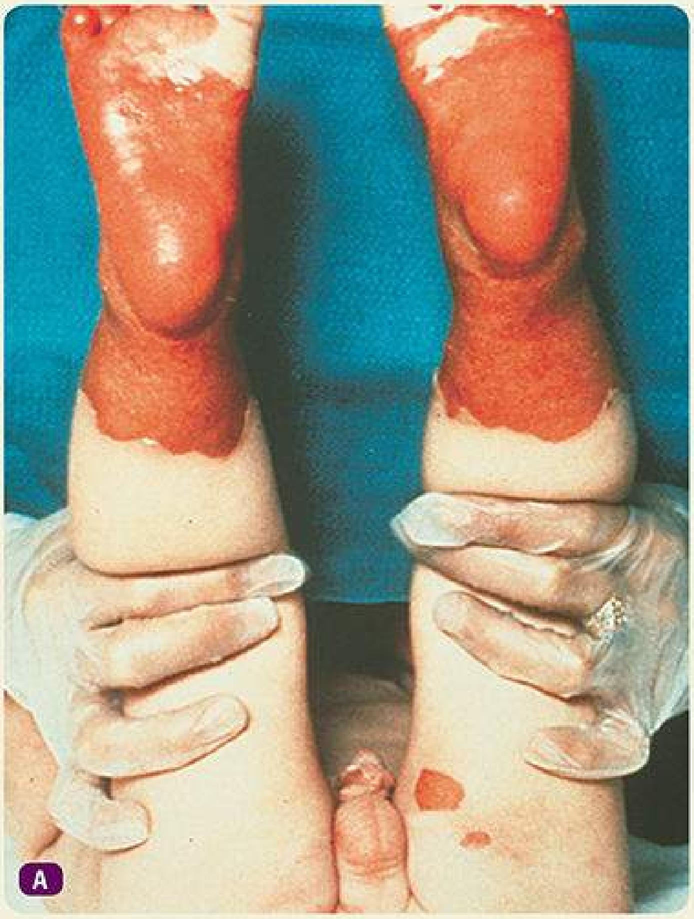

Figure 34-40 Signs of child abuse. **A.** A scald. **B.** Multiple injuries at different stages of healing.

Courtesy of Ronald Dieckmann, MD.

A complete fracture in a pediatric patient indicates that the child was exposed to significant traumatic force.

Shaken Baby Syndrome

Infants may sustain life-threatening head trauma by being shaken or struck on the head, a condition called **shaken baby syndrome**. With this condition, there is bleeding within the head and damage to the cervical spine as a result of intentional, forceful shaking. The infant will be found unconscious, often without evidence of external trauma. The call for help may be for an infant who has stopped breathing or is unresponsive. The infant may appear to be in cardiopulmonary arrest, but what has likely occurred is that the shaking tore blood vessels in the brain, resulting in bleeding around the brain. The pressure from the blood results in an increased cranial pressure, leading to coma and/or death.

Words of Wisdom

It is normal to have concerns about the care of children, but do not let your personal judgments cloud the true nature of a situation. You may feel upset by challenging socioeconomic factors that impact where a child lives, the condition of the home environment, and the child's sources of food. However, the parents or caregivers may have the best of intentions and may be doing everything possible for the child. In these situations, let the hospital staff or a supervisor know that the child and his or her family may need some assistance or community support.

Neglect

Neglect is refusal or failure on the part of the parent or caregiver to provide life necessities, such as food, water, clothing, shelter, personal hygiene, medicine, comfort, and personal safety.

Children who are neglected are often dirty or too thin or appear developmentally delayed because of a lack of stimulation. You may observe such children when you are making calls for unrelated problems. Report all cases of suspected neglect.

Symptoms and Other Indicators of Abuse

An abused child may appear withdrawn, fearful, or hostile. Be particularly concerned if the child refuses to discuss how an injury occurred. Occasionally, the parent or caregiver will reveal a history of several "accidents." Be alert for conflicting stories or a marked lack of concern from the parents or caregiver. Remember, the abuser may be a parent, caregiver, relative, or friend of the family. Sometimes the abuser is an acquaintance of a single parent.

EMTs in all states must report all cases of suspected abuse, even if the ED fails to do so. Most states have special forms for reporting. Supervisors are generally forbidden to interfere with the reporting of suspected abuse, even if they disagree with the assessment. You do not have to prove that there has been abuse. Law enforcement and child protection agencies are mandated to investigate all reported cases. Take all necessary precautions to protect yourself, your team, and the pediatric patient involved in this situation.

Sexual Abuse

Children of any age and either gender can be victims of sexual abuse. Maintain an index of suspicion regardless of the patient's social or economic situation. This type of sexual abuse is often the result of long-standing abuse by relatives.

Your assessment of a child who has been sexually abused should be limited to determining the type of dressing any injuries require. Sometimes, a sexually abused child is also beaten. Therefore, treat any bruises or fractures as well. Do not examine the genitalia of a young child unless there is evidence of bleeding or there is an injury that must be treated.

In addition, if you suspect that a child is a victim of sexual abuse, do not allow the child to wash, urinate, or defecate before a physician completes a physical examination. Although this step can be difficult for the victim, it is important to preserve evidence. If possible, ensure that an EMT or police officer of the same gender remains with the child, unless locating one will delay transport.

You must maintain professional composure the entire time you are assessing and caring for a sexually abused child. Assume a concerned, caring approach, and shield the child from onlookers and curious bystanders. Obtain as much information as possible from the child and any witnesses. The child may be hysterical or unwilling to say anything at all, especially if the abuser is a relative or family friend. You are in the best position to obtain the most accurate firsthand information about the incident. Therefore, record any information carefully and completely on the patient care report. Transport all children who are victims of sexual assault. Sexual abuse of a child is a crime. Cooperate fully with law enforcement officials in their investigations.

Sudden Infant Death Syndrome

The death of an infant or a young child is called **sudden infant death syndrome (SIDS)** when, after a complete autopsy, the cause of death remains unexplained. According to the CDC, about 3,500 infants die of SIDS annually. To reduce the risk of SIDS, the American Academy of Pediatrics recommends that an infant be placed on his or her back on a firm mattress, in a crib that is free of bumpers, blankets, and toys. The CDC recommends having the baby sleep in the same room, but not in the same bed, chair, or sofa, as an adult.

Although it is impossible to predict SIDS, there are several known risk factors:

- Mother younger than 20 years
- Mother smoked during pregnancy
- Low birth weight

Deaths as the result of SIDS can occur at any time of the day; however, these children are often discovered in the morning when the parents or caregivers go in to check on the infant. If you are the first provider at the scene of suspected SIDS, you will face three tasks: assessment of the scene, assessment and management of the patient, and communication and support of the family.

Patient Assessment and Management

SIDS is a diagnosis of exclusion. All other potential causes must first be ruled out, a process that can be time-consuming for physicians. An infant who has been a victim of SIDS will be pale or blue, not breathing, and unresponsive. Other causes for such a condition include the following:

- Overwhelming infection
- Child abuse
- Airway obstruction from a foreign object or as a result of infection
- Meningitis
- Accidental or intentional poisoning
- Hypoglycemia (low blood glucose level)
- Congenital metabolic defects

Regardless of the cause, assessment and management of the infant remain the same. Remember that what you find in assessing the infant and the scene may provide important diagnostic information.

Begin with an assessment of the ABCs, and provide interventions as necessary. Depending on how much time has passed since the child was discovered, he or she may show signs of postmortem changes. These include stiffening of the body, called rigor mortis, and dependent lividity, which is the pooling of blood in the lower parts of the body or those that are in contact with the floor or bed.

If the child shows such signs, call medical control. In some EMS systems, a victim of SIDS may be declared dead on the scene. Deciding whether to start CPR on a child who shows clear signs of rigor mortis or dependent lividity can be very difficult. Family members may consider anything less as withholding critical care. In this situation, the best course of action may be to initiate CPR and transport the patient and the family to the nearest ED, where the family can receive more extensive support (follow local protocols). If there is no evidence of postmortem changes, begin CPR immediately.

As you assess the infant, pay special attention to any marks or bruises on the child before performing any procedures, including CPR. Also note any intervention such as CPR that was done by the parents or caregivers before you arrived.

Scene Assessment

Carefully inspect the environment, following local protocols, noting the condition of the scene where the parents or caregivers found the infant. Your assessment of the scene should concentrate on the following:

- Signs of illness, including medications, humidifiers, or thermometers
- The general condition of the house
- Signs of poor hygiene
- Family interaction. Do not allow yourself to be judgmental about family interactions at this time. Note and report any behavior that is clearly not within the acceptable range, such as physical and verbal abuse.
- The site where the infant was discovered. Note all items in the infant's crib or bed, including pillows, stuffed animals,

toys, and small objects.

Communication and Support of the Family After the Death of a Child

The death of a child, whether sudden death of an infant or otherwise, is a devastating event for a family; it also tends to evoke strong emotional responses among health care providers, including EMS personnel. Part of your job at this point is to allow the family to express their grief in ways that may differ from your own cultural, religious, and personal practices. Provide emotional support in whatever ways you can.

In addition to any medical treatment the child may require, you must be prepared to offer the family a high level of empathy and understanding as they begin the grieving process. First, the family may want you to initiate resuscitation efforts, which may or may not conflict with your EMS protocols. If the child is clearly deceased and, under protocol, can be declared dead in the field, but family members are so distraught that they insist that resuscitation efforts be made, initiate CPR and transport the child.

The extent of your interaction with the family will depend, to some degree, on the number of providers available at the scene. Always introduce yourself to the child's parents or caregivers, and ask about the child's date of birth and medical history. If and when the decision is made to start or stop resuscitation efforts, inform the family immediately. Find a place for family members to watch resuscitation without being in the way. Do not, in any case, speculate on the cause of the child's death. The family will want to see the child and should be asked whether they want to hold the child and say good-bye. Parents and caregivers may be experiencing strong feelings of denial.

The following interventions are helpful in caring for the family at this time:

- Learn and use the child's name rather than the impersonal "your child."
- Speak to family members at eye level, and maintain good eye contact with them.
- Use the word "dead" or "died" when informing the family of the child's death; euphemisms such as "passed away" or "gone" are ineffective.
- Acknowledge the family's feelings ("I know this is devastating for you,"), but never say "I know how you feel," even if you have experienced a similar event; the statement will anger many people.
- Offer to call other family members or clergy if the family wishes.
- Keep any instructions short, simple, and basic. Emotional distress may limit their ability to process information.
- Ask each adult family member individually whether he or she wants to hold the child.
- Wrap the dead child in a blanket, as you would if he or she were alive, and stay with family members while they hold the child. Ask them not to remove tubes or other equipment that was used in an attempted resuscitation.

Table 34-17 lists additional guidelines for helping the family of a deceased child.

Remember that each individual and each culture expresses grief in a different way, some more visibly than others. Some will require intervention; others will not. Most parents or caregivers feel directly or indirectly responsible for the death of a child and may express this immediately; this does not mean that they are actually responsible. Although you should keep the possibility of abuse or neglect in mind, your role is not that of investigator. Any further inquiry is the responsibility of law enforcement.

Table 34-17 How You Can Help the Family of a Deceased Child

When Arriving on Site
- Introduce yourself quickly.
- Obtain a brief history.
- When possible, one EMT should stay with the family.
- Ask the child's name and refer to the child by that name.

If Resuscitation Is Attempted
- Give brief, frequent updates and explanations.
- Allow family members to stay within viewing distance if they wish.
- Allow family members to accompany the child to the hospital when possible.

If No Resuscitation Is Performed
- Sit down with the family.
- Inform the family immediately.
- Explain why no resuscitation will be attempted.
- Offer to arrange for religious support, including baptism or last rites.

Beginning the Grieving Process
- Learn and use the child's name.
- Allow the family to express emotions; be nonjudgmental.
- Give brief explanations and answers.
- Explain to the family that the cause of death is still unknown.
- Allow time for questions.

DO
- Tell the family how sorry you are.
- Tell the family whom they can call if they have questions later.
- Give written instructions and referrals.

DO NOT
- Say, "I know how you feel."
- Say, "You have other children," or "You can have other children."
- Attempt to answer the question "Why did this happen?"
- Try to tell the family that they will feel better in time.

Many times family members will ask specific questions about the event: Why did this happen? How did this happen? Let them know that their concerns will be addressed but that answers are not immediately available Table 34-18. Remember to always use the child's name when speaking to family members. If possible, allow the family to spend time with the child and to ride in the ambulance to the hospital.

Table 34-18 Common Questions Following the Death of a Child

Q: Was there pain?
A: This often can be answered by a simple "No." If you are uncertain, you may give an indirect answer such as, "We really don't know what patients feel in these circumstances."
Q: What did the child die of?
A: Do not answer this question; you would probably be guessing.
Q: Why did this happen?
A: Do not answer this question either, as the answer depends on one's own individual philosophy or religion. "I wish I had an answer for you," is usually the most appropriate response.
Q: What happens now?
A: This question usually concerns the next few minutes or the next hour. If you know, give the family a general idea of what will happen. For example, if there is no history of illness, you can say, "A medical examination will be done, and then [child's name] will be taken to the mortuary."

Some EMS systems arrange for home visits after the death of a child so that EMS providers and family members can come to some sort of closure together. This also gives the family an opportunity to ask any remaining questions about the event. However, you need special training for such visits.

Coping with the death of a child can be very stressful. You may find yourself with unexpected feelings of pain and loss. It is helpful to take some time before going back on the job to work through your feelings and to talk about the event with your EMS colleagues. Be alert for signs of posttraumatic stress in yourself and others, including nightmares, restlessness, difficulty sleeping, and changes in appetite. Consider the need for professional help if these signs or symptoms continue. Arrange for a proper debriefing after your involvement with the case comes to a close. This can be a session with a trained counselor or a group discussion with your colleagues or the entire health care team. As discussed in Chapter 2, *Workforce Safety and Wellness*, all EMS programs should have critical incident stress management protocols and debriefing teams available for traumatic incidents.

Although you may consider the death of a child to be a failure, your skill at coping with this kind of emotional event can be a great comfort to the family, helping them to accept their loss and begin the long process of grieving.

Words of Wisdom

Most parents or caregivers of children who die suddenly will experience extremely strong emotional responses for a long time after the death. Counseling and support services begin with your care, including immediate referral to longer-term services. You can usually make this referral through social services personnel in a hospital you work with; familiarize yourself with available resources. Many communities also have support groups for grieving families. Make sure the parents or caregivers are aware of available services, offer to put them in touch while you are there, and leave the contact information in written form for their later reference even if you have helped them make the contact.

Apparent Life-Threatening Event

Infants who have cyanosis and apnea and are unresponsive when found by their families sometimes resume breathing and color with stimulation. These children have had what is called an **apparent life-threatening event (ALTE)**, called near-miss SIDS in the past. In addition to cyanosis and apnea, a classic ALTE is characterized by a distinct change in muscle tone (limpness) and choking or gagging. Given the limited understanding of ALTEs and the inability to identify subtle causes in the field, parents and caregivers should be encouraged to have their infant promptly transported to an appropriate facility for a full evaluation. After the ALTE, you may find a child that appears healthy and shows no signs of illness or distress. Nevertheless, you must complete a careful assessment and provide rapid transport to the ED.

Pay strict attention to management of the airway. Assess the infant's history and, if possible, the environment. Be aware the ALTE might be the result of abuse. Allow parents or caregivers to ride in the ambulance if appropriate. If asked, explain that you cannot say what caused the event and that the physicians will have to determine the cause at the hospital.

YOU are the Provider — SUMMARY

1. How does a child's airway and respiratory system differ from an adult's?

Proportionately, infants and children have a larger, rounder occiput (back of the head). The child's tongue is proportionately larger than an adult's tongue and larger relative to the small mandible, which makes it easier to block the airway. In addition, the pediatric airway is narrower with a proportionately larger and floppier epiglottis when compared to an adult. Because of their relatively smaller lungs, infants and children need to breathe faster to adequately exchange oxygen and carbon dioxide. Children have both a higher metabolic rate and a higher demand for oxygen due in part to the actual size of the lung tissues and the volume of air that can be exchanged. Finally, breathing in children also requires use of both the diaphragm and intercostal muscles.

2. What are some airway and breathing problems that are unique to pediatric patients?

Foreign body airway obstruction is common in children; it commonly occurs when children put a small toy or other object in their mouths. A number of respiratory illnesses are unique to the pediatric population, including bacterial tracheitis, croup (laryngotracheobronchitis), epiglottitis, asthma, bronchiolitis, and pertussis (whooping cough).

3. Why did you not immediately perform a hands-on assessment of this child?

If an infant or child is clearly experiencing a life-threatening condition, such as unconsciousness or major trauma, then an immediate hands-on assessment is indicated. However, since the child is conscious, you can use the pediatric assessment triangle (PAT) to quickly form a general impression of the child without touching her. Based on the findings of the PAT, you should be able to determine whether the child is in stable condition, in which case you can continue with your assessment, or unstable condition, in which case you should begin immediate treatment and prepare for transport.

4. On the basis of your observations so far, is this child experiencing respiratory distress or respiratory failure?

Although the child appears fearful of your presence—a normal reaction for a young child—she is alert, exhibiting age-appropriate behavior, and maintaining eye contact with you. Her skin is pink and appears to be dry; however, she is experiencing increased work of breathing, as noted by an increased respiratory rate, obvious breathing difficulty, nasal flaring, and prominent retractions. This clinical presentation is consistent with respiratory distress.

5. What is the most likely cause of this child's respiratory distress?

On the basis of the child's clinical presentation and the progression of her symptoms, you should suspect that she has croup. This general impression is further reinforced by the presence of a high-pitched cough, a low-grade fever, and preceding cold symptoms. Her breath sounds are clear to auscultation bilaterally; this makes a lower airway problem highly unlikely. In addition, it is autumn; croup most commonly occurs during the autumn and early winter.

6. Should you separate this child from her parents to provide further treatment? Why or why not?

The decision to separate a sick or injured child from his or her parents is based on the child's condition and the parents' reaction to the situation. Although this child is experiencing respiratory distress, she is clinically stable and is clinging to her mother, who is showing no evidence of emotional distress. For these reasons, do not separate the child from her mother. If you do, you will likely find that the child will become more anxious. Anxiety can easily worsen the child's condition by making her breathe harder and making her heart beat faster.

7. How has this child's condition changed? What should you do next?

Compared with earlier assessments, the child's condition has obviously deteriorated; she is now in respiratory failure. When infants and children decompensate, they often do so with alarming speed. In this case, the child decompensated in the time it took to move her from the residence to the back of your ambulance! Clinical signs of this child's deterioration include a decreased level of activity; she was previously conscious and maintaining eye contact. She is breathing slower and her retractions have markedly weakened; this indicates chest wall muscle fatigue from prolonged increased work of breathing. She is developing cyanosis around her mouth (perioral cyanosis), indicating a decreased level of oxygen in her blood. This sign is further verified by the marked decrease in her oxygen saturation level. Perhaps the most ominous sign is the marked decrease in her heart rate. When the body is no longer able to compensate, the heart rate begins to fall; this is a sign of impending cardiopulmonary arrest.

You must act immediately to prevent this child from developing respiratory or cardiac arrest. Begin assisting her ventilations with a BVM and high-flow oxygen and transport immediately. If possible, coordinate an intercept with an ALS unit en route to the hospital. If her condition continues to deteriorate, she may require advanced airway management or medication therapy.

8. How could an ALS intercept benefit this child?

You are caring for a child who, at a minimum, requires assisted ventilation. If her condition continues to deteriorate, she may require CPR. ALS providers can perform advanced airway management, administer cardiac medications, and monitor the patient's cardiac rhythm. In some cases, children with respiratory failure require more than oxygen and assisted ventilations; certain medications may also be required. Because these interventions would clearly benefit the child—especially if she experiences cardiac arrest—consider an ALS intercept if it will lead to faster access to advanced care.

9. Are you providing adequate ventilations? How can you tell?

The child's level of consciousness (still listless) and slow, shallow respirations are clear indicators for the continued use of assisted ventilation. However, she is showing signs of improvement, indicating that your ventilations are adequate.

The child's heart rate has increased from 90 beats/min to 110 beats/min; as with any patient, an improvement in the heart rate is a sign of adequate artificial ventilation. The child's oxygen saturation has also improved significantly (from 85% to 96%); this indicates that you are adequately oxygenating her blood. The cyanosis around her mouth is resolving; this is also an indicator of adequate ventilation.

Despite the fact that you have noted clinical improvement with assisted ventilation, this does not mean that you can stop. The child is still breathing at a slow rate and the depth of her breathing is shallow. Also, she is not resisting your treatment, thus indicating that her level of consciousness is still depressed, and she is still fatigued. Continue to assist her ventilations.

10. Why is it especially important to avoid hyperventilating infants and children?

In the unprotected airway (ie, in the patient who is not intubated), hyperventilation forces excess air into the stomach, which causes gastric distention. Gastric distention increases the risk of aspiration if vomiting occurs. In infants and small children, there is the additional risk of pushing the diaphragm into the thoracic cavity, which may reduce the effectiveness of your ventilations. It takes much less air in the stomach of an infant or child to inhibit adequate positive pressure ventilations than it does in an adult.

EMS Patient Care Report (PCR)

Date: 1-15-16	**Incident No.:** 013210	**Nature of Call:** Respiratory distress		**Location:** 545 W. San Antonio St.	
Dispatched: 2323	**En Route:** 2324	**At Scene:** 2330	**Transport:** 2340	**At Hospital:** 2353	**In Service:** 2359

Patient Information

Age: 4 **Sex:** F **Weight (in kg [lb]):** 16 kg (35 lb)	**Allergies:** No known drug allergies **Medications:** None **Past Medical History:** Recent cold **Chief Complaint:** Respiratory distress

Narrative

Medic 3 dispatched to a residence for a 4-year-old child with respiratory distress. Arrived on scene and found the patient sitting on the couch next to her mother. She was conscious, maintained eye contact, and began clinging to her mother. Her airway was patent; however, her breathing was obviously labored. Visual assessment revealed that her skin was pink and appeared dry. She had prominent supraclavicular retractions and nasal flaring during inhalation. Administered blow-by oxygen via pediatric nonrebreathing mask and performed further assessment. Patient's mother states that she has had a cold for the past 2 days, and slowly developed a low-grade fever and high-pitched cough, which she described as a "barking seal." Mother denies that her child has any significant past medical history; she has been giving her ibuprofen as needed for her low-grade fever. Auscultation of breath sounds revealed that they were clear and equal bilaterally, but prominent intercostal retractions were noted on exposure of the chest. Capillary refill time, 1 second. Continued blow-by oxygen as patient's father carried her to the ambulance. Shortly after securing the child to the stretcher, reassessment revealed that her level of consciousness had markedly decreased. Her respiratory rate also decreased, her retractions were weak, and her oxygen saturation level markedly decreased. Began assisting the child's ventilations with a BVM and high-flow oxygen and began rapid transport. Attempted to coordinate ALS intercept; however, the closest ALS unit was too far away and would have resulted in unnecessary delay in transport. Notified receiving facility of the patient's condition and of our estimated arrival time and continued assisting ventilations. Reassessment revealed that the child was still listless and was not resistant to treatment; however, her heart rate, skin color, and oxygen saturation improved. Continued ventilatory assistance and delivered child to the emergency department. Verbal report was given to staff physician. Medic 3 cleared the hospital and returned to service at 2359.**End of report**

Prep Kit

Ready for Review

- Children are not only smaller than adults and more vulnerable, they are also anatomically, physiologically, and psychologically different from adults in important ways.
- Infancy is the first year of life. If possible, allow the parent or caregiver to hold the infant during the assessment.
- The toddler (age 1 to 3 years) may experience separation or stranger anxiety but may be able to be distracted by a special object (blanket) or toy.
- Preschool-age children (ages 3 to 6 years) can understand directions and can identify painful areas when questioned. Tell these children what you are going to do before you do it to prevent the development of frightening fantasies.
- School-age children (ages 6 to 12 years of age) are familiar with the physical examination process. Talk with them about their interests to distract them during a procedure.
- Adolescents (ages 12 to 18 years) are physically similar to adults, but are still children on an emotional level. Respect the adolescent's modesty at all times.
- General rules for dealing with pediatric patients of all ages include appearing confident, being calm, remaining honest, and keeping parents or caregivers together with the pediatric patient as much as possible.
- The growing bodies of the pediatric patient create some special considerations.
- The tongue is large relative to other structures, so it poses a higher risk of airway obstruction than in an adult.
- An infant breathes faster than an older child.
- Breathing requires the use of chest muscles and the diaphragm.
- The airway in a child has a smaller diameter than the airway in an adult and is therefore more easily obstructed.
- A rapid heartbeat and blood vessel constriction help pediatric patients to compensate for decreased perfusion.
- Children's internal organs are not as insulated by fat and may be injured more severely, and children have less circulating blood. Therefore, children exhibit the signs of shock more slowly, but they go into shock more quickly, with less blood loss.
- Children's bones are more flexible and bend more with injury, and the ends of the long bones, where growth occurs, are weaker and may be injured more easily.
- Because a young child might not be able to speak, your assessment of his or her condition must be based in large part on what you can see and hear. Families may be able to provide vital information about an incident or illness.
- Use the pediatric assessment triangle (PAT) to obtain a general impression of the infant or child.
- You will need to carry special sizes of airway equipment for pediatric patients.
- Use length-based resuscitation tape to determine the appropriately sized equipment for children.
- The three keys to successful use of the BVM in a child are: (1) have the appropriate equipment in the right size; (2) maintain a good face-to-mask seal; and (3) ventilate at the appropriate rate and volume.
- Signs of shock in children are tachycardia, poor capillary refill time (>2 seconds), and mental status changes. You must be alert for signs of shock in pediatric patients because they can decompensate rapidly.
- Begin treating shock by assessing the ABCs. In pediatric patients with obvious life-threatening external hemorrhage, address this first, as always.
- Febrile seizures may be a sign of a more serious problem such as meningitis.
- The most common cause of dehydration in children is vomiting and diarrhea. Life-threatening diarrhea can develop in an infant in a matter of hours.
- Fever is a common reason why parents or caregivers call 9-1-1. Body temperatures of 100.4°F (38°C) or higher are considered to be abnormal.
- Trauma is the number one killer of children in the United States.
- A victim of sudden infant death syndrome (SIDS) will be pale or blue, not breathing, and unresponsive. He or she may show signs of postmortem changes, including rigor mortis and dependent lividity; if so, call medical control to report the situation.
- Carefully inspect the environment where a SIDS victim was found, looking for signs of illness, abusive family interactions, and objects in the child's crib.
- Provide emotional support for the family in whatever way you can, but do not make judgmental statements.
- The death of a child is devastating for family members and for health care providers. In dealing with family members, acknowledge their feelings, keep any instructions short and simple, use the child's name, and maintain eye contact.
- Be prepared to respond to philosophic as well as medical questions. Indicate concern and understanding; do not be specific

about the cause of death.

- Be alert for signs of posttraumatic stress in yourself and others after dealing with the death of a child. It can help to talk about the event and your feelings with your EMS colleagues.

Vital Vocabulary

adolescents Children between ages 12 to 18 years.

apparent life-threatening event (ALTE) An event that causes unresponsiveness, cyanosis, and apnea in an infant, who then resumes breathing with stimulation.

blanch To turn white.

bradypnea Slow respiratory rate; ominous sign in a child that indicates impending respiratory arrest.

bronchiolitis Inflammation of the bronchioles that usually occurs in children younger than 2 years and is often caused by the respiratory syncytial virus.

central pulses Pulses that are closest to the core (central) part of the body where the vital organs are located; include the carotid, femoral, and apical pulses.

child abuse A general term applying to all forms of abuse and neglect of children.

croup An inflammatory disease of the upper respiratory system that may cause a partial airway obstruction and is characterized by a barking cough; usually seen in children.

epiglottitis A disease in which the epiglottis becomes inflamed and enlarged and may cause an upper airway obstruction.

fontanelles Areas where the neonate's or infant's skull has not fused together; usually disappear at approximately 18 months of age.

generalized tonic-clonic seizure A seizure that features rhythmic back-and-forth motion of an extremity and body stiffness. feelings, keep any instructions short and simple, use the child's name, and maintain eye contact.

grunting An "uh" sound heard during exhalation; reflects the child's attempt to keep the alveoli open; a sign of increased work of breathing.

infancy The first year of life.

length-based resuscitation tape A tape used to estimate an infant or child's weight on the basis of length; appropriate drug doses and equipment sizes are listed on the tape.

meningitis An inflammation of the meningeal coverings of the brain and spinal cord; it is usually caused by a virus or a bacterium.

nares The external openings of the nostrils. A single nostril opening is called a naris.

neglect Refusal or failure on the part of the parent or caregiver to provide life necessities.

Neisseria meningitides A form of bacterial meningitis characterized by rapid onset of symptoms, often leading to shock and death.

pediatric assessment triangle (PAT) A structured assessment tool used to rapidly form a general impression of the infant or child without touching him or her; consists of assessing appearance, work of breathing, and circulation to the skin.

pediatrics A specialized medical practice devoted to the care of the young.

pertussis An airborne bacterial infection that affects mostly children younger than 6 years, in which the patient is feverish and exhibits a "whoop" sound on inspiration after a coughing attack; highly contagious through droplet infection. Also called whooping cough.

preschool-age Children between ages 3 to 6 years.

school-age Children between ages 6 to 12 years.

shaken baby syndrome A syndrome seen in abused infants and children; the patient has been subjected to violent, whiplash-type shaking injuries inflicted by the abusing individual that may cause coma, seizures, and increased intracranial pressure due to tearing of the cerebral veins with consequent bleeding into the brain.

sniffing position An upright position in which the patient's head and chin are thrust slightly forward to keep the airway open; the optimum position for the uninjured child who requires airway management.

sudden infant death syndrome (SIDS) Death of an infant or young child that remains unexplained after a complete autopsy.

tachypnea Increased respiratory rate.

toddler A child age 1 to 3 years.

tracheitis Inflammation of the trachea.

tripod position An upright position in which the patient leans forward onto outstretched arms with the head and chin thrust slightly forward.

work of breathing An indicator of oxygenation and ventilation; reflects the child's attempt to compensate for hypoxia.

Assessment *in Action*

You and your partner are called to an elementary school for an 8-year-old boy with an altered mental status. On arrival, you find the child lying supine on the cafeteria floor. A teacher is waiting with the patient and the scene is safe. The teacher states that the child finished his lunch and began "shaking" in his chair, at which point the teacher moved him to the floor.

Your general impression provides the following information: there are no obvious life threats; he is alert; his work of breathing is unlabored; his skin color is pink. Your assessment reveals his airway is open and clear, his respiratory rate is 20 breaths/min, and his pulse rate is 90 beats/min. The child is responsive to verbal stimuli and is confused as to what happened and where he is. You do not see any injuries or skin rashes.

1. Which of the following would be the least likely cause of the patient's altered mental status?

A. Hypoglycemia
B. Drug ingestion
C. Hypoxia
D. Head injury

2. Which of the following assessment tools would you use to form a general impression of this patient without touching him?

A. Pediatric assessment triangle (PAT)
B. Glasgow Coma Scale
C. AVPU scale
D. TICLS mnemonic

3. The teacher tells you that the child has a history of seizures and recently had a medication change. Given the situation, which of the following would be the least likely cause of this seizure?

A. Fever or infection
B. Head injury
C. Hypoglycemia
D. Medication changes or errors

4. To evaluate this child's level of consciousness, you must note the mental status and assess his:

A. skin color.
B. pupil size.
C. chest rise.
D. age-appropriate responses to your questions.

5. The teacher reports that after the child was moved to the floor, he stopped "shaking" and his breathing became rapid. This period is referred to as the:

A. recovery state.
B. postictal state.
C. aural state.
D. reversal state.

6. If this patient were experiencing status epilepticus, the teacher would have described a seizure continuing every few minutes without regaining consciousness, or a single seizure lasting longer than:

A. 30 minutes.
B. 45 minutes.
C. 60 minutes.
D. 120 minutes.

7. If the patient begins seizing again during your care, which of the following would be your treatment priority?

A. Stop the seizure.
B. Secure and clear the airway.
C. Provide rapid transport.
D. Maintain the patient's body temperature.

8. During transport and your secondary assessment of the patient, which finding will help you determine when this patient is no longer in a postictal state?

A. Level of consciousness
B. Respiratory rate
C. Muscle tone
D. Blood pressure

9. Explain how seizure activity in an infant differs from that of an older child.

10. When you are using the pediatric assessment triangle, what information can you obtain by evaluating the appearance

of a pediatric patient?

CHAPTER
35

Geriatric Emergencies

National EMS Education Standard Competencies

Special Patient Populations

Applies a fundamental knowledge of growth, development, and aging and assessment findings to provide basic emergency care and transportation for a patient with special needs.

Geriatrics

› Impact of age-related changes on assessment and care (pp 1301–1310)
› Changes associated with aging, psychosocial aspects of aging and age-related assessment and treatment modifications for the major or common geriatric diseases and/or emergencies
  • Cardiovascular diseases (pp 1287–1289, 1301–1305)
  • Respiratory diseases (pp 1286–1287, 1301–1305)
  • Neurological diseases (pp 1290–1293, 1301–1305)
  • Endocrine diseases (pp 1295, 1301–1305)
  • Alzheimer disease (pp 1291, 1301–1305)
  • Dementia (pp 1291, 1301–1305)

Patients With Special Challenges

› Recognizing and reporting abuse and neglect (pp 1312–1313 and Chapter 34, *Pediatric Emergencies*)
› Health care implications of
  • Abuse (pp 1312–1313 and Chapter 34, *Pediatric Emergencies*)
  • Neglect (pp 1312–1313 and Chapter 34, *Pediatric Emergencies*)
  • Homelessness (Chapter 36, *Patients With Special Challenges*)
  • Poverty (Chapter 36, *Patients With Special Challenges*)
  • Bariatrics (Chapter 36, *Patients With Special Challenges*)
  • Technology dependent (Chapter 36, *Patients With Special Challenges*)

- Hospice/terminally ill (Chapter 36, *Patients With Special Challenges*)
- Tracheostomy care/dysfunction (Chapter 36, *Patients With Special Challenges*)
- Homecare (Chapter 36, *Patients With Special Challenges*)
- Sensory deficit/loss (Chapter 36, *Patients With Special Challenges*)
- Developmental disability (Chapter 36, *Patients With Special Challenges*)

Trauma

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

Special Considerations in Trauma

› Recognition and management of trauma in the:
- Pregnant patient (Chapter 33, *Obstetrics and Neonatal Care*)
- Pediatric patient (Chapter 34, *Pediatric Emergencies*)
- Geriatric patient (pp 1306–1310)

› Pathophysiology, assessment, and management of trauma in the:
- Pregnant patient (Chapter 33, *Obstetrics and Neonatal Care*)
- Pediatric patient (Chapter 34, *Pediatric Emergencies*)
- Geriatric patient (pp 1306–1310)
- Cognitively impaired patient (Chapter 36, *Patients With Special Challenges*)

Knowledge Objectives

1. Define the term geriatrics. (p 1283)
2. Recognize some of the special aspects of the lives of older people. (pp 1283–1285)
3. Know generational considerations when communicating with a geriatric patient. (pp 1283–1284)
4. Describe the common complaints and the leading causes of death in older people. (p 1285)
5. Discuss the physiologic changes associated with the aging process and the age-related assessment and treatment modifications that result. (pp 1285–1299)
6. Define polypharmacy and the toxicity issues that can result. (pp 1297–1298)
7. Discuss the effect of aging on behavioral emergencies. (pp 1298–1299)
8. Explain the GEMS diamond and its role in the assessment and care of the geriatric patient. (pp 1299–1300)
9. Explain special considerations when performing the patient assessment process on a geriatric patient with a medical condition. (pp 1301–1305)
10. Discuss the effects of aging on environmental emergencies. (p 1306)
11. Explain special considerations when performing the patient assessment process on a geriatric patient with a traumatic injury. (pp 1306–1310)
12. Explain special considerations when responding to calls at nursing and skilled care facilities. (pp 1310–1311)
13. Define an advance directive and considerations with older patients. (pp 1311–1312)
14. Discuss the prevalence of elder abuse and neglect; include why the extent of elder abuse is not well known. (pp 1312–1313)
15. Recognize acts of commission or omission by a caregiver that result in harm, potential harm, or threat of harm to a geriatric patient. (p 1312)
16. Explain the assessment and care of a geriatric patient who has potentially been abused or neglected. (pp 1313–1314)

Skills Objectives

There are no skills objectives for this chapter.

Introduction

Geriatrics is the assessment and treatment of disease in someone who is 65 years or older. In this chapter, 65 years is used as the threshold age to be consistent with the definition used by other medical groups and governmental agencies. How fast one ages, though, is a function of genetics, lifestyle, and, perhaps, attitude.

People born between 1946 and 1964, known as the baby boomer generation, are much more active today than people their age were in previous generations. The older population continues to increase. It is projected that between 2012 and 2050, the population aged 65 and older is expected to nearly double. This is a significant trend for EMS because older people are major users of both emergency medical services and health care systems in general.

Geriatric patients present a special challenge for health care providers because the classic presentations of injuries and illness are often altered by chronic conditions, multiple medications, and the physiology of aging. To provide effective treatment for this growing population, you must understand the issues related to aging and modify some of your assessment and treatment approaches accordingly.

Being a patient advocate for an older patient involves much more than management of medical and traumatic emergencies. As the older population increases, communities, companies, and hospitals are encouraging awareness of geriatric issues through the media and creating programs that promote prevention of injuries. EMTs who respond to the homes of geriatric patients are in an ideal position to provide key information to others in health care and social services systems. Interventions for geriatric patients may include reviewing the home environment to ensure that safe and tolerable living conditions exist, providing information on how to prevent falls, and making referrals to appropriate social service agencies when a patient needs assistance. Often, simple preventive measures can help older people avoid further injury, costly medical treatment, and death. You are in a position to not only recognize and manage a serious emergency, but also to help prevent problems before they occur.

Generational Considerations

It is important to understand and appreciate how the life of an older person might differ from yours. You will see older people who have recently lost a spouse and are struggling to fill the spouse's role, such as by managing the finances or doing the housework. Many older people also live on a fixed income, which can be very challenging. Some older people may not take all of their medications in an effort to save money. Many struggle to stay independent as long as possible and are living in the homes in which they raised their children—children who have now moved far away.

YOU are the Provider — PART 1

At 0625 hours, you are dispatched to a residence at 644 Yolanda Street for an 82-year-old woman whose daughter called 9-1-1 because her mother is experiencing shortness of breath. You and your partner respond to the scene, which is located only a short distance away.

1. As an EMT, why is it important for you to understand the anatomic and physiologic changes that occur with aging?
2. How does the process of aging affect a person's respiratory system?

Figure 35-1 Physical activity can help older people reduce their risk of illness and injury.

Courtesy of the National Cancer Institute.

It takes time and patience to interact with an older person. Always treat the patient with respect. Make every attempt to avoid *ageism*, which is a stereotyping of older people that often leads to discrimination. Common stereotypes include assuming that the patient has dementia, is hard of hearing, has a sedentary lifestyle, or is immobile. Older people can stay fit and be active, even though they are not able to perform at the same level as they did in their youth **Figure 35-1**.

Communication and Older Adults

Effective verbal communication skills are essential to the successful assessment and treatment of older patients. Communication with older people can be challenging. The aging process brings with it changes in vision, hearing, taste, smell, touch, and pain sensation. Also, there are changes in communication abilities that accompany aging, such as dementia and other diseases. These challenges are consequences of aging and should be expected, but not assumed.

Words of Wisdom

Older patients who learned English as a second language may revert back to their native language when stressed or in a crisis situation. Do not assume that the patient cannot understand you just because he or she is speaking another language.

Communication Techniques

Your first words to the patient and the attitude behind them can gain or lose a patient's trust. Speak respectfully when you introduce yourself. Address the patient by using "sir" or "ma'am." If you know the patient's last name, use "Mr.," "Mrs.," or "Miss." Using the patient's name shows respect and helps the patient focus on your questions. Older people may be insulted, however, if you use only their first name. Asking the patient how he or she prefers to be addressed can build trust. Never use familiar or casual terms such as "honey" or "dear" when referring to your patient unless he or she has invited you to do so.

When you interview an older patient, the following techniques should be used:

- **Identify yourself.** This helps to establish a relationship.
- **Be aware of how you present yourself.** Avoid showing frustration and impatience through body language, such as crossed arms.
- **Look directly at the patient at eye level and ensure good lighting.**
- **Speak slowly and distinctly.** Do not raise your voice. Try to talk in a lower tone; some older people can hear certain pitches better than others.
- **Have one person talk to the patient and ask only one question at a time.** Do not answer questions for patients out of frustration or impatience.
- **Do not assume that all older patients are hard of hearing.** Ask the patient if he or she can hear you, and verify by asking him or her to confirm understanding of what you just said. Be aware of the presence of hearing aids.
- **Give the patient time to respond unless the condition appears urgent.**
- **Listen to the answer the patient gives you.**
- **Explain what you are going to do before you do it.** Use simple terms to explain the use of medical equipment and procedures; avoid using medical jargon or slang.
- **Do not talk about the patient in front of him or her as though the patient was not there.** This gives the patient the feeling that he or she does not have a say in decisions about his or her care. This is easy to forget when the patient has impaired cognitive (thought) processes or has difficulty communicating.

Keep in mind the patient may be very nervous about going to the hospital. This may be due to fears of dying, a loss of independence, or being placed in a care center. By using effective communication skills, you can earn the patient's trust and help him or her feel more at ease.

Words of Wisdom

Remember, as with patients of any age, older patients may have more difficulty communicating clearly when they are stressed by an emergency or personal crisis.

Common Complaints and the Leading Causes of Death in Older People

The changing physiology of geriatric patients can predispose this population to a host of problems not seen in youth. A simple rib fracture in a 30- or 40-year-old patient can be inconsequential in the long-term. The same injury in a geriatric patient who is age 80 or 90 years can result in pneumonia and even death. A hip fracture from a low-mechanism fall is common in older people and may have dire consequences. Hip fractures are more likely to occur when bones are weakened by osteoporosis or infection. Sedentary behavior while healing can predispose the patient to pneumonia and blood clots that may interfere with healing and can cause death. Many older patients who experience hip fractures do not return to their preinjury levels of activity. Many older patients are well aware of this and may be frightened. All of these factors make assessment and treatment decisions more complex and patient complaints potentially more serious.

The most frequently occurring conditions in older people and the leading causes of death in the geriatric population are listed in Table 35-1.

Changes in the Body

The process of aging is gradual and starts much earlier than most people realize. Human growth and development peaks in the late 20s and early 30s, at which point the aging process begins. A 35-year-old is aging just as fast as an 85-year-old, but the older person exhibits the cumulative results of a longer process. Of course, the aging process can vary dramatically from one person to another. You have probably seen 60-year-olds who look frail, and 80-year-olds who could run marathons.

Table 35-1 Common Conditions and the Leading Causes of Death in Geriatric Patients

Common Conditions

- Hypertension
- Arthritis
- Heart disease
- Cancer
- Diabetes mellitus
- Asthma
- Chronic bronchitis or emphysema
- Stroke

Leading Causes of Death

- Heart disease
- Cancer
- Chronic lower respiratory disease
- Stroke
- Alzheimer disease
- Diabetes mellitus
- Influenza and pneumonia

Source: Federal Interagency Forum on Aging-Related Statistics. *Older Americans 2012: Key Indicators of Well-Being*. Federal Interagency Forum on Aging-Related Statistics. Washington, DC: U.S. Government Printing Office. June 2012. http://www.agingstats.gov/agingstatsdotnet/Main_Site/Data/2012_Documents/Docs/EntireChartbook.pdf.Accessed Dec. 22, 2014.

The aging process is inevitably accompanied by changes in physiologic function, such as a decline in the function of the liver and kidneys. All tissues in the body undergo aging, albeit not at the same rate. The decrease in the functional capacity of various organ systems is normal, but it can affect the way a patient responds to illness.

As a health care professional, you need to be knowledgeable about decreased function in organ systems in older people because this knowledge will enable you to correctly respond to a patient's illness. For example, if you are unaware of the normal changes of aging, you may mistake the changes for signs of illness and give treatment when none is necessary. At the other end of the spectrum, there is a widespread—and unfortunate—tendency to attribute genuine disease symptoms to "just getting old" and to neglect their treatment.

Changes in the Respiratory System

Anatomy and Physiology

Age-related changes in the respiratory system can predispose an older adult to respiratory illness. Even a minor lung infection can become a life-threatening event. One of the conditions contributing to breathing problems is the weakening of the airway musculature that can cause decreased breathing capacity. This decreased muscle mass means that older patients have less help from muscles in the chest wall when they have trouble breathing. As one gets older, the alveoli in lung tissue can become enlarged and the elasticity decreases, making it harder to expel used air (air trapping). This change in lung tissue quality is comparable to a balloon that has been expanded and then deflated; the balloon loses some of its ability to contract to its original state after inflation. The lack of elasticity results in a decreased ability to exchange oxygen and carbon dioxide. The body's chemoreceptors, which monitor the changes in oxygen and carbon dioxide levels in the blood, slow with age. This, in turn, can make the body respond more slowly to hypoxia, a dangerous condition in which the body tissues and cells do not have enough oxygen.

In addition, loss of mechanisms that protect the upper airway include decreased cough and gag reflexes, resulting in a decreased ability to clear secretions. There is also a decrease in the number of cilia that line the bronchial tree; this lessens an older person's ability to cough and clear secretions, therefore increasing the chance of infection.

Pathophysiology

Pneumonia

Perhaps due to the prevalent use of tobacco during their generation, chronic lower respiratory disease, influenza, and pneumonia remain in the top five causes of geriatric deaths. In fact, one of the most common causes of death in older patients is infection with *Pneumococcus* bacteria.

Pneumonia is an inflammation of the lung from bacterial, viral, or fungal causes. Pneumonia is the leading cause of death from infection in Americans older than 65 years. It especially affects people who are chronically and terminally ill. The process of aging causes some degree of immune suppression and increases the risk of contracting infections like pneumonia. Increased mucus production, pulmonary secretions, and the inflammatory effects of infection all interfere with the ability of the alveoli to oxygenate the blood. Your management of pneumonia remains the same as described in Chapter 15, *Respiratory Emergencies*; however, it is important to maintain a high index of suspicion for any geriatric patient with signs and symptoms of possible pneumonia. Remember to wear respiratory protection when you are assessing a patient with a potentially infectious respiratory disease. You can also place a surgical mask on the patient.

Pulmonary Embolism

Another condition that can cause respiratory distress in older people is a **pulmonary embolism**. Pulmonary embolism is a condition that causes a sudden blockage of an artery by a venous clot. Clots develop in the veins of the legs or pelvis and then break off and embolize (move) through the pulmonary artery or one of its branches, where they lodge. A patient with a pulmonary embolism will present with shortness of breath and sometimes chest pain; thus, the pulmonary embolism can be confused with a cardiac, lung, or musculoskeletal problem. The top risk factors for a pulmonary embolism include living in a nursing home or recent hospitalization for medical illness or surgery (especially in a lower extremity). Other factors include trauma, cancer, history of blood clots or heart failure, presence of a pacemaker or central venous catheter, paralyzed extremities, obesity, recent long-distance travel, and sedentary behavior, especially after surgery.

The presentation can be subtle or dramatic depending on how large the clot is and how much lung tissue is damaged. Patients present with tachycardia; sudden onset of dyspnea (shortness of breath, which differentiates this from an infection like pneumonia); shoulder, back, or chest pain; cough; syncope in patients in whom the clot is larger; anxiety, which may be communicated as a sense of impending doom; apprehension; and possibly a low-grade fever or **hemoptysis** (the coughing up of blood). Also look for leg pain, redness, and swelling in just one ankle and foot for the source of the clot. The patient may present with profound fatigue and may go into cardiac arrest in a worst-case scenario.

Treatment should focus on airway, ventilatory, and circulatory support. Hemoptysis is usually not severe, but any blood that has been coughed up should be cleared from the airway. Because a considerable amount of lung tissue may not be functioning, supplemental oxygen is mandatory in a patient with a pulmonary embolism. Place the patient in a comfortable position, usually sitting, and apply high-flow oxygen via a nonrebreathing mask. Aggressive airway management may be necessary because a large pulmonary embolus may cause significant impairment of the patient's ability to breathe and could result in cardiac arrest if not managed properly. In this situation, ventilate with a bag-valve mask (BVM), using an oropharyngeal or nasopharyngeal airway. When a patient is in respiratory and/or cardiac arrest, manage according to current Emergency Cardiovascular Care guidelines and local protocol.

Changes in the Cardiovascular System

Anatomy and Physiology

A variety of changes occur in the cardiovascular system as a person grows older, with the net effect of a decrease in the efficiency of the system. Specifically, the heart hypertrophies (enlarges) with age, probably in response to the chronically increased afterload imposed by stiffened blood vessels. Bigger is not better, however. Over time, cardiac output (the amount of blood pumped out of the heart in one minute) declines, mostly as a result of a decreasing stroke volume (the amount of blood pumped out of the heart in one beat).

Arteriosclerosis—a disease that causes the arteries to thicken, harden, and calcify—contributes to systolic hypertension in many older patients, which places an extra burden on the heart. This phenomenon may be a consequence of disease states such as diabetes, atherosclerosis, and renal compromise, and it is associated with an increased risk of cardiovascular disease, dementia, and death. Compliance of the vascular walls depends on the production of collagen and elastin, proteins that are the primary components of muscle and connective tissue. An increase in pressure (normal hypertension seen with aging) leads to overproduction of abnormal collagen and decreased quantities of elastin; these actions contribute to vascular stiffening. The result is a widening pulse pressure, decreased coronary artery perfusion, and changes in cardiac ejection efficiency.

Some changes in cardiovascular performance are probably not a direct consequence of aging, but rather reflect the deconditioning effect of a sedentary lifestyle. Whether because of other disabilities (such as arthritis) or for behavioral reasons, many people tend to limit physical activity and exercise as they grow older. The phrase, "Use it or lose it," applies just as much to the cardiac muscle as to the biceps muscle.

Pathophysiology

Cardiac output is a measure of the workload of the heart. A younger person's body normally compensates for an increased demand on the cardiovascular system by increasing the heart rate, increasing the contraction of the heart, and constricting the blood vessels to nonvital organs. However, with aging, a person's ability to speed up contractions, increase contraction strength, and constrict or narrow blood vessels (vasoconstriction) is decreased because of stiffer vessels. As stroke volume is reduced, cardiac output decreases. The heart may lose its ability to raise cardiac output to meet the needs of the body.

Geriatric patients are at risk for **atherosclerosis**, an accumulation of fat and cholesterol in the arteries **Figure 35-2**. Major complications of atherosclerosis include myocardial infarction (heart attack) and stroke. Atherosclerotic disease originates in the teen years and affects more than 60% of people older than 65 years. The presence of atherosclerosis makes stroke, heart disease, hypertension, and bowel infarction more likely.

Older people are also at an increased risk for formation of an **aneurysm**, an abnormal, blood-filled dilation of the wall of a blood vessel. Severe blood loss can occur when an aneurysm ruptures.

The blood vessels themselves become stiff, which results in a higher systolic blood pressure. As a result, the left ventricle, which pushes blood out into the body, becomes thicker and eventually loses elasticity, resulting in decreased filling of the left ventricle, which in turn causes decreased cardiac output.

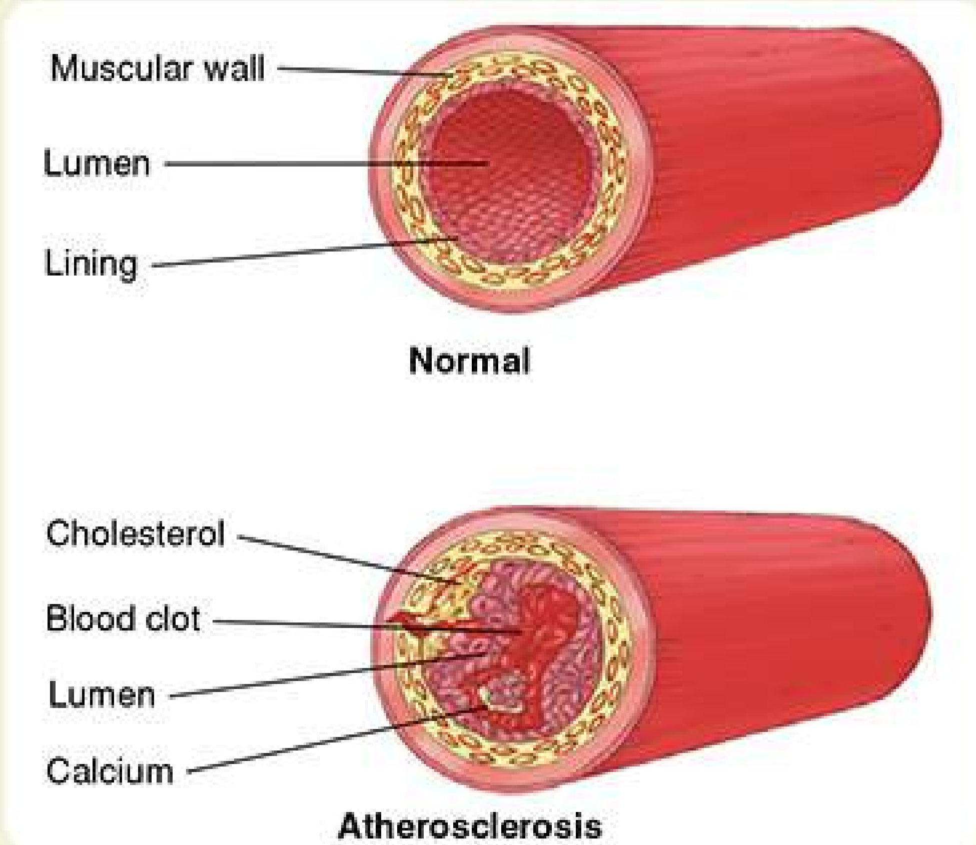

Figure 35-2 Atherosclerosis, the buildup of fat and cholesterol on arterial walls.

Other anatomic changes include stiffening and degeneration of the heart valves, which may impede normal blood flow in and out of the heart. Aging also alters the heart's electrical conduction system. The sinoatrial node is the normal pacemaker of the heart, but by the age of 75 years, the number of the cells in the sinoatrial node will decrease by 90%. This event, combined with fibrosis and fatty deposits attaching to the electrical pathway, makes it likely that the patient will have some kind of heart rhythm disturbance, or dysrhythmia. This can cause a heart rate that is too fast, too slow, or too erratic to provide effective blood flow to the body.

Another condition that affects older people is orthostatic hypotension (postural hypotension), which is a drop in blood pressure with a change in position. In younger people, the body senses changes in blood pressure and quickly compensates. In older people, you may see a drop in the systolic blood pressure of 20 mm Hg when an older patient moves from a sitting position to a standing position. This happens because the patient has become less sensitive to rapid changes in blood pressure. The body, therefore, is less able to adapt to rapid postural changes.

Another vessel-related problem is called venous stasis. Stasis means motionless state and in this context refers to loss of proper function of the veins in the legs that would normally carry blood back to the heart. This condition creates problems such as blood clots in the superficial veins (superficial phlebitis) and blood clots in the deep veins, known as **deep venous thrombosis**. Deep vein thrombosis is a serious concern because it can lead to pulmonary embolism.

People with venous stasis usually exhibit edema, or swelling, of the legs and ankles. Patients will report a feeling of fullness, aching, or tiredness in their legs, especially when standing. This condition eventually causes a red-brown discoloration on the skin and, in some cases, skin ulcers.

Myocardial Infarction (Heart Attack)

Chest pain is a common complaint of older people and can often mean heart-related issues like myocardial infarction. It is important to remember that the classic symptoms of a heart attack are often not present in geriatric patients. As many as one-third of older patients have "silent" heart attacks in which the usual chest pain is not present. This is particularly common in women and people with diabetes. Do not assume that your patient is not having a myocardial infarction because he or she is not reporting the classic, pressure-type, substernal chest pain. Any of the following symptoms may be a manifestation of acute cardiac disease in the older patient and should be evaluated by advanced life support (ALS) personnel for an underlying cardiac disorder: dyspnea; epigastric and abdominal pain; loss of bladder and bowel control; nausea and vomiting; weakness, dizziness, light-headedness, and syncope; fatigue; and confusion.

Other signs and symptoms in older people that can indicate a cardiovascular problem include issues with circulation; diaphoresis (profound sweating); pale, cyanotic (blue), or mottled skin; abnormal or decreased breath sounds; and increased peripheral edema (swelling).

It is essential to obtain baseline vital signs because this information will provide you with a primary picture of the severity of your patient's condition, and you can use these findings to measure against in your ongoing assessment of the patient. Pulse rates can be too slow, too fast, weak, or irregular. A blood pressure reading can show hypertension or hypotension, either of which is significant in the presence of cardiac chest pain. The respiratory rate may be higher as the body attempts to take in and use more oxygen to aid an ailing heart.

At the EMT level, treatment of an older patient's cardiac problem mostly consists of airway, ventilatory, and circulatory support. Give oxygen with adjuncts appropriate to the patient's condition. Some EMS system protocols allow EMTs to administer aspirin or assist patients with the administration of medications, such as nitroglycerin. Continue to evaluate your patient treatment through reassessment. Cardiac problems can be expected to worsen suddenly, so be prepared.

Heart Failure

The signs and symptoms of heart failure will differ depending on the extent to which the right and/or left side of the heart is not functioning correctly.

Right-sided heart failure occurs when the fluid backs up into the body. You will see **jugular vein distention** (visual bulging of the jugular veins in the neck), **ascites** (fluid in the abdomen), and peripheral edema in the body tissues. An enlarged liver may also be present from blood backing up through the portal vein. This may be determined by palpation. Right-sided heart failure is often caused by left-sided heart failure, so it is common to see signs of both when assessing the patient who has left-sided heart failure.

With left-sided heart failure, fluid backs up into the lungs. The excess fluid in the lungs causes pulmonary edema, and the patient will have severe shortness of breath and hypoxia with crackles in the lungs.

Paroxysmal nocturnal dyspnea is a condition that is characterized by a sudden attack of respiratory distress that wakes the person at night when the patient is in a reclining position. The respiratory distress is caused by fluid accumulation in the lungs. Patients report coughing, feeling suffocated, and cold sweats, and you will notice tachycardia. The term for not being able to breathe while lying down is orthopnea. If you suspect that your patient may have congestive heart failure, one question you can ask is, "Do you sleep sitting up?"

Treatment should consist of airway, ventilatory, and circulatory support. Provide oxygen with adjuncts appropriate to the patient's condition, and prepare for the next level of deterioration.

Stroke

Stroke (cerebrovascular accident, or CVA) is a leading cause of death in older people. The likelihood of having a stroke becomes greater as a person gets older. Causes of strokes are both preventable and nonpreventable. Preventable risk factors include smoking, hypertension, diabetes, atrial fibrillation, obesity, and a sedentary lifestyle. Uncontrollable factors include age, race, and gender.

Signs and symptoms of stroke include acute altered level of consciousness (LOC); numbness, weakness, or paralysis on one side of the body; slurred speech; difficulty speaking (aphasia); visual disturbances; headache and dizziness; incontinence; and, in the worst cases, seizure. See Chapter 17, *Neurologic Emergencies*, for more information on stroke assessment.

Hemorrhagic strokes, in which a broken blood vessel causes bleeding into the brain, are less common and more likely to be fatal. Ischemic strokes occur when a blood clot blocks the flow of blood to a portion of the brain. Brain tissue distal to this clot is deprived of oxygen and will die if the clot is not broken down.

The treatment goal is to salvage as much of the surrounding brain tissue as possible. Many communities now have stroke centers that specialize in fast, effective treatment of stroke. Determining the onset of the symptoms of stroke is important. If the symptoms occurred within the past few hours, the patient will be a candidate for stroke center therapy and has a higher chance for recovery. Remember that transient ischemic attack (TIA) can have the same signs and symptoms as a stroke. Always manage the patient as if he or she is having a stroke unless medical control directs otherwise.

YOU are the Provider — PART 2

You arrive at the scene and are met at the door by the patient's daughter. She advises you that her mother has emphysema and that her respiratory distress has worsened during the past few days. You find the patient sitting in a chair in her living room; she has a blanket wrapped around her and is in mild respiratory distress. You introduce yourself to the patient and perform a primary assessment.

Recording Time: 0 Minutes	
Appearance	Obvious respiratory distress; chills
Level of consciousness	Conscious but confused
Airway	Open; clear of secretions and foreign bodies
Breathing	Increased rate; labored
Circulation	Radial pulse, irregular and weak; skin is pink, warm, and dry; no obvious bleeding

The patient is using home oxygen at 2 L/min via nasal cannula. She lives alone but her daughter visits daily. The patient's home appears to be well kept, and you can see numerous medication containers on a nearby table.

3. What is the GEMS diamond? How can it facilitate your overall care of an older patient?

Changes in the Nervous System

Anatomy and Physiology

Aging produces changes in the nervous system that are reflected in the neurologic examination. Changes in thinking speed, memory, and posture stability are the most common normal findings in older people. Studies have documented age-associated declines in mental function, especially slower central processing of sensory stimuli and language, and longer retrieval times for short- and long-term memory. Common findings during the physical examination include slow responses to questions and requests to repeat a question.

The brain decreases in terms of weight (10% to 20%) and volume as a person ages. This increases the amount of space in the cranium, thus increasing the chance for head injuries. Head injuries with a minimal mechanism are commonly missed in older people. In addition, there is a 5% to 50% loss of neurons in older people. Neurons are responsible for transmission of impulses, so the motor and sensory neural networks slow down with age. This affects the control of the rate and depth of breathing, heart rate, blood pressure, hunger, thirst, and body temperature. However, the functional significance of these changes is not clear. The human brain has an enormous reserve capacity, and having a smaller and lighter brain does not necessarily interfere with the mental capabilities of all older people, as evidenced by older people who remain active and productive.

Undeniably, though, the performance of most of the sense organs declines with increasing age. The senses of taste and smell diminish as a person ages. Visual changes may begin as early as age 40 years, such that as many as 50% of patients older than 65 years have vision problems. Causes of visual impairment in older people may include diabetic retinopathy and age-related macular degeneration.

Vision

Visual acuity, depth perception, and the ability of the eyes to accommodate to light change with age. The pupils require more time to adjust, which can make driving and even walking more hazardous **Figure 35-3**. **Cataracts**, clouding of the lenses or their surrounding membranes, interfere with vision and make it difficult to distinguish colors and see clearly, increasing the likelihood of falls, accidents, and mistakes in taking medications. Decreased tear production leads to drier eyes. An inability to differentiate colors and decreased night vision develop in older people, affecting their ability to drive. Vision changes, however, can occur earlier in life. Many people in their 40s lose the ability to see up close and may have to get eyeglasses for the first time. This condition is called presbyopia and is caused by a loss of elasticity of the crystalline lens.

Figure 35-3 Changes in vision, hearing, posture, and motor ability predispose older people to a greater risk of being struck by a vehicle or being involved in a motor vehicle crash.

A number of other disease processes plague the vision of older adults. These can include glaucoma, macular degeneration, and retinal detachment. Increased intraocular pressure is a risk factor for glaucoma, which can cause damage to the optic nerve. It sometimes causes headache with nausea and vomiting and visual disturbances. Macular degeneration is a deterioration of the macula, which is in the central portion of the retina; this condition generally affects adults older than 50 years. It causes a vision loss in the central part of the visual field. Retinal detachment is a medical emergency requiring prompt surgical treatment to preserve vision. In retinal detachment, the retina is pulled away from the choroid, a thin layer of blood vessels that supply nutrients and oxygen to the retina. This condition leaves the retinal cells deprived of oxygen; therefore, there is a potential for permanent vision loss. The patient may report floaters, debris in the visual field, sudden flashes of light or shadow, or visual blurring.

Hearing

Hearing is the sensory change that affects the most older people. Typical hearing problems cause changes in the inner ear and make hearing high-frequency sounds difficult. Changes in the ear can also cause problems with balance and make falls more likely. **Presbycusis** is age-related hearing loss. Over time, the wear and tear on the ears from noise damages the inner ear. Heredity and long-term exposure to loud noises are the main factors that contribute to hearing loss. When assessing your patient, check for the use of hearing aids. If the patient wears hearing aids, ensure that the aids are properly in place and turned on. Some patients may want you to talk into their “good ear.”

Taste

Even the sense of taste can be diminished for an older person because of a decrease in the number of taste buds. The negative result might be lessened interest in eating, which can lead to weight loss, malnutrition, and complaints of fatigue.

Touch

An older person may have a decreased sense of touch and pain perception from the loss of the end nerve fibers. This loss, in conjunction with the slowing of the peripheral nervous system, can create situations in which an older person may be injured and not know it. Specifically, there is a decreased sensation of hot and cold. An older person may be slow to react when touching something hot. This delayed response to pain could result in a burn. This is an especially acute problem in people with diabetes, who also lose sensation because of diabetic neuropathy or nerve damage.

Pathophysiology

Dementia

You may come across an older patient who is exhibiting delusions, hallucinations, or aggressive behavior. This patient may have dementia. **Dementia** is the slow onset of progressive disorientation, shortened attention span, and loss of cognitive function. It is a chronic, generally irreversible condition that causes a progressive loss of cognitive abilities, psychomotor skills, and social skills. Dementia develops slowly over a period of years rather than a few days. Dementia is the result of many neurologic diseases. Alzheimer disease, Parkinson disease, cerebrovascular accidents, and genetic factors may cause dementia.

To help you determine the patient's normal mental status, question family members or friends if present at the scene. You should evaluate the history, risk factors, and current medications.

On assessment, the patient might exhibit loss of cognitive function. It helps to determine if this was gradual or acute (began suddenly). Patients with dementia may have short- and long-term memory problems and a decreased attention span, or they may be unable to perform their daily routines. They also may show a decreased ability to communicate and appear confused. Again, determine why you were called, and establish a baseline of the person's cognitive abilities and functioning.

Other aspects of dementia can complicate your ability to assess and manage the patient. Sometimes patients are not only confused, but angry as well. They will generally be poor historians and have impaired judgment. Patients may be unable to vocalize areas of pain and current symptoms, or they may be unable to follow commands. Patients may exhibit disorganized thoughts: inattention, memory loss, disorientation, hallucinations, delusions, and a reduced level of consciousness.

Patients with dementia may express anxiety over movement out of their current residence. They may not understand why they need to go to the hospital and often express anxiety and fear of treatment. Their level of tolerance to changes in their routine may be very low. You have to exercise extreme tolerance and patience with patients who have altered mental status or are experiencing dementia.

Special Populations

Alzheimer disease is a common cause of dementia. Although its cause is unknown, the disease results in loss of brain tissue. Symptoms include memory loss, lack of spontaneity, subtle personality changes, disorientation, impaired thinking, restlessness, agitation, wandering, impaired judgment, and inappropriate social behavior. In late stages of the disease, the patient shows indifference to food, an inability to communicate, incontinence, and seizures. Patients with Alzheimer disease may live at home with a spouse or child who is also the caregiver or they may live in a specialized nursing facility. As with all patients, you must treat patients with Alzheimer disease with patience and respect.

Delirium

Delirium is a sudden change in mental status, consciousness, or cognitive processes, and is marked by the inability to focus, think logically, and maintain attention. According to *The Merck Manual Home Edition* delirium affects 15% to 50% of hospitalized people aged 70 years or older.

Acute anxiety may be present in addition to the other symptoms. Usually memory remains intact. Delirium is commonly marked by acute or recent onset and is a red flag for some type of new health problem. This condition is generally the result of a reversible physical ailment, such as tumors or fever. However, delirium can also be present from metabolic causes. Any time a patient has an acute onset of delirious behavior, consider the evaluation of pathophysiology through history, possible risk factors, and current medications.

Other important things to look for in the history are intoxication or withdrawal from alcohol; withdrawal from sedatives; medical conditions such as a **urinary tract infection (UTI)** (caused by bacteria), bowel obstruction, dehydration, fever, cardiovascular disease, and hyperglycemia or hypoglycemia; psychiatric disorders like depression; malnutrition or vitamin deficiencies; and environmental emergencies.

Assess the patient for the following specific conditions that can be managed at the prehospital level:

- Hypoxia
- Hypovolemia
- Hypoglycemia
- Hypothermia

Any of these four conditions, if unrecognized or untreated, can be rapidly fatal. With these conditions, delirium has a rapid onset and is usually curable if identified early. The onset may be described in terms of minutes, hours, or days. Critical BLS and ALS interventions may include supplemental oxygen, treatment of shock, glucose, and rewarming measures.

During the physical examination, you may see changes in circulation, breath sounds, motor function, and pupillary response. Hypotension can be an indication of hypovolemia. Dilated pupils could suggest hypoxia; wheezing, crackles, and rhonchi are the result of disease processes that impair breathing and oxygenation.

Treatment will depend on the results of your assessment but should include airway, ventilatory, and circulatory support and oxygen with airway adjuncts appropriate to the patient's condition if tolerated by the patient. ALS personnel will attempt venous access to introduce fluids that will help correct hypovolemia.

Syncope

You should always assume that syncope, or fainting, in an older patient is a life-threatening problem until proven otherwise. **Syncope** is often caused by an interruption of blood flow to the brain. Syncope has many causes—some are serious and others are not. Regardless, an older person who has a period of unconsciousness should be examined to determine the cause of the syncope. **Table 35-2** shows some of the causes of syncope in geriatric patients.

Table 35-2 Possible Causes of Syncope in Geriatric Patients

Cause	Description
Dysrhythmias and heart attack	The heart is beating too fast or too slowly, the cardiac output drops, and blood flow to the brain is interrupted. A heart attack can also cause syncope.
Vascular and volume changes	Medication interactions can cause venous pooling and vasodilation, the widening of a blood vessel that results in a drop in blood pressure and inadequate blood flow to the brain. Another cause of syncope can be a drop in blood volume because of hidden bleeding (such as an aneurysm).
Neurologic cause	Syncope can be a sign of transient ischemic attack or stroke.

Neuropathy

Your patient could be experiencing a neuropathy, a disorder of the nerves of the peripheral nervous system in which function and structure of the peripheral motor, sensory, and autonomic neurons are impaired. Symptoms depend on whether the nerves affected are motor, sensory, or autonomic and where the nerves are located.

- **Motor nerves:** muscle weakness, cramps, spasms, loss of balance, and loss of coordination
- **Sensory nerves:** tingling, numbness, itching, and pain; burning, freezing, or extreme sensitivity to touch

- **Autonomic nerves:** affect involuntary functions that could include changes in blood pressure and heart rate, constipation, bladder and sexual dysfunction

Neuropathies are treated with medication and other therapies not available in a prehospital setting. You should make your patient as comfortable as possible and transport.

Changes in the Gastrointestinal System

Anatomy and Physiology

Changes in the mouth include a reduction in the volume of saliva, with a resulting dryness of the mouth. Dental loss is not a normal result of the aging process, but rather the result of disease of the teeth and gums; nevertheless, dental loss is widespread in the geriatric population and contributes to nutritional and digestive problems. Both of these oral changes increase the risk of choking.

Like oral secretions, gastric secretions are reduced as a person ages—although enough acid is still present to produce ulcers under certain conditions. Changes in gastric motility also occur, which may lead to slower gastric emptying—a factor of some importance when assessing the risk of aspiration.

Function of the small and large bowel changes little as a consequence of aging, although the incidence of certain diseases involving the bowel (such as diverticulosis) increases as a person grows older. In addition, nutrients from food are not as readily absorbed.

Blood flow to the liver declines. There are changes in hepatic enzyme systems, with some systems declining in activity and others increasing. Notably, the activity of the enzyme systems involved with the detoxification of drugs declines as a person ages.

Pathophysiology

Gastrointestinal issues in older people are attributable to changes related to age or to the diseases that come with advanced age. Age-related changes in the gastrointestinal system include issues with dental problems; decrease in saliva and sense of taste leading to poor nutrition; and poor muscle tone of the smooth muscle sphincter between the esophagus and stomach that can cause regurgitation and lead to heartburn and acid reflux. Other changes include a decrease in hydrochloric acid in the stomach and alterations in absorption of nutrients and slowing peristalsis (motion that moves feces through the colon), which can cause constipation. The rectal sphincter may also become weak, resulting in fecal incontinence, or lack of bowel control.

Changes in the liver predispose older people to a number of problems. The liver, which is responsible for removing toxins and breaking down drugs in the body, shrinks with age. Blood flow to the liver declines, and there is decreased metabolism. This has a direct effect on how medications may affect the patient.

Serious gastrointestinal issues that affect older people are gastrointestinal bleeding caused by disease processes, inflammation, infection, and obstruction of the upper and lower intestinal tract. Gastrointestinal bleeding is usually heralded by hematemesis (the vomiting of blood) or coffee ground–like vomitus. Bleeding that travels through the lower digestive tract usually manifests as **melena** (black, tarry stools), whereas red blood usually means a local source of bleeding, such as hemorrhoids. A patient with gastrointestinal bleeding may experience weakness, dizziness, or syncope. Bleeding into the gastrointestinal system can be life threatening because of the potential for blood loss and shock.

Specific gastrointestinal problems that are more common in older patients include diverticulitis, bleeding in the upper and lower gastrointestinal system, peptic ulcer disease, gallbladder disease, and bowel obstruction. Diverticulosis is a condition in which the walls of the gut weaken and small pouches protrude from the colon along those weakened segments. When inflammation develops in one of these pouches, the condition is called diverticulitis. A geriatric patient with diverticulitis generally presents with left lower quadrant pain and fever. Fever suggests a condition that requires immediate attention.

Upper gastrointestinal bleeding occurs in the esophagus, stomach, or duodenum. These bleeding episodes are sometimes seen in people who are long-term users of nonsteroidal anti-inflammatory drugs (NSAIDs) like celecoxib (Celebrex), ibuprofen, and naproxen or people who are long-term alcohol users. Irritation of the lining of the stomach or ulcers can cause forceful vomiting that tears the esophagus. Hepatitis and cancer can also contribute to bleeding problems.

Lower gastrointestinal bleeding occurs in the colon or rectum. Lower gastrointestinal bleeding can be serious, especially in cases where the patient presents with tachycardia and hypotension.

Peptic ulcer disease is more common in older adults, especially people who use NSAIDs. The patient will report a gnawing, burning pain in the upper abdomen that improves after eating but returns later. Complications of peptic ulcer disease include bleeding, anemia, and bowel perforation, which are medical emergencies.

Gallbladder disease is more common in older adults and they have a higher risk of complications from gallstones. The risk of death from surgery to remove the gallbladder increases with age. Patients with inflammation of the gallbladder, cholecystitis, will have fever and right upper quadrant pain that may radiate to the shoulder. Patients may also have jaundice, which is a yellow appearance of the eyes and skin. This condition is dangerous because infection can spread to the blood, causing sepsis and shock.

Bowel obstructions occur frequently in the geriatric population. The ability of the gastrointestinal tract to move feces through the system slows with aging, and patients can experience problems having bowel movements. When patients strain to have a bowel movement, they can stimulate the vagus nerve, which can cause a vasovagal response; this is a condition in which the heart rate drops dramatically and the patient becomes dizzy or passes out. The patient will usually be in stable condition on your arrival but requires transport to rule out other conditions.

In general, patients with gastrointestinal issues are agitated and are unable to find a comfortable position. When assessing patients with gastrointestinal problems, ask about NSAID and alcohol use. Presentation can include pale or yellow, thin skin; frail musculoskeletal system; peripheral, sacral, and periorbital edema; hypertension; fever; tachycardia; and dyspnea.

If permitted by local protocol, orthostatic vital signs can help determine if a patient is hypovolemic. Blood pressure and pulse rates are taken with the patient lying, sitting, and then standing. Note any drop in blood pressure and increase in heart rate that occurs as the patient moves to an upright position. Do not attempt to assess orthostatic vitals on a patient with obvious signs of shock, hypotension, altered level of consciousness, or possible spinal injury.

Treatment consists of airway, ventilatory, and circulatory support. Oxygen should be delivered with adjuncts appropriate to the patient’s condition.

The Acute Abdomen—Nongastrointestinal Complaints

Because of an aging nervous system, abdominal complaints in geriatric patients are extremely difficult to assess. A number of life-threatening problems are common in older patients. In the prehospital setting, the most serious threat from abdominal complaints is blood loss, which can lead to shock and death. **Abdominal aortic aneurysm (AAA)** is one of the most rapidly fatal conditions. An AAA (triple A) tends to develop in people who have a history of hypertension and atherosclerosis. The walls of the aorta weaken, and blood begins to leak into the layers of the vessel, causing the aorta to bulge like a bubble on a tire. If enough blood loss occurs into the vessel wall itself, shock occurs. If the vessel wall bursts, it rapidly leads to fatal blood loss. When the problem is found early, there is a chance to repair the vessel before rupture, and fatal blood loss is less likely to occur.

A patient with an AAA most commonly reports abdominal pain radiating through to the back with occasional flank pain. If the AAA becomes large enough, it can be felt as a pulsating mass just above and slightly to the left of the navel during your physical examination. If you see or palpate a pulsating mass, do not continue manipulation or allow other providers to palpate the mass. Occasionally, the AAA causes a decrease in blood flow to one of the legs, and the patient reports some discomfort in the affected extremity. Assessment may also reveal diminished or absent pulses in the extremity. Compensated shock (early shock) and decompensated shock (late shock) as a result of blood loss are common occurrences. Because of a decrease in blood volume and decreased blood flow to the brain, the patient may experience syncope. You should treat the patient for shock, including high-flow oxygen and thermal regulation, and ensure prompt transport to the hospital.

Changes in the Renal System

Anatomy and Physiology

The genitourinary system includes the reproductive organs and the urinary system. The largest component of the urinary system is the kidneys, or renal organs. Age-related changes in the genitourinary system specific to the kidney include a reduction in renal function, a reduction in renal blood flow, and tubule degeneration. For the genitourinary system in general, there is decreased bladder capacity, decline in sphincter muscle control, decline in voiding senses, increase in nocturnal voiding, and, in men, benign prostatic hypertrophy (enlarged prostate).

Age brings changes in the kidneys as well. The kidneys are responsible for maintaining the body’s fluid and electrolyte balance and have important roles in maintaining the body’s long-term acid-base balance and eliminating drugs from the body. In a young adult, the kidneys weigh 8 to 9 oz (250 to 270 g); in a healthy 70 year old, they weigh 6 to 7 oz (180 to 200 g). This decline in weight results from a loss of functioning nephron units, or tubule degeneration, translating into a smaller effective filtering surface. At the same time, renal blood flow decreases by as much as 50% as a person ages.

Pathophysiology

Although the kidneys of an older person may be capable of dealing with day-to-day demands, they may not be able to meet unusual challenges, such as those imposed by illness. For that reason, acute illness in older patients is often accompanied by derangements in fluid and electrolyte balance. Aging kidneys, for example, respond sluggishly to sodium deficiency. An older patient may have a great deal of sodium loss before the kidneys halt urinary sodium excretion, a problem that is exacerbated by the markedly decreased thirst mechanism in older people. The net result may be a rapid development of severe dehydration.

Bowel and bladder continence require anatomically correct gastrointestinal and genitourinary tracts, functioning and intact sphincters, and properly working cognitive and physical functions. Urinary incontinence (involuntary loss of urine) can have significant social and emotional impact, but relatively few people admit to the problem and even fewer seek treatment. Incontinence is not a normal part of aging and can lead to skin irritation, skin breakdown, and urinary tract infections. As people age, the capacity of the bladder decreases. As a consequence, an older person may find it difficult to postpone voiding or may have involuntary bladder contractions. An increase in nocturnal voiding is common. Two major types of incontinence are distinguished: stress and urge. Stress incontinence occurs during activities such as coughing, laughing, sneezing, lifting, and exercise. Urge incontinence is triggered by hot or cold fluids, running water, and even thinking about going to the bathroom. Treatment of incontinence consists of medications, physical therapy, and possibly surgery.

The opposite of incontinence is urinary retention or difficulty urinating. Patients may have difficulty voiding or absence of voiding as a result of many medical causes. In men, enlargement of the prostate can place pressure on the urethra, making voiding difficult. Bladder and urinary tract infections can also cause inflammation. In severe cases of urinary retention, patients may experience renal failure.

Changes in the Endocrine System

Anatomy and Physiology

The endocrine system functions as the control center of the body. It uses hormones to control physiologic processes. A significant change that occurs in an older person is decreased metabolism of thyroxine. This is a thyroid hormone that affects the body's metabolism, temperature, growth, and heart rate. A reduction in thyroid hormones can cause a condition called hypothyroidism. Most of the signs and symptoms people experience are attributed to the process of aging and include slower heart rate, fatigue, drier skin and hair, cold intolerance, and weight gain.

Other endocrine system changes include an increase in the secretion of antidiuretic hormone, causing fluid imbalance; hyperglycemia; and an increase in the levels of norepinephrine, possibly having a harmful effect on the cardiovascular system.

Pathophysiology

Hyperosmolar hyperglycemic nonketotic syndrome (HHNS) is a diabetic complication in older people, and occurs more often in people with type 2 diabetes than in those with type 1 diabetes. Unlike diabetic ketoacidosis (DKA), the resulting high blood glucose level does not cause ketosis; instead, it leads to osmotic diuresis and a shift of fluid to the intravascular space that results in dehydration. The signs and symptoms of HHNS and DKA often overlap. Associated signs and symptoms include hyperglycemia, polydipsia (thirst), polyuria (urination), and polyphagia (hunger), as well as dizziness, confusion, altered mental status, and possibly seizures.

On assessment, you may see changes in circulation such as warm, flushed skin; poor skin turgor; pale, dry, oral mucosa; and a furrowed tongue. The patient may present with signs and symptoms of hypotension and shock, including tachycardia. The blood glucose level will be variable in DKA, whereas in HHNS, the value is typically 600 mg/dL or higher. Another assessment difference is that patients with DKA will present with Kussmaul respirations (deep and labored), and patients with HHNS will not.

Assessment of the patient should include obtaining blood pressure, distal pulses, auscultation of breath sounds, temperature, and assessment of blood glucose level if permitted by local protocol.

Treatment should include airway, ventilatory, and circulatory support. Provide oxygen with adjuncts appropriate to the patient's condition.

Changes in the Immune System

Infections are commonly seen in older people because they generally have an increased risk of infection and are less able to fight infections once they occur. With age, systemic and cellular immune responses become less effective at fighting infection. Fevers are unable to develop in many older patients, but these patients may in fact be hypothermic as a manifestation of severe systemic infection. Anorexia, fatigue, weight loss, falls, or changes in mental status be the primary symptoms of infection in these patients. Pneumonia and urinary tract infection are common in patients who are bedridden. When infection occurs, signs and symptoms may be decreased or minimized by the patient because of the loss of sensation, lack of awareness, or fear of being hospitalized.

Changes in the Musculoskeletal System

Anatomy and Physiology

Aging brings a widespread decrease in bone mass in men and women, but especially among postmenopausal women. Bones become more brittle and tend to break more easily. The disks between the vertebrae of the spine begin to narrow, and a decrease in height between 2 and 3 inches may occur through the lifespan, along with changes in posture. Joints lose their flexibility and may be further immobilized by arthritic changes. In fact, more than half of all older people have some form of arthritis. A decrease in the amount of muscle mass often results in less strength.

Pathophysiology

Changes in physical abilities can affect older adults' confidence in their mobility. The muscle system atrophies and weakens with age. Muscle fibers become smaller and fewer, motor neurons decline in number, and strength declines. The ligaments and cartilage of the joints lose their elasticity. Cartilage also goes through degenerative changes with aging, contributing to arthritis.

The stooped posture of older people comes from atrophy of the supporting structures of the body. Two of every three older patients will show some degree of **kyphosis** (a forward curling of the spine, also called humpback or hunchback). A loss of height in older adults generally results from compression in the spinal column, first in the disks and then from the process of osteoporosis in the vertebral bodies.

Osteoporosis, a condition that affects men and women, is characterized by a decrease in bone mass leading to reduction in bone strength and greater susceptibility to fracture. The extent of bone loss that a person undergoes is influenced by numerous factors, including genetics, smoking, level of activity, diet, alcohol consumption, hormonal factors, and body weight. The most rapid loss of bone occurs in women during the years following menopause, and many postmenopausal women use hormone replacement therapy as a means to reduce the loss of bone. Calcium and vitamin D supplementation is another treatment of the condition, and many other medications are available to improve bone strength. Older people should remain active and engage in a low-impact exercise program to maintain bone and muscle strength.

YOU are the Provider — PART 3

Further assessment of the patient reveals that she has a fever and has not been eating lately. She has a weak cough, which is producing thick green sputum. Auscultation of her breath sounds reveals coarse rhonchi in all fields. Your partner takes her vital signs as you ask additional questions regarding her past medical history.

Recording Time: 5 Minutes	
Respirations	22 breaths/min; labored
Pulse	68 beats/min; weak and irregular
Skin	Hot to the touch; pink and dry
Blood pressure	158/88 mm Hg
Oxygen saturation (Spo_2)	92% on 2 L/min oxygen via nasal cannula

The patient's daughter advises you that in addition to emphysema, her mother has hypertension, atrial fibrillation, rheumatoid arthritis, and Alzheimer disease. You inquire about her confusion, and her daughter tells you that it has worsened in the last couple of days. She hands you a long list of medications and states that she personally gives her mother her medications every day.

4. Based on the patient's current condition, how appropriate is the current oxygen therapy?
5. What should concern you about patients who take numerous medications?
6. What other assessments, if any, should be performed for this patient?

Osteoarthritis is a progressive disease of the joints that destroys cartilage, promotes the formation of bone spurs in joints, and leads to joint stiffness. This type of arthritis is thought to result from "wear and tear" and, in some cases, from repetitive trauma to the joints. It affects 35% to 45% of the population older than 65 years. Typically, osteoarthritis affects several joints of the body, most commonly those in the hands, knees, hips, and spine. Patients report pain and stiffness that gets worse with exertion. The end result is often substantial disability and disfigurement. Patients are typically treated with anti-inflammatory medications and physical therapy to improve the range of motion.

Changes in Skin

The proteins that make the skin pliable decline with age. The layer of fat under the skin also becomes thinner because of the redistribution of fluids and proteins. As the elasticity of the skin declines, bruising becomes more common because the skin can tear more easily. Exocrine (sweat) glands do not respond as readily to heat because of atrophy and because of changes to the tissues of the dermal layer of the skin.

Another problem that affects the skin is pressure ulcers, sometimes referred to as bedsores or **decubitis ulcers**. Pressure ulcers form when a patient is lying or sitting in the same position for a long time. The pressure from the weight of the body cuts off the blood flow to the area of skin. With no blood flow to the skin, a sore develops. These sores can develop in as little as 45 minutes. To help prevent these ulcers, take special care to pad under any bony prominences and in the voids in a patient who may be immobilized for an extended period.

You may see these ulcers in the following various stages of development:

- **Stage I:** Nonblanching redness with damage under the skin
- **Stage II:** Blister or ulcer that can affect the dermis and epidermis
- **Stage III:** Invasion of the fat layer through to the fascia
- **Stage IV:** Invasion to muscle or bone

Decubitis ulcers can be painful and cause complications like bleeding, sepsis, and bone inflammation called osteomyelitis.

Toxicology

There are several pathophysiologic changes that cause older people to be susceptible to toxicity. These include decreased kidney function, altered gastrointestinal absorption, and decreased vascular flow in the liver that alters metabolism and excretion. The kidneys undergo many changes with age. The rate of filtration decreases an average of 50% between the ages of 50 and 90 years. Decreased liver function makes it harder for the liver to detoxify the blood and eliminate substances such as medications and alcohol. These metabolic issues can also make it difficult for physicians to find the appropriate dosage for new medications.

The use of medications by older people accounts for one-quarter of the prescribed medications and one-third of the over-the-counter (OTC) medications sold in the United States. Typical OTC medicines used by older people include aspirin, antacids, cough syrups, and decongestants **Figure 35-4**. Many people believe OTC medications cannot be dangerous, but these medications can have negative effects when mixed with each other and/or with herbal substances, alcohol, and prescription medications.

Polypharmacy refers to the use of multiple prescription medications by one patient. Many patients have more than one physician: a family physician for everyday care, a cardiologist for the heart, and an endocrinologist for the care of diabetes. All of them may prescribe medication. But what if patients do not tell each physician about all of the other medications that he or she takes? Patients may not remember what medications another doctor prescribed or may not want to tell one doctor about seeing another. This problem can be less of an issue if the patient receives all of his or her care within an integrated health system that maintains an electronic medical record that includes information from multiple physicians and health care providers, but this is not always the case. Also, many drugstore chains have a computerized database that can recognize multiple prescriptions, but this setup is helpful only if the patient deals exclusively with that one drugstore chain.

Negative effects can include overdosing and negative medication interaction. Adverse reactions occur when medications taken together change the absorption, distribution, or excretion of medications in the body or the effects of the medications on the body.

Figure 35-4 **A.** Over-the-counter medications such as aspirin, antacids, cough syrups, and decongestants can interact negatively with prescription medications. **B.** Grapefruit juice cannot be taken with several medications because it can interfere with the actions of those medications. **C.** Over-the-counter medicines such as diphenhydramine (Benadryl), nonsteroidal anti-inflammatory drugs, iron preparations, and mineral oil (used for constipation) were once thought to be harmless, but are now known to be potentially harmful in older adults.

Another complication associated with polypharmacy is the fact that a patient may have multiple prescriptions of different amounts that need to be taken at different times of the day. Patients can easily forget what they have taken and overdose or forget to take them altogether and underdose. Both scenarios can lead to serious problems.

Medication noncompliance in older patients is also an issue and may occur because of financial challenges; inability to open containers; or impaired cognitive, vision, and hearing ability. If you suspect medication noncompliance, you should check prescription dates and the number of pills available.

The geriatric population is more likely to have cases of polypharmacy because older people are affected most by the process of aging. Physiologic factors known to be true about the hepatic and renal functions of excretion and metabolism of medications can change in the face of multiple prescriptions being consumed at once. Always be mindful of this issue when obtaining the patient's medication history.

Behavioral Emergencies

For most older people, the later years are ones of fulfillment and satisfaction with a lifetime of accomplishments. For some older adults, however, later life is characterized by physical pain, emotional distress, doubts about the significance of life's accomplishments, financial concerns, loss of loved ones, dissatisfaction with living conditions, and seemingly unbearable disability. When these factors lead to hopelessness about the possibility for positive change in their lives, depression and, unfortunately, even suicide are possible outcomes. You are often the first health care professional to have contact with older adults who are depressed and, for some older patients, the only health care contact.

Depression

Depression is not part of normal aging, but rather a medical disease. This common, often debilitating psychiatric disorder affects millions of older Americans. Older adults residing in skilled nursing facilities are even more likely to be depressed. Depression is diagnosed three times more commonly in women than in men. In contrast with the normal emotional experiences of sadness, grief, loss, and temporary bad moods, depression is extreme and persistent and can interfere significantly with an older adult's ability to function.

The good news is that depression is treatable with medication and therapy. The bad news is that if depression goes unrecognized or untreated, it is associated with a higher suicide rate in the geriatric population than in any other age group. Depression in older patients can mimic the effects of many other medical problems (such as dementia). Risk factors for depression in older people include a history of depression, chronic disease, and loss (function, independence, or significant others).

It is impossible to predict which older adults will have depression, but studies indicate that substance abuse, isolation, prescription medication use, and chronic medical conditions all contribute to the onset of significant depression. Treatment of severe depression in older adults usually consists of behavioral counseling, medication, or a combination of both. For many older adults, simply reestablishing relationships with the community or with family is enough to lessen the severity of the illness.

Suicide

Depression may be difficult to recognize in older people because many do not want to complain about feeling sad, worthless, or unwanted. Disturbingly, most suicides involving older people occur in people who have recently been diagnosed with depression. In addition, most suicide victims have seen their primary care physician within the month before the event.

Older men have the highest suicide rate of any age group in the United States. Caucasian men over age 65 are eight times more likely to kill themselves than women of the same age. The suicide rate among older Caucasian men is almost twice the rate of all other male groups. At highest risk are white men 85 years and older, who use firearms as their suicide method of choice. Older people who attempt suicide choose much more lethal means than younger victims and generally have diminished recuperative capacity to survive an attempt. Unlike younger people, geriatric patients typically do not make suicidal gestures or attempt to get help. Instead, the rate of completed suicide is disproportionately high in the geriatric population. Many geriatric patients see no other way out when they have a terminal illness or debilitating cardiac or neurologic condition (such as severe heart disease or stroke).

Suicide can happen in any family, regardless of socioeconomic class, culture, race, or religious affiliation. Some common predisposing events and conditions include death of a loved one, physical illness, depression and hopelessness, alcohol abuse, alcohol dependence, and loss of meaningful life roles. Keep in mind that only a small percentage of older people pursue medical treatment for behavioral issues. Not only do many older adults fail to seek care, but they also frequently deny the problem when asked about it. When assessing the patient who is displaying signs of depression, it is appropriate to ask if he or she is considering suicide. If the answer is "yes," the next question should be, "Do you have a plan?" Include this information in your documentation and in your report as you transfer care at the hospital. It is vital that all members of the health care team be aware of these issues and take appropriate steps to ensure their own safety, as well as patient safety.

The GEMS Diamond

When you are called on to care for older patients, it is important to remember certain key concepts. The GEMS diamond Table 35-3 was created to help you remember what is different about older patients. The GEMS diamond is not intended to be a format for your approach to geriatric patients, nor is it intended to replace the ABCs of care. Instead, it serves as an acronym for the issues to be considered when assessing every older patient.

The "G" of the GEMS diamond stands for "geriatric patients." When responding to an emergency involving an older patient, you should consider that older patients are different from younger patients and may present atypically. Be familiar with the normal changes of aging and treat older patients with compassion and respect.

The "E" of the GEMS diamond stands for an environmental assessment. Assessment of the environment can help give clues to the patient's condition and the cause of the emergency. Is the home too hot or too cold? Is the home well kept and secure? Are there hazardous conditions? Preventive care is also very important for a geriatric patient, who may not carefully study the environment or may not realize where risks exist.

The "M" of the GEMS diamond stands for medical assessment. As stated, older patients tend to have a variety of medical problems and may be taking numerous prescription, OTC, and herbal medications. Obtaining a thorough medical history is very important in older patients.

The "S" stands for social assessment. Older people may have a smaller social network because of the death of a spouse, family members, and friends. Older people may also need assistance with activities of daily living (ADLs), such as dressing and eating. There are numerous social agencies that are readily available to help geriatric patients. Consider obtaining information pamphlets about some of the agencies for older people in your area. If you have these brochures with you and encounter a person in need, you can provide this valuable information. Social agencies that deal with the older population will be more than happy to share a listing of the services they provide.

Table 35-3 The GEMS Diamond

G Geriatric Patients

- Present atypically
- Deserve respect
- Experience normal changes with age

E Environmental Assessment

- What is the physical condition of the home? Is the interior or exterior of the home in need of repair? Is the home secure?
- Are hazardous conditions present (eg, poor wiring, rotten floors, unventilated gas heaters, broken window glass, clutter that prevents adequate egress)?
- Are smoke detectors present and functional?
- Is the home too hot or too cold?
- Is there a fecal or urine odor in the home?
- Are pets well cared for?
- Is food present in the home? Is it adequate and unspoiled?
- Are liquor bottles present (lying empty)?
- Is bedding soiled or urine-soaked?
- Are there burn patterns on the walls, cabinets, or floors?
- If the patient has a disability, are appropriate assistive devices (such as a wheelchair or walker) present and in adequate condition?
- Does the patient have access to a telephone?
- Are medications prescribed to someone else, expired, unmarked, or from many physicians?
- If the patient is living with others, is he or she confined to one part of the home?
- If the patient is residing in a nursing facility, does the care appear to be adequate to meet the patient's needs?

M Medical Assessment

- Older patients tend to have a variety of medical problems, making assessment more complex. Keep this in mind in all cases—that is, both trauma and medical. A trauma patient may have an underlying medical condition related to the traumatic event.
- Obtaining a medical history is very important in older patients—no matter what the primary complaint is.
- Primary assessment
- Reassessment

S Social Assessment

- Assess the activities of daily living (ADLs):
  - Eating
  - Dressing
  - Bathing
  - Toileting
- Are these activities being provided for the patient? If so, by whom?
- Are there delays in obtaining food, medication, or toileting? The patient may report this, or the environment may be suggestive of this.
- Does the patient have regular visits from family members, live with family members, or live with a spouse?
- If in an institutional setting, is the patient able to feed himself or herself? If not, is food still sitting on the food tray? Has the patient been lying in his or her own urine or feces for prolonged periods of time?
- Does the patient have a social network? Does the patient have ways to interact socially with others on a daily basis?

The GEMS diamond provides an organized way to remember the important issues for older patients. Using this concept will help you make appropriate referrals, and, as a result, you will help older patients maintain their quality of life.

Special Considerations in Assessing a Geriatric Medical Patient

Assessing an older person can be challenging because of communication issues, hearing and vision deficits, alteration in consciousness, complicated medical histories, and the effects of medications. Previous injury or illnesses that are not associated with the current problem may also alter the assessment findings. These may include medications that mask changes in vital signs that you might expect, such as tachycardia in shock. A previous stroke may have changed a patient's baseline level of consciousness and neurologic status.

Words of Wisdom

Medical and trauma conditions are often superimposed on each other. A simple fall may have been preceded by weakness and dizziness, suggesting a serious medical condition. What looks like an obvious trauma call could easily have been caused by a serious medical emergency.

Scene Size-up

Every emergency call begins with a thorough scene size-up. Is the scene safe? How many patients do you have? What is the nature of illness (NOI)? Have you taken proper standard precautions?

Geriatric patients are commonly found in their own homes, retirement homes, or skilled nursing facilities, but calls for assistance can come from any location. Many older people live alone. Access to them may be hampered if their condition prevents them from getting to the door to let you in. Police or fire department assistance may be required.

Many older people try to maintain their independence as long as they can. They may or may not have someone who checks on their welfare. You will find some people living in conditions that are not safe or appropriate. You need to take note of negative or unsafe environmental conditions. Is the home well maintained and sanitary? Are the utilities working? Look for clues that might explain the patient's medical history or current problem: Is it too hot or too cold? A geriatric patient can have hypothermia or heat stroke in temperatures that are not considered extreme. Is there food available? Is there evidence of abuse or alcohol or illegal drug use? Are there medications on the nightstand in the bedroom?

In a nursing home or residential care facility, you will need to locate the patient's room and find a staff member who can explain why you were called. In any case in which the patient's mental status is altered, you need to find someone who can tell you the patient's history and whether the patient's behavior or level of consciousness is normal or altered. The presence of a hospital bed, oxygen tanks, or therapeutic devices can give you a clue to the patient's medical history. The environment may give you the answer to questions when the patient cannot.

The NOI may be difficult to determine in older people who may have an altered mental status or dementia. Often it is someone other than the patient who called, so you must ask the family member, caregiver, or bystander why he or she called. Multiple and chronic disease processes may also complicate the determination of the NOI. Complaints from an older person may be vague, such as weakness, dizziness, or fatigue. These could be indicators of a more serious problem and require more assessment. You may need to ask specifically what is different *today* or specifically why the person called to determine acute versus chronic complaints. Chest pain, shortness of breath, and an altered level of consciousness should always be considered serious. You also may find that the patient's complaint is a symptom of something more serious. For example, sudden changes in the ability to talk could indicate a stroke, or the need to sleep on five pillows could suggest early congestive heart failure.

Primary Assessment

Once you have confirmed that the scene is safe, perform the primary assessment to address life threats such as problems with airway, breathing, and circulation. Determine the priority of your patient based on his or her condition. The priority of your patient may limit on-scene time and/or treatment. Maintain a high index of suspicion for serious injuries even with mechanisms of injury that might seem minor in younger patients.

The general impression is an important aspect of all patient assessment. As you approach the patient, you should be able to tell if the patient is generally in a stable or unstable condition. You will use this information to help you with your further assessment. Use the AVPU scale to determine the patient's level of consciousness.

Remember that anatomic changes that occur as a person ages predispose geriatric patients to airway problems. Aging and disease can compromise a patient's ability to protect his or her airway with loss of a gag reflex and normal swallowing mechanisms. Changes in level of consciousness, dementia, and poststroke weakness or paralysis can cause airway obstruction or aspiration. Ensure that the patient's airway is open and is not obstructed by dentures, vomitus, fluids, or blood. Suction may be necessary.

Anatomic changes with aging also affect a person's ability to breathe effectively. Increased chest wall stiffness, brittle bones, weakening of the airway musculature, and decreased muscle mass contribute to breathing problems. Loss of mechanisms that protect the upper airway, like cough and gag reflexes, cause a decreased ability to clear secretions. A decrease in the number of cilia that line the bronchial tree results in the inability of the patient to remove material from the lung, which can cause infection. In some patients, the alveoli are damaged, and a lack of elasticity results in a decreased ability to exchange oxygen and carbon dioxide. Superimposed on the physiologic changes are the chronic respiratory diseases common in older people that affect the ability of the patient to breathe effectively. Airway and breathing issues should be treated rapidly and monitored constantly.

Poor perfusion is a serious issue in an older adult. People who normally live with compromised circulation have little in the way of reserves during a circulatory crisis. Physiologic changes may negatively affect circulation. Less responsive nerve stimulation may lower the rate and strength of the heart's contractions, so lower heart rates and weaker and irregular pulses are common in older patients. Vascular changes and circulatory compromise might make it difficult to feel a radial pulse on an older patient. If choosing an alternative pulse point like the carotid, press gently. Another option is to listen to the apical pulse right over the heart. The pulse may be irregular because of common heart rhythm problems. It is important to determine if cardiac abnormalities in an older patient indicate an acute emergency or a chronic condition. Acute emergencies should be managed rapidly.

Patient assessment is more complicated in an older adult, and multiple problems can exist. Any complaints that compromise airway, breathing, or circulation should result in transportation of the patient as a priority patient. Priority patients include patients who have a poor general impression, airway or breathing problems, acute altered level of consciousness, shock, any severe pain, or uncontrolled bleeding. Your most important task is to determine conditions that are life threatening, treat them to the best of your ability, and provide transport. Older people do not have the reserves that younger people do, and they will easily decompensate. Even a general complaint of weakness and dizziness can be an indication of something more serious like a heart problem or pneumonia. Consider early on if ALS treatment and immediate transport is appropriate and available. If possible, try to take the patient to a facility where the patient has been treated before and his or her medical records reside.

Words of Wisdom

Dentures should not be removed unless they obstruct the airway or interfere with ventilation when rescue breathing is needed.

Words of Wisdom

Because of fear related to hospitalization, many older people will delay calling 9-1-1 until their problem is life threatening. Be prepared for a worst-case scenario.

History Taking

Begin by inquiring about the chief complaint or history of the present illness. Find and account for all medications. If a patient lives alone, look for a list of medications on the refrigerator or a notice by the front door. The Vial of Life Project is one program that recommends creating a medication history for caregivers or EMS personnel. There also may be similar local programs in your area.

Communication may be more complicated with an older adult, but it is critical that you obtain a thorough patient history. It is best to obtain what information you can directly from the patient, but family or caregivers may need to assist.

The determination should be made early on as to whether an altered level of consciousness is acute or chronic. Remember that chronic mental status impairment is not a normal process of aging but is caused by a pathologic or disease process. You should never accept confusion as normal. It is important for you to determine your patient's baseline mental status; question family members, if available.

Multiple disease processes and multiple and/or vague complaints can make assessment complicated, and older people may not show severe symptoms even if they are very ill. Ask questions to assess the nature of the problem, and determine whether it may or may not be life threatening. Take a full set of vital signs, and ask what is "normal" for that patient. You may be able to determine the exact nature of the problem and will need to use your general impression to guide you.

Getting an accurate SAMPLE history can also be complicated. The chances are good that the chief complaint is related to a chronic medical problem and the patient may have experienced it before. Symptoms should be determined to be acute or chronic. Also note the signs you observe and your general impression. Allergies to food and medications are important. Is the patient taking any new medications? Make sure you have a list of the patient's medications or take the medications with you to the hospital if possible. Patient medications can tell much about a patient's history. The hospital will also need to determine if the patient has been taking the medications as instructed. If time and opportunity allow, check the patient's pill sorter. Has the patient taken every dose this week? Has the patient taken the medications that are scheduled for tomorrow or the next day?

The last meal is particularly important in a patient with diabetes. A history of last oral intake can indicate that the patient may be dehydrated. Last, what is the event that prompted the call? Again, it is advantageous to provide transport to a facility that "knows" the patient's medical history if the patient's condition and other factors allow.

Secondary Assessment

The secondary assessment may be performed on scene, en route to the emergency department (ED), or in some cases, not at all. The priority of the patient will determine this for you.

Perform a physical examination when appropriate. You may find that your older patient is not comfortable with being exposed. Protect his or her modesty. Older people are often cold, and you may have to remove several layers of clothing. Consider the need to keep your patient warm during the exam.

Vital signs may be different in older people because of the physiologic changes that come with aging, chronic disease, and the effects of medications. The heart rate should be in the normal adult range but may be compromised by medications such as beta-blockers. These medications keep the heart rate low and prevent the tachycardia that might be typically seen in dehydration or shock. Weak and irregular pulses are common in older patients. The pulse may be irregular secondary to atrial fibrillation. Circulatory compromise may make it difficult to feel a radial pulse on an older patient, and other pulse points may need to be considered.

Blood pressure tends to be higher in older people. A geriatric patient who has a blood pressure in a normal adult range could be hypotensive. Hypertension could signal impending stroke. Try to confirm if the patient has missed taking any medications for hypertension.

Capillary refill is not a good assessment tool in older adults because of skin changes and reduced circulation to the skin.

The respiratory rate should be in the same range as in a younger adult, but remember that chest rise will be compromised by increased chest wall stiffness. Be sure to auscultate breath sounds to listen for crackles associated with pulmonary edema, rhonchi associated with pneumonia, and wheezes associated with asthma.

Careful interpretation of pulse oximetry data is necessary in older adults because the pulse oximetry device requires adequate perfusion to get an accurate reading. Older adults may have poor circulation, vasoconstriction, hypotension, hypothermia, lack of red blood cells, or carbon monoxide poisoning that could result in an inaccurate reading. Adhesive probes, if available and in local protocol, might help confirm accuracy of the data.

Try to determine what the patient's normal blood pressure is. Your baseline blood pressure on this patient and any change from the patient's normal baseline can alert you to a potential problem.

Reassessment

Reassess the geriatric patient often because the condition of an older adult may deteriorate quickly. Repeat the primary assessment. Reassess the vital signs and the patient's complaint. Recheck interventions. Identify and treat changes in the patient's condition.

An older patient with a complaint of shortness of breath will want to sit up or assume the tripod position. Accommodate positioning requests when possible. The patient's position may be maintaining a patent airway. Forcing a patient who is short of breath into a supine position may result in respiratory distress or failure. Allow the patient to maintain a position of comfort unless contraindicated. Assist ventilation as needed.

Other interventions include administration of glucose in a patient with diabetes who has altered mental status and a manageable airway. In specific cases, you may also assist with nitroglycerin, aspirin, or inhalers. Pharmacologic interventions require medical direction and are based on local protocol (see Chapter 11, *Principles of Pharmacology*).

Administration of oxygen may be a useful therapy for many geriatric problems, including vague complaints of weakness or dizziness if the Spo_2 level indicates hypoxia. When administering oxygen, be mindful of monitoring the level of consciousness in a patient with chronic obstructive pulmonary disease and the risks of providing a prolonged high concentration of oxygen. Be prepared to ventilate if breathing becomes inadequate.

Words of Wisdom

In general, allow the patient to maintain a position of comfort unless contraindicated. If immobilization on a backboard is necessary, remember to pad the void spaces. You may have to weigh the risk of supine immobilization versus respiratory distress or failure. Be sure to document the reasons for your decision.

Last, and critically important in older adults, is providing emotional support. An older person is often fearful of what may be happening and that he or she may never return home from the hospital. Listen to your patient, respond to your patient, and provide reassurance. This is an important component of patient advocacy.

Communicate your findings and the interventions you used to ED personnel. Remember to document all history, medication, assessment, and intervention information.

A summary of the special considerations to keep in mind when assessing a geriatric patient can be found in Table 35-4.

YOU are the Provider — PART 4

You advise the patient that she should be transported to the hospital for evaluation; however, she is reluctant to go. Her daughter reassures her that everything will be okay and that she will meet her at the hospital. After several minutes of deliberation, the patient consents to transport. Your partner increases the oxygen flow rate to 15 L/min by nonrebreathing mask as you reassess the patient's vital signs.

Recording Time: 15 Minutes	
Level of consciousness	Conscious but confused
Respirations	22 breaths/min; labored
Pulse	84 beats/min; weak and irregular
Skin	Hot to the touch; pink and dry
Blood pressure	152/90 mm Hg
Spo_2	94% on 15 L/min via nonrebreathing mask

The patient's blood glucose level is assessed and is noted to read 98 mg/dL. You place her onto the stretcher, place her in a position of comfort, load her into the ambulance, and begin transport to the hospital. Her daughter tells you that she will follow you to the hospital in her own vehicle.

7. Why do older patients commonly refuse EMS transport?

8. On the basis of the patient's past medical history and signs and symptoms, what do you suspect as the cause of her problem?

Table 35-4 Geriatric Patient Assessment Guidelines

- When entering the home, take note of issues that would make it environmentally unsafe.
- Introduce yourself, show respect, and use patience to gain an older patient's confidence.
- Assessment of an older patient can be complicated by multiple medical or traumatic conditions, alterations in level of consciousness, and hearing and vision impairments.
- Airway, breathing, circulation, and vital signs are changed by the normal process of aging.
- Many older patients use multiple medications. Be aware of the possibility of overdose, underdose, and drug interactions.
- An older person's body does not have the flexibility or reserves of a younger person's body when facing illness or injury.
- Older people are more easily affected by poor nutrition.
- Older people cannot thermoregulate easily and tend to be cold.
- The memory and cognition of an older person may be impaired.
- The skin of an older adult may be fragile and can tear easily. Consider patient transfer options that are safe and appropriate.

Trauma and Geriatric Patients

In general, the risk of serious injury or death is more common in older patients who experience trauma than in younger patients. Slower homeostatic compensatory mechanisms, limited physiologic reserves, normal effects of aging on the body, and existing medical issues create risk and complicate the assessment of geriatric patients. Physical findings in an older adult may be more subtle and more easily missed. The mechanisms that cause serious injury in older people are usually much more minimal than in younger people. There is also the consideration that recuperation from trauma is longer and often less successful in older people. For that reason, many injuries in older people are undertriaged and undertreated.

Older pedestrians are more likely to have life-threatening complications after being struck by a vehicle because of changes in the body, such as more fragile bones. Although older pedestrians commonly suffer injury to the legs and arms, other injuries can be caused by a secondary crash onto the street, often involving the head. Any of these mechanisms can cause fractures, traumatic brain injury, spinal injury, and paralysis.

Older people are more likely to experience burns because of altered mental status, inattention, and a compromised neurologic status. Their risk of mortality from burns is increased when preexisting medical conditions exist, the immune system is weakened, and fluid replacement is complicated by renal compromise.

There is higher mortality from penetrating trauma in older adults, especially in the case of gunshot wounds. Penetrating trauma can easily cause serious internal bleeding. An older patient's limited physiologic reserves and more subtle presentation can affect proper management and transportation options.

Finally, falls are the leading cause of fatal and nonfatal injuries in older adults. Nearly half of fatal falls in geriatric patients result in traumatic brain injury. Unfortunately, physical abuse is another common cause of trauma in older adults. Elder abuse will be discussed later in the chapter.

Anatomic Changes and Fractures

Changes in pulmonary, cardiovascular, neurologic, and musculoskeletal systems make older patients more susceptible to trauma. The brain shrinks, leading to higher risk of cerebral bleeding following head trauma. Skeletal changes cause curvature of the upper spine that often requires additional padding during spinal immobilization. Loss of strength, sensory impairment, and medical illness all increase the risk of falls.

A geriatric patient's overall physical condition may lessen the ability of the patient's body to compensate for the effects of even simple injuries. For example, the aging body has a heart that no longer can beat faster when it needs to compensate for blood loss, vessels that cannot constrict due to atherosclerosis, and lungs that do not exchange oxygen as well. Additional changes in the circulatory system leave the geriatric patient's body unable to maintain normal vital signs during hemorrhage. Also, a geriatric patient's blood pressure drops sooner than in a younger adult patient during a traumatic emergency.

Words of Wisdom

The inability of the blood to clot normally can become a big issue in trauma and will be seen in patients who take warfarin (Coumadin), heparin, or other blood-thinning medications.

As a result of bone loss from osteoporosis, older patients are prone to fractures, especially of the hip. Hip fractures are much more common among women. People with osteoporosis may fracture a hip from a standing fall. This is considered a pathologic fracture because it would not occur in a person with normal bone density. However, not all hip fractures are the result of trauma, and may in fact result from the stresses of ordinary activity such as getting in and out of a chair. Other contributing factors include vitamin D and calcium deficiencies, metabolic bone diseases, and tumors. Injuries to the hip also tend to be recurring. A previous fracture increases the likelihood of a future injury.

Older people with osteoporosis are also at risk for pelvic fractures **Figure 35-5**. A pelvic fracture may also be caused by a low-energy mechanism or a standing fall. The person may sustain this injury when getting out of the bathtub or descending stairs. These injuries do not usually damage the structural integrity of the pelvic ring but may fracture an individual bone.

Recovering from these kinds of injuries can be complicated for an older person, especially one with a compromised immune system or diabetes. The fact that the person will be bedridden for a considerable amount of time may inhibit his or her ability to continue to live independently.

With age, the spine stiffens as a result of shrinkage of disk spaces, and vertebrae become brittle. Compression fractures of the spine are more likely to occur. As with a head injury, you must be suspicious of the possibility of other fractures and complicating issues.

Because brain tissue shrinks with age, older patients are more likely to sustain closed head injuries, such as subdural hematomas. This is where tiny veins between the surface of the brain and its outer covering (the dura) stretch and tear, allowing blood to collect. In older people, the veins are often already stretched because of brain atrophy (shrinkage) and are more easily injured.

Figure 35-5 Vacuum mattresses that conform to body contours can be a good choice for immobilizing geriatric patients with possible pelvic fractures.

Acute subdural hematomas are among the deadliest of all head injuries. Blood fills the skull very rapidly, compressing brain tissue, which often results in brain injury. This type of bleeding can go unnoticed initially because the blood has a void to fill before it can produce pressure in the skull; only then will the familiar signs of head trauma appear. Also, serious head injuries are often missed in older patients because the mechanism may seem relatively minor. These chronic subdural hematomas may go unnoticed for many days to weeks.

Other factors that predispose an older patient to a serious head injury include long-term abuse of alcohol, recurrent falls or repeated head injury, and/ or anticoagulant medication (blood thinners, including aspirin).

Environmental Injury

Internal temperature regulation slows with age owing to a slowed endocrine system. Heat gain or loss in response to environmental changes is delayed by slowed circulation and decreased sweat production in the skin. In addition, thermoregulation can be adversely affected by chronic disease, medication use, and alcohol use, all of which are more common in older people.

Not surprisingly, about half of all deaths from hypothermia occur in older people, and most indoor hypothermia deaths involve geriatric patients. Although living where harsh winters occur is a risk factor, hypothermia can develop at temperatures above freezing when an older person is exposed for a prolonged period.

The death rates from hyperthermia more than double in older people compared with younger people; people older than 85 years are at highest risk. Arizona has an abnormally high rate of heat-related deaths due to its very long, hot summers and large geriatric population.

Special Considerations in Assessing Geriatric Trauma Patients

Trauma is never isolated to a single issue when you are assessing and caring for a geriatric patient. An isolated hip fracture in a healthy 25-year-old adult is rarely associated with overall decline. However, the same injury in an 85-year-old patient can produce a wide-ranging, systemic impact that results in deterioration, shock, and life-threatening hypoxia.

Scene Size-up

As with all scenes, ensure your own safety first. Take standard precautions. Consider the number of patients, especially in the case of a motor vehicle crash. Determine if you need additional or specialized resources.

Gather information on the mechanism of injury (MOI). As with any call, look for clues that indicate your patient's traumatic incident may have been preceded by a medical incident like syncope, a cardiac problem, or a diabetic issue. Bystander information may help determine if a loss of consciousness occurred before the incident. You should use the same thought processes when you have a patient who has fallen. Was the fall mechanical, or was an episode of weakness or dizziness a factor?

The MOI is also important in establishing whether an injury is considered critical and it affects treatment and transport considerations.

Primary Assessment

During the primary assessment you will address life threats. Determine whether this is a priority patient and to which facility the patient will be transported. Because patients over the age of 55 have an increased risk of major injury and death, it is recommended that older trauma patients be transported to a trauma center. Once you have determined that the patient has a potentially life-threatening condition, limit any on-scene treatment to that which is absolutely necessary for patient stabilization. Follow your local protocols.

The general impression is an important aspect of all patient assessment. As you approach the patient, note if he or she is generally in stable or unstable condition. Determining neurologic status may be difficult if you do not know the patient's baseline. Try to get information from someone familiar with the patient, if possible. Use the AVPU mnemonic and the Glasgow Coma Scale to determine mental status. An important consideration with any patient is the inability to remember the event.

If the patient is talking to you, the airway is patent. Patients who have noisy respirations may have airway compromise. Older patients may have a diminished ability to cough, so suctioning is important. Suction any blood or foreign material. Dentures may cause an airway obstruction, so assess for the presence of dentures but do not remove them unless they are creating an airway patency problem. It is more difficult to ventilate a patient with no teeth.

In an unresponsive patient, open the airway with a modified jaw-thrust maneuver. Use an oropharyngeal or nasopharyngeal airway as appropriate, and ventilate with a BVM if the patient's respiratory effort is inadequate or absent. Any curvature of the patient's spine will require padding to keep the patient supine and the airway open.

Breathing problems caused by trauma can be made worse by preexisting respiratory disease and the compromised respiratory effort that comes with aging. Remember that minor chest trauma can cause lung injury. Perform a thorough respiratory assessment and physical assessment of the chest, and treat accordingly. Use pulse oximetry to monitor oxygenation.

Manage any external bleeding immediately. Be suspicious of signs and symptoms of internal bleeding. Drinking alcohol and taking anticoagulant medications can make internal bleeding worse, or make external bleeding more difficult to control. Remember that physiologic changes due to aging can worsen the effects of trauma, and older people do not heal as easily as do younger adults. Older patients can more easily go into shock. Also, remember that patients who were hypertensive prior to injury may have a normal blood pressure when they are actually in shock.

Words of Wisdom

Geriatric Patients With Head Trauma

Older people are more predisposed to head injuries, such as subdural hematomas. The mechanism may be minor, thus the severity of these injuries is often underestimated. Consider that the signs and symptoms of head trauma can sometimes mimic the signs and symptoms of a stroke. Be sure to ask about these risk factors during your assessment of a patient with a potential head injury:

- Long-term abuse of alcohol

- Recurrent falls
- Repeated head injury
- Use of anticoagulant medication (blood thinners, including aspirin)

History Taking

Considerations in your assessment of the patient's condition and stability must include past medical conditions, even if they are not currently acute or symptomatic. For example, you respond to a call for a patient with a history of unstable angina who sustains a simple isolated fracture of the ankle. You must consider this patient to have the potential for an unstable condition and provide prompt transport before the stress of the simple trauma worsens the angina and an unstable overall scenario develops. In these patients, the remainder of the assessment can be performed en route to the ED.

Be sure to get a history of risk factors when you assess a geriatric patient with a potential head injury. If a patient shows signs and symptoms of increased intracranial pressure, ask about recent head trauma.

Secondary Assessment

The physical examination should be performed on a geriatric trauma patient in the same manner as for any adult but with consideration of the higher likelihood of damage from trauma. Remember that any head injury can be life threatening in an older adult. When examining the chest, consider that breathing may be impaired. Check lung sounds, and look to see if there is any evidence of a pacemaker or previous cardiac surgery. Even though it may appear that the patient has only experienced trauma, keep in mind that this does not mean he or she may not also be having medical problems **Figure 35-6**. When assessing the abdomen, remember that older patients have a flaccid abdominal wall and may not present with pain and rigidity in the abdomen when trauma has been sustained. Decreased muscle size in the abdomen may mask abdominal trauma. Look for bruising and other evidence of trauma. Injury to the liver or spleen may present with diffuse abdominal pain, or pain may refer to the left shoulder.

Assess the pulse, blood pressure, and skin signs. Capillary refill is unreliable in older people because of compromised circulation. Remember that some older people take beta-blockers, which will inhibit their heart from becoming tachycardic as you would expect in shock. Even a heart rate in normal ranges may be high for someone taking beta-blockers. Try to determine if the patient's blood pressure is normal for him or her. Remember that a blood pressure that may be normal for an older adult could indicate shock in a younger patient.

Figure 35-6 Remember that when you treat a geriatric trauma patient, you must assess the injuries and carefully look for the cause of the incident. Always consider medical causes that may have led to syncope.

Reassessment

Reassessment of primary assessment, level of consciousness, vital signs, and interventions should be performed and documented as with any patient, but remember that a geriatric patient has a higher likelihood of decompensating after trauma. Be prepared.

Safety Tips

Falls in the geriatric population, even those with apparently minor mechanisms, can cause life-threatening or debilitating problems. Assess the patient's environment for potential hazards, and recommend changes.

Broken bones are common and should be splinted in a manner appropriate to the injury. Because of the amount of flexion that occurs in the spinal column, hips, and knees of older patients, effective application of conventional splints and backboards to immobilize them may be difficult or impossible unless a large amount of padding is used. What is considered a normal anatomic position for children and adults is often very abnormal for some geriatric trauma patients. Trying to force a patient into a normal anatomic position can harm the patient **Figure 35-7**. Some devices, such as traction splints, simply do not work on patients with flexed hips and knees and should not routinely be used to treat hip fractures. Splinting devices, such as vacuum mattresses that conform to body contours, may be a good choice for immobilization when indicated. In hip and pelvic fractures, avoid log rolling the patient because you risk causing the patient increased pain. When immobilization is indicated, patients with kyphosis will often need padding **Figure 35-8**. In general, padding should be done for comfort and to help decrease the likelihood of decubitis ulcer formation. Consider also that patients with chronic cardiac or respiratory disorders, particularly congestive heart failure, may have immense difficulty lying supine. An alternative solution may be to consider a spinal immobilization device like a KED intended for a patient in a seated position.

Figure 35-7 When applying a cervical collar to a geriatric patient, do not attempt to straighten out the patient's neck.

Remember that older people do not have the mechanisms that help keep them warm. Provide blankets and heat to prevent hypothermia.

Communication with older people can be challenging in any situation, but it can become even more complicated when the patient is in pain or is experiencing fear from trauma. Older people also tend to fear that a trauma may end their mobility and independence. Remember to provide psychological support, as well as medical treatment. Document assessment, treatment, and reassessment, including any changes in the patient's status.

Figure 35-8 Placing padding in void space between the patient's body and the backboard is an important component of immobilizing a geriatric patient. **A.** Pad the void space below the kyphotic spine. The pillows and blankets should be as wide as the backboard to allow for effective immobilization and support. **B.** Place blankets and pillows under an injured extremity to provide support to a fracture site.

Assessment of Falls

As mentioned, falls are a leading cause of injury in geriatric patients. Falls can be caused by a medical condition such as fainting, a cardiac rhythm disturbance, or a medication interaction. Safety and environment factors such as poor lighting, loose floor coverings, and lack of handrails are often responsible for falls. Physiologic factors include vision and balance issues, decreased visual acuity, and decreased strength.

Whenever you assess a geriatric patient who has fallen, it is critically important to find out why the fall occurred. Was it simply a mechanical fall, or was it preceded by a medical event (pathologic)? Was the patient dizzy before the fall? Does the patient remember the fall? Did a fainting episode cause the fall and injury, or did the patient trip on something and lose his or her balance? Cardiac, neurologic, and metabolic issues can create weakness, dizziness, or syncope, resulting in a fall. Traumatic and medical factors are much more interconnected in older people. Sometimes, a recent history of starting or stopping blood pressure medication is enough to cause a patient to become dizzy and fall.

Consider that the fall may have been caused by a life-threatening medical condition, and look carefully for clues from the patient, bystanders, and the environment. In motor vehicle crashes, be alert to the possibility that a medical emergency may have caused the incident, especially in single vehicle crashes with no apparent cause.

Response to Nursing and Skilled Care Facilities

With many of your geriatric patients with whom you interact, the call will occur at a nursing home or other skilled care facility. Relatively healthy and active seniors live in age-restricted active adult communities that offer resort-type amenities. A less expensive option is age-restricted apartments that provide seniors with the physical and emotional security that comes with living with other seniors. A similar type of facility, but one that also provides communal meals, social events, and other types of support, is an independent living facility. People living in this type of facility are more likely to have minor health problems. Assisted living residential facilities support residents with activities of daily living and provide 24-hour assistance. Residents get assistance with daily medication administration, and some facilities address specialized patient issues like Alzheimer disease and dementia.

Nursing homes, also called convalescent homes or long-term care facilities, are facilities that serve patients who need 24-hour care and are sometimes a step down from an acute care hospital. Patients require assistance with daily living and need therapeutic or rehabilitation services.

Calls to these types of facilities can sometimes be challenging. Patients often have an altered level of consciousness and may not be able to give you a nature of illness or MOI. The staff is usually spread thin and may not be familiar with what needs to be done to assist you when transport is necessary. The caregiver who greets you may not even be familiar with the patient. The most important piece of information you need to establish immediately is, "What is wrong with the patient that is new or different today that made you call 9-1-1?" As soon as possible, establish the baseline status of the patient by talking to the staff who directly care for the patient on a daily basis.

With potentially limited information, you need to do an assessment to determine if the patient's problem is life threatening and/or requires ALS level care. Optimally, the facility will provide you with a transfer record that provides critical information on the patient's history, medications, allergies, and current complaint. This information is critical because the ED staff needs to know how to best manage the patient. Ideally, and when appropriate, transport the patient to the acute care facility where the patient has been treated before and his or her records are available.

Infection control needs to be a high priority when you visit these facilities. You not only need to protect yourself, but good handwashing and standard precautions can inhibit the spread of infectious pathogens to older people who already have compromised immune systems. You should also be cognizant of potential airborne pathogens. Something as simple as a cold or flu virus could result in a life-threatening pneumonia for a compromised older adult. An infection in an older patient can lead to life-threatening sepsis. Be sure to mask yourself if you have an upper respiratory infection, and mask the patient if he or she has one. Some risks to these patients and EMTs are described next.

Methicillin-resistant Staphylococcus aureus (MRSA) infections are common among people who live in close quarters like nursing homes. The organism can be found in decubitus ulcers (bedsores), on feeding tubes, and on indwelling urinary catheters. The symptoms of MRSA depend on the type of infection. It can cause mild infections on the skin or invade the bloodstream, lungs, or the urinary tract. MRSA is primarily spread by broken skin-to-skin contact but is also acquired by touching objects that have the bacteria on them. To protect yourself and reduce the spread of MRSA infections, you should wash your hands before and after every patient contact, properly dispose of or disinfect all medical equipment, and take appropriate standard precautions with every patient.

Similarly, many infections in hospitals are caused by **vancomycin-resistant enterococci (VRE)**. Enterococci are bacteria that are normally present in the human intestines and the female reproductive tract. Under the right circumstances, these bacteria can cause infection. Some of the enterococci have become resistant to vancomycin, the antibiotic commonly used to treat these infections.

The **respiratory syncytial virus (RSV)** causes an infection of the upper and lower respiratory tracts. Although more typically seen in children, the virus can also cause serious illness in older people, especially those with lung disease or weakened immune systems. The symptoms are similar to the common cold but can be more severe and last longer. The virus is highly contagious and is found in discharges from the nose and throat of an infected person. Respiratory syncytial virus is also transmitted by direct contact with droplets from coughs or sneezes and by touching a contaminated surface.

MRSA and respiratory syncytial virus infections can be life threatening, especially in an immune-compromised patient. Look for isolation signs or ask about contagious disease when you approach a patient. Be sure to wear appropriate personal protective equipment and decontaminate your ambulance and diagnostic equipment after contact with nursing home residents whether a history of infectious disease is known or not. Be sure to document the infection control issue; advise the receiving facility; and, depending on local protocol, report an infectious disease to your company or the local health department.

Clostridium difficile (C diff) is a bacterium responsible for the most common cause of hospital-acquired infectious diarrhea and regularly causes sporadic cases of diarrhea in nursing homes. It is a bacterium that normally grows in the intestines. Antibiotic use may account for the rapid increase in toxic strains that ultimately cause illness. Health care workers may carry this bacterium following contact with contaminated feces. It can also be found on environmental surfaces like furniture, floors, toilets, sinks, and bedding. The symptoms from the resultant colitis can range from minor diarrhea to a life-threatening inflammation of the colon. Typical alcohol-based hand sanitizers do not inactivate or kill *C diff*. Contact precautions with gowns and gloves and handwashing with soap and water after each and every patient contact is essential to prevent transmission.

Dying Patients

As older patients are living longer, more terminally ill patients are choosing to die at home rather than in a hospital. Many have family support and/or hospice support. Often the patient comes to terms with his or her impending death before the family does. Dying patients receive what is called palliative, or comfort, care. Palliative care recognizes that death is a normal part of the life cycle. Palliative care does not hasten or prolong death, but focuses on relieving pain and providing emotional support and comfort for the patient and his or her loved ones.

You may be called on to interact with a dying patient. One thing to remember is that this interaction will have a long-term effect on the family. Be understanding, sensitive, and compassionate, although the situation may be uncomfortable for you as well. Determine if the family wishes the patient to go to the hospital or stay in the home.

Advance Directives

Many people today make use of **advance directives**. Also called living wills, advance directives are specific legal papers that direct relatives and caregivers about what kind of medical treatment may be given to patients who cannot speak for themselves. Dealing with advance directives has become more common for EMS providers because more people are electing to use hospice services and spend their final days at home.

Advance directives may also take the form of a do not resuscitate (DNR) order. A DNR order gives you permission not to attempt resuscitation for a patient in cardiac arrest. However, for a DNR order to be valid, the form must be signed by the patient or legal surrogate and by one or more physicians or other licensed health care providers. In the presence of a DNR order, if the patient is still alive, you are obligated to provide supportive measures that may include oxygen delivery, pain relief, and comfort. DNR does not mean do not treat. Basic airway, breathing, and circulatory support should be provided; however, cardiopulmonary resuscitation may not.

A health care power of attorney is an advance directive that is exercised by a person who has been authorized by the patient to make medical decisions for him or her. Be sure to follow your service's protocol when faced with any advance directive.

Although advance directives may be in place, family members or caregivers who are faced with the final moments of life or worsening of the patient's condition often become alarmed and call 9-1-1. Family members and caregivers may then become upset when you take resuscitative action and begin transportation to the hospital.

Another common situation is the transportation of patients from nursing facilities. Specific guidelines vary from state to state; however, you should consider the following general guidelines:

- Patients have the right to refuse treatment, including resuscitative efforts, provided that they are able to communicate their wishes.

- A DNR order is valid in a health care facility only if it is in the form of a written order by a physician.
- You should periodically review state and local protocols and legislation regarding advance directives.
- When you are in doubt or when there are no written orders, you should try to resuscitate the patient.

Every service should also provide training on the actions you should take when presented with advance directives. When in doubt, your best course of action is to take resuscitative action that is appropriate to the situation and to practice sound medical treatment.

Elder Abuse and Neglect

Trauma in older people can also be caused by abuse. Reports and complaints of abuse, neglect, and other related problems among the nation's older population are on the rise. **Elder abuse** is defined as any action on the part of an older person's family member, caregiver, or other associated person that takes advantage of the older person's person (for example, physical abuse), property, or emotional state. Abuse can result from acts of commission (words or actions that cause harm), such as verbal, physical, or sexual assault. Abuse can also result from acts of omission (failure to act), such as denying an older person adequate nutrition or medical care.

The exact extent of elder abuse is not known for several reasons, including the following:

- Elder abuse is a problem that has been largely hidden from society.
- The definitions of abuse and neglect among the geriatric population vary.
- Victims of elder abuse are often hesitant to report the problem to law enforcement agencies or human and social welfare personnel.

YOU are the Provider — PART 5

During transport, the patient remains conscious, although confused. You reassess her vital signs and then call your radio report to the hospital. During your radio report, the nurse asks you if the patient is normally confused. You inform her that the patient has Alzheimer disease and that this is her baseline mental status.

Recording Time: 30 Minutes	
Level of consciousness	Conscious, but confused
Respirations	22 breaths/min; labored
Pulse	70 beats/min; weak and irregular
Skin	Hot to the touch; pink and dry
Blood pressure	148/88 mm Hg
Spo_2	95% on 15 L/min via nonrebreathing mask

During the remainder of the transport, you reassure the patient that the hospital staff will take good care of her. Although confused, she looks at you and smiles. You deliver her to the hospital, transfer patient care to the emergency department staff, and return to service.

9. How does dementia differ from delirium? Is dementia a normal part of the aging process?

10. What strategies should you use when communicating with older patients?

The abused person may feel traumatized by the situation or be afraid that the abuser will punish him or her for reporting the abuse. The abused person may be frail and have multiple chronic medical conditions or dementia. The person may sleepwalk, have an impaired sleep cycle, and periodically shout at others. The person may also be incontinent and dependent on others for activities of daily living.

Elder abuse occurs most often in women older than 75 years. The physical and emotional signs of abuse, such as rape, spouse beating, and nutritional deprivation, are often overlooked or not accurately identified. Older women in particular are not likely to report incidents of sexual assault to law enforcement agencies. Patients with sensory deficits, dementia, and other forms of altered mental status, such as drug-induced depression, may not be able to report abuse.

Abusers of older people are sometimes products of child abuse, and the abuse that is inflicted on the older person may be retaliatory. Most of these abusers are not trained in the particular care that older people require and have little relief time from the constant care demands of their own family, children, and spouse. Their lives are significantly complicated by the constant, demanding needs of the older person they have to care for.

The abuser may also have marked fatigue, be unemployed with financial difficulties, or abuse one or more substances.

With a careful eye, you can recognize the clues to these stressful situations and help guide the family toward programs in their community that are geared to helping the whole family. Programs such as adult day care, Meals on Wheels, and many local individualized programs help to decrease the stress put on the family and lower the chances of abuse.

Abuse is not restricted to the home. Environments such as nursing and convalescent homes and continuing care centers are also sites where older people sustain physical, psychologic, financial, or pharmacologic harm. Often, care providers in these environments consider older people to be management problems or categorize them as obstinate and undesirable patients. Consult local authorities, but in general you should assume that you have the same obligation to report suspected elder abuse as you do suspected child abuse. Notify receiving hospital personnel of your concerns, report to the proper authorities based on local protocols, and factually document your findings. If you are in doubt, err on the side of caution and make a report. Note that it is not your responsibility to prove that the abuse occurred, only to report your findings according to protocols.

Assessment of Elder Abuse

Abuse comes in many forms and may include physical assault. Be aware of the environment and conditions a patient lives in, and take note of soft-tissue injuries that cannot be explained by the person's lifestyle and physical condition.

While assessing the patient, try to obtain an explanation of what happened. You should suspect abuse when answers to questions about what caused the injury are concealed or avoided.

You must also suspect abuse when you are given unbelievable answers. Be suspicious if you think "Does this make sense?" or "Do I really believe this story?" while reviewing the patient's history. As an EMT, you may be the first health care provider to observe the signs of possible abuse. Information that may be important in assessing possible abuse includes the following:

- Caregiver apathy about the patient's condition
- Overly defensive reaction by caregiver to your questions
- Caregiver does not allow patient to answer questions
- Repeated visits to the emergency department or clinic
- A history of being accident-prone
- Soft-tissue injuries
- Unbelievable, vague, or inconsistent explanations of injuries
- Psychosomatic complaints
- Chronic pain without medical explanation
- Self-destructive behavior
- Eating and sleep disorders
- Depression or a lack of energy
- A history of substance and/or sexual abuse

You should remember that many patients who are being abused are so afraid of retribution that they make false statements. A geriatric patient who is being abused by family members may lie about the origin of abuse for fear of being thrown out of the home. In other cases of elder abuse, sensory deprivation or dementia may hinder adequate explanation.

Repeated abuse can lead to a high risk of death. As an EMT, you can help to reduce additional maltreatment of the patient by identifying the abuse Table 35-5. This preventive measure may allow for referral and protective services of human, social, and public safety agencies.

Table 35-5	Categories of Elder Abuse
Physical	■ Assault ■ Neglect or abandonment ■ Dietary (malnutrition) ■ Poor maintenance of home ■ Poor personal hygiene ■ Sexual assault
Psychological	■ Benign neglect ■ Verbal ■ Treating the person as an infant ■ Deprivation of sensory stimulation
Financial	■ Theft of valuables ■ Embezzlement

Signs of Physical Abuse

Signs of abuse may be quite obvious or subtle. Injuries may be the result of acute or chronic abuse or neglect. Inflicted bruises are usually found on the buttocks and lower back, genitals and inner thighs, cheeks or ear-lobes, neck, upper lip, and inside the mouth. Pressure bruises caused by the human hand may be identified by oval grab marks, pinch marks, or handprints. Human bites are typically inflicted on the upper extremities and can cause lacerations and infection. You should inspect the patient's ears for indications of twisting, pulling, or pinching and evidence of frequent blows to the outer ears. You should also investigate multiple bruises in various states of healing by asking the patient and reviewing the patient's activities of daily living.

Words of Wisdom

As with other legally complex and emotionally charged issues, the possibility of elder abuse demands particularly careful documentation. Be thorough, objective, and factual, avoiding unsupported opinions and personal judgments. You may be called on to explain your report in a legal proceeding. Report your suspicions to the appropriate authorities and follow local protocols. Typically, the authorities will want to know specifics (name, contact information, etc) about the person you suspect is being abused and why you suspect abuse.

Burns are a common form of abuse. If you see burns, especially cigarette burns or physical marks that indicate that certain parts of the patient's body have been scalded systematically, you must suspect abuse. Typical abuse from burns is caused by contact with cigarettes, matches, heated metal, forced immersion in hot liquids, chemicals, and electrical power sources.

It may be difficult to see a failure to thrive in an older patient who has been abused. You should observe the patient's weight and try to determine whether the patient appears undernourished or has been unable to gain weight in the current environment. Does the patient have a ravenous appetite? Has medication been withheld? Is money being withheld, so the patient cannot buy food or medicine? You should also check for signs of neglect, such as evidence of a lack of hygiene, poor dental hygiene, poor temperature regulation, or lack of reasonable amenities in the home **Figure 35-9**.

You must regard injuries to the genitals or rectum with no reported trauma as evidence of sexual abuse in any patient. Geriatric patients with altered mental status may never be able to report sexual abuse. In addition, many women do not report cases of sexual abuse because of shame and the pressure to remain silent and forget.

Figure 35-9 Signs of neglect include evidence of a lack of hygiene, poor dental hygiene, poor temperature regulation, or lack of reasonable amenities in the home.

YOU are the Provider SUMMARY

1. As an EMT, why is it important for you to understand the physiologic changes that occur with aging?

Understanding the normal anatomic and physiologic changes that occur with aging is important when you are assessing and treating an older patient who is experiencing an illness or injury. You do not want to mistake these changes for signs of illness and provide treatment when it is not indicated, nor do you want to attribute them to "just getting old" and fail to provide treatment when it is indicated.

2. How does the process of aging affect a person's respiratory system?

The decreased muscle mass in older patients means they have less help from the muscles in the chest wall during respiratory distress.

Airway mechanisms, such as the cough and gag reflexes, decrease with age, resulting in a decreased ability of older adults to clear secretions from the airway. These upper and lower airway changes decrease the patient's ability to cough, which increases the risk of a respiratory infection.

The elasticity of the alveoli in older patients decreases, making it harder for the patient to exhale. As a result, pulmonary respiration—the exchange of oxygen and carbon dioxide in the lungs—decreases.

3. What is the GEMS diamond? How can it facilitate your overall care of an older patient?

The GEMS diamond serves as a useful mnemonic for the issues to consider when assessing every older patient. The four components of the GEMS diamond are: G-geriatric patients; E-environmental assessment; M-medical assessment; and S-social assessment. It provides an organized way for you to remember the important issues when assessing older patients.

4. Based on the patient's current condition, how appropriate is the current oxygen therapy?

The amount of oxygen being delivered to the patient should be increased. The patient reports dyspnea and has abnormal lung sounds. Despite being placed on 2 L/min of oxygen, the Spo_2 level is only 92%. Current guidelines for oxygen therapy state the Spo_2 level should be maintained at or above 94%.

5. What should concern you about patients who take numerous medications?

The risks of inadvertent overdosing or negative medication interactions increase when patients take numerous medications. Furthermore, the physiologic changes that occur with aging make an older patient susceptible to drug toxicity—even if the patient takes all of his or her medications as prescribed. Medications tend to stay in the body for longer periods.

When numerous medications are combined, it is impossible to predict how they may interact with each other. Some medication interactions can produce acute, life-threatening emergencies. When caring for a patient who takes numerous medications, consider the possibility of an interaction as the underlying cause of, or a contributor to, his or her problem.

6. What other assessments, if any, should be performed for this patient?

The patient history revealed she has not been eating lately. The daughter stated her mother's level of consciousness has been altered more than usual over the last couple of days. Based on the patient's fever, multiple medications, decreased appetite, and altered LOC, you should assess her blood glucose level if consistent with your local protocol.

7. Why do older patients commonly refuse EMS transport?

The most common reason why older patients are resistant to EMS transport is fear. They often fear that when they are loaded into an ambulance and leave the safety of their own home, they will be moved to a nursing home or, even worse, never leave the hospital. As an EMT, you are always obligated to treat the patient to the best of your abilities, but you must acknowledge and respect the older patient's need for independence and the emotional attachment that he or she may have to the home.

8. On the basis of the patient's past medical history and signs and symptoms, what do you suspect as the cause of her problem?

On the basis of the patient's past medical history, which includes emphysema, and her current presentation—fever, chills, worsened shortness of breath, and coarse rhonchi—you should suspect pneumonia.

The presence of a preexisting lower respiratory disease (eg, chronic obstructive pulmonary disease), coupled with age-related deterioration of the respiratory and immune systems, makes older patients especially prone to pneumonia.

9. How does dementia differ from delirium? Is dementia a normal part of the aging process?

Dementia is a slow onset of progressive disorientation, as well as a progressive loss of cognitive function, psychomotor skills, and social skills. It is a chronic, generally irreversible condition that develops slowly—typically over a period of years—and is the result of a progressive deterioration in cerebral function. There are a number of causes of dementia, such as Alzheimer disease. In contrast, delirium is an acute change in mental status or cognitive function. It is marked by the inability to focus, think logically, and maintain attention, and signals the onset of a new health problem. Unlike dementia, many causes of delirium are reversible. In older patients, delirium is commonly the result of a urinary tract infection, hypoglycemia or hyperglycemia, dehydration, bowel obstruction, fever, and vitamin deficiencies. Other causes include acute alcohol intoxication, drug overdose, withdrawal from drugs or alcohol, hypoxia, and hypovolemia, among others.

Any change in a patient's level of consciousness or mentation, regardless of his or her age, is abnormal. Confusion, abnormal behavior, and other changes in cognitive function do not come automatically with age; they should be regarded as an indicator of an underlying illness or injury.

10. What strategies should you use when communicating with older patients?

Speak respectfully when you introduce yourself, and identify yourself as a medical professional. This helps establish a rapport with the patient. Asking the patient how he or she prefers to be addressed is a trust-building technique.

Look directly at the patient and speak slowly and distinctly. Do not assume that the patient is hearing-impaired simply because of his or her age.

When you ask the patient a question, allow adequate time for him or her to respond, unless the condition is urgent or critical. When the patient responds, listen carefully to what he or she is saying.

Explain what you are going to do before you do it. Use simple terms to explain the use of medical equipment and procedures, and avoid medical jargon and slang.

Do not talk about the patient in front of him or her as though he or she was not there. This can potentially give the patient the feeling that he or she does not have a say in decisions about his or her care.

EMS Patient Care Report (PCR)

Date: 11-28-16	**Incident No.:** 013309	**Nature of Call:** Shortness of breath		**Location:** 644 Yolanda St.	
Dispatched: 0625	**En Route:** 0626	**At Scene:** 0630	**Transport:** 0652	**At Hospital:** 0705	**In Service:** 0716

Patient Information

Age: 82 **Sex:** F **Weight (in kg [lb]):** 48 kg (105 lb)	**Allergies:** Erythromycin **Medications:** Plavix, Digoxin, Aricept, Verapamil, Celebrex, Albuterol, Flovent **Past Medical History:** Emphysema, atrial fibrillation, Alzheimer disease, rheumatoid arthritis, hypertension **Chief Complaint:** Difficulty breathing

Vital Signs

Time: 0635	**BP:** 158/88	**Pulse:** 68	**Respirations:** 22	**Spo_2:** 92%
Time: 0645	**BP:** 152/90	**Pulse:** 84	**Respirations:** 22	**Spo_2:** 94%
Time: 0700	**BP:** 148/88	**Pulse:** 70	**Respirations:** 22	**Spo_2:** 95%

EMS Treatment (circle all that apply)

Oxygen @ 15 L/min via (circle one): **NC NRM BVM**		**Assisted Ventilation**	**Airway Adjunct**	**CPR**
Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** Position of comfort; emotional support

Narrative

Medic 53 dispatched to a residence for a woman with respiratory distress. Arrived on scene and found the patient, an 82-year-old woman, sitting in a chair in her living room. She was conscious but confused. Her airway was patent, and her breathing was labored. The patient had a blanket wrapped around her and was shivering. Her daughter, who was present at the scene, advised that the patient has a history of emphysema and that her usual shortness of breath has worsened during the past few days. The patient was currently receiving home oxygen at 2 L/min via nasal cannula. The daughter further stated that the patient has been running a fever, 101°F (38°C), and has had a cough, which is producing thick green sputum. Other past medical history significant for A-Fib, Alzheimer disease, hypertension, and rheumatoid arthritis. Inquired about patient's current mental status (confused) and was advised by the daughter that her mother has been more confused than normal over the last couple of days. Further assessment revealed bilateral basilar rhonchi on auscultation of breath sounds. Obtained vital signs, and increased oxygen flow rate to 15 L/min by nonrebreathing mask. Advised patient that transport to the hospital for evaluation was necessary; however, she stated that she did not want to go. The patient's daughter reassured her and advised that she would follow the ambulance to the hospital. After reassurance by the daughter and EMS, the patient consented to transport. Placed patient onto stretcher, placed her in a position of comfort, loaded her into the ambulance, and began transport. En route, patient's condition remained unchanged; she remained confused and short of breath, and her vital signs remained stable. Continued to provide emotional support and reassurance to the patient; she was able to answer some questions but had difficulty with others. Delivered patient to emergency department staff, gave verbal report to staff nurse, and transferred patient care. Medic 53 returned to service at 0716.**End of report**

Prep Kit

Ready for Review

- With changes in the respiratory system, such as a decreased ability to cough, geriatric patients are more likely to present with pneumonia.
- Changes in the cardiovascular system can lead to atherosclerosis, aneurysm, stiffening heart valves, orthostatic hypotension, venous stasis, deep venous thrombosis, heart attack, heart failure, and stroke.
- Many patients do not present with the classic symptom of chest pain when experiencing a heart attack. Atypical presentations are seen mostly in women, older patients, and patients with diabetes.
- Dementia and delirium are both abnormal processes and must be carefully evaluated in geriatric patients.
- As the body ages, the bones become more fragile. This leads to a higher risk of fracture in geriatric patients.
- Polypharmacy and changes in medications can cause serious problems for geriatric patients.
- Depression is treatable with medication and therapy but is a risk factor for suicide if it remains untreated in geriatric patients.
- Although assessment of geriatric patients involves the same basic approach as that for any other patient, you must take a more wary approach.
- Assessing an older person can be challenging because of communication issues, hearing and vision deficits, alteration in consciousness, complicated medical history, and the effects of multiple medications.
- To obtain an accurate history for a geriatric patient, patience and good communication skills are essential. A slow, deliberate approach to the patient history, with one EMT asking questions, is generally the best strategy.
- The risk of serious injury or death is more common in geriatric patients who experience a traumatic injury.
- When you treat a geriatric trauma patient, assess the injuries and carefully look for the cause of the injury. A medical condition such as fainting could actually be the cause of a fall. The injuries from the fall and the medical condition will need to be addressed.
- When responding to nursing and skilled care facilities, you should determine the patient's chief complaint on that day and what initial problem caused the patient to be admitted to the facility.
- Be aware of signs of abuse and neglect. Carefully document these signs, and report suspected elder abuse or neglect according to your local protocols.

Vital Vocabulary

abdominal aortic aneurysm (AAA) A rapidly fatal condition in which the walls of the aorta in the abdomen weaken and blood leaks into the layers of the vessel, causing it to bulge.

advance directives Written documentation that specifies medical treatment for a competent patient should the patient become unable to make decisions; also called a living will or health care directive.

aneurysm An abnormal enlargement of a part of an artery, resulting from weakening of the arterial wall.

arteriosclerosis A disease that causes the arteries to thicken, harden, and calcify.

ascites Fluid in the abdomen.

atherosclerosis An accumulation of fat and cholesterol in the arteries.

cataracts Clouding of the lens of the eye or its surrounding transparent membranes.

decubitus ulcers Sores caused by the pressure of skin against a surface for long periods; can range from a pink discoloration of the skin to a deep wound that may invade into bone or organs; also known as bedsores.

deep venous thrombosis The formation of a blood clot within the larger veins of an extremity, typically following a period of prolonged immobilization.

delirium A sudden change in mental status marked by the inability to focus, think logically, and maintain attention; this condition is generally acute and reversible.

dementia The slow onset of progressive disorientation, shortened attention span, and loss of cognitive function; this condition is generally chronic and irreversible.

dyspnea Shortness of breath or difficulty breathing.

elder abuse Any action on the part of an older person's family member, caregiver, or other associated person that takes advantage of the older person's person, property, or emotional state.

geriatrics The assessment and treatment of disease in someone who is 65 years or older.

hemoptysis The coughing up of blood.

jugular vein distention A visual bulging of the jugular veins in the neck that can be caused by fluid overload, pressure in the chest, cardiac tamponade, or tension pneumothorax.

kyphosis A forward curling of the back caused by an abnormal increase in the curvature of the spine.

melena Black, foul-smelling, tarry stool containing digested blood.

methicillin-resistant Staphylococcus aureus (MRSA) A bacterium that causes infections in different parts of the body and is often resistant to commonly used antibiotics; can be found on the skin and in surgical wounds, the bloodstream, lungs, and urinary tract.

neuropathy A group of conditions in which the nerves leaving the spinal cord are damaged, resulting in distortion of signals to or from the brain.

osteoporosis A generalized bone disease, commonly associated with postmenopausal women, in which there is a reduction in the amount of bone mass leading to fractures after minimal trauma in either sex.

peptic ulcer disease An abrasion of the stomach or small intestine.

pneumonia An inflammation of the lung from a bacterial, viral, or fungal cause.

polypharmacy The use of multiple medications on a regular basis.

presbycusis An age-related condition of the ear that produces progressive bilateral hearing loss that is most noted at higher frequencies.

pulmonary embolism A condition that causes a sudden blockage of the pulmonary artery by a venous clot.

respiratory syncytial virus (RSV) A highly contagious virus that causes an infection of the upper and lower respiratory system.

syncope A fainting spell or transient loss of consciousness, often caused by an interruption of blood flow to the brain.

urinary tract infection (UTI) A bacterial infection that affects the urinary tract.

vancomycin-resistant enterococci (VRE) A bacterium that is normally present in the human intestines and the female reproductive tract, but which can cause infection and which is resistant to the antibiotic vancomycin.

Assessment *in Action*

It is 0300 hours and you and your partner are called to a private residence for an 86-year-old man reporting a sudden onset of shortness of breath. On arrival, you observe an older home in need of repair. When you enter the home, you find that there are seven cats, and there is the strong odor of stale cat food and litter boxes.

1. You find your patient sitting upright in his bed with four pillows behind him. He is having difficulty speaking because of a previous stroke. Which interview technique should you use when addressing the patient?

   A. Speak loudly and slowly.
   B. Listen carefully to the answers the patient provides.
   C. Refer to the patient by his first name.
   D. Have both you and your partner ask questions.

2. The patient explains that he was awakened by a sudden feeling of suffocation and respiratory distress. What are his symptoms a characteristic of?

   A. Orthopnea
   B. Exertional dyspnea
   C. Intermittent sleep apnea
   D. Paroxysmal nocturnal dyspnea

3. What assessment question should you ask to help clarify his symptoms of a sudden feeling of suffocation and respiratory distress?

   A. "How many hours of sleep do you get each night?"
   B. "In what position do you normally sleep?"
   C. "How many pillows do you sleep on?"
   D. "Do you take any medication to help you sleep at night?"

4. On auscultation of the patient's lungs, your partner hears crackles. These lung sounds are caused by air passing through:

A. constricted airways.
B. thick secretions in the airways.
C. fluid in the alveoli.
D. inflamed airways.

5. The pulse oximeter is unable to provide an accurate reading. What is a possible cause for this finding?

A. Poor circulation
B. Hypertension
C. Fever
D. Increased red blood cell count

6. Observing and documenting the condition in which you find the home is part of the GEMS ___________ assessment.

A. general
B. environmental
C. medical
D. social

7. Which condition is considered to be a risk factor for congestive heart failure?

A. Coronary artery disease
B. Emphysema
C. Dementia
D. Diabetes

8. Explain the importance of performing a social assessment when caring for a geriatric patient.

9. Your patient tells you that he takes numerous medications every day for his heart and blood pressure; however, he cannot remember their names. He points to a plastic bag by the bedside that contains 11 prescription bottles with similar medications, and some of the medications were not prescribed to him. What problems might this situation pose?

CHAPTER
36

Patients With Special Challenges

© Karl Gehring/The Denver Post/Getty.

National EMS Education Standard Competencies

Special Patient Populations

Applies a fundamental knowledge of growth, development, and aging and assessment findings to provide basic emergency care and transportation for a patient with special needs.

Patients With Special Challenges

Recognizing and reporting abuse and neglect (Chapter 34, *Pediatric Emergencies*, and Chapter 35, *Geriatric Emergencies)*

Health care implications of

› Abuse (Chapter 34, *Pediatric Emergencies*, and Chapter 35, *Geriatric Emergencies*)
› Neglect (Chapter 34, *Pediatric Emergencies*, and Chapter 35, *Geriatric Emergencies*)
› Homelessness (p 1339)

› Poverty (p 1339)
› Bariatrics (pp 1331–1332)
› Technology dependent (pp 1333–1337)
› Hospice/terminally ill (p 1338)
› Tracheostomy care/dysfunction (pp 1333–1334)
› Home care (p 1338)
› Sensory deficit/loss (pp 1326–1329)
› Developmental disability (pp 1324–1326)

Trauma

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

Special Considerations in Trauma

Recognition and management of trauma in
› Pregnant patient (Chapter 33, *Obstetrics and Neonatal Care*)
› Pediatric patient (Chapter 34, *Pediatric Emergencies*)
› Geriatric patient (Chapter 35, *Geriatric Emergencies*)

Pathophysiology, assessment, and management of trauma in the
› Pregnant patient (Chapter 33, *Obstetrics and Neonatal Care*)
› Pediatric patient (Chapter 34, *Pediatric Emergencies*)
› Geriatric patient (Chapter 35, *Geriatric Emergencies*)
› Cognitively impaired patient (pp 1324–1326)

Knowledge Objectives

1. Give examples of patients with special challenges EMTs may encounter during a medical emergency. (p 1323)
2. Explain the special patient care considerations required when providing emergency medical care to patients with intellectual disabilities, including patients with autism spectrum disorder (ASD), Down syndrome, or prior brain injuries. (pp 1324–1326)
3. Describe the different types of visual impairments and the special patient care considerations required when providing emergency medical care for visually impaired patients, depending on the level of their disability. (pp 1326–1327)
4. Describe the various types of hearing impairments and the special patient care considerations required when providing emergency medical care for hard-of-hearing patients, including tips for effective communication. (pp 1327–1329)
5. Describe the various types of hearing aids worn by patients; include strategies to troubleshoot a hearing aid that is not working. (pp 1328–1329)
6. Explain the special patient care considerations required when providing emergency medical care to patients who have cerebral palsy, spina bifida, or paralysis. (pp 1330–1333)
7. Define obesity. (p 1331)
8. Explain the special patient care considerations required when providing emergency medical care to bariatric patients; include the best way to move bariatric patients. (p 1332)
9. Explain the special patient care considerations required when providing emergency medical care to patients who rely on a form of medical technological assistance, including the following: (pp 1333–1337)
   • Tracheostomy tube
   • Mechanical ventilator
   • Apnea monitor
   • Internal cardiac pacemaker
   • Left ventricular assist device (LVAD)
   • External defibrillator vest
   • Central venous catheter
   • Gastrostomy tube
   • Ventricular peritoneal shunt
   • Vagus nerve stimulator

- Colostomy bag, ileostomy bag, or urostomy bag

10. Describe home care, the types of patients it serves, and the services it encompasses. (p 1338)
11. Contrast hospice and palliative care with curative care. (p 1338)
12. Explain the responsibilities of EMTs when responding to calls for terminally ill patients who have DNR orders. (p 1338)
13. Discuss the issues of poverty and homelessness in the United States, their negative effects on a person's health, and the role of EMTs as patient advocates. (p 1339)

Skills Objectives

1. Demonstrate different strategies to communicate effectively with a patient who has a hearing impairment. (p 1328)

Introduction

The approach to health care in the United States continues to focus on decreasing the length of hospitalization. At the same time, medicine and medical technology continue to improve. As a result, the number of children and adults with chronic diseases and injuries who live at home or in environments outside of a hospital setting continues to grow. You should be familiar with the special challenges of patients with chronic diseases and conditions.

Some examples of patients with special challenges include:

- Children who were born prematurely and who have associated respiratory problems
- Infants or small children with congenital heart disease
- Patients with neurologic disease (occasionally caused by hypoxemia at the time of birth, as with cerebral palsy)
- Patients with congenital or acquired diseases resulting in altered body function that requires medical assistance for breathing, eating, urination, or bowel function
- Patients with sensory deficits such as hearing or visual impairments
- Geriatric patients with chronic diseases requiring visitation from a home health care service

You may be called to treat children and adults who live at home and depend on mechanical ventilators, intravenous pumps, or other devices to maintain their lives. You should assess and care for patients with special challenges the same way you care for your other patients. Your priority is the assessment and treatment of the ABCs. Do not be distracted by the noise and mechanics of the medical equipment—focus on the patient the medical equipment may be assisting. If the emergency is the result of medical equipment failure, use the equipment on the ambulance. Some families will have a "go bag," which is a collection of spare equipment and supplies for such situations.

Words of Wisdom

During stressful emergency events, it is imperative to use the TEAM approach (Trust Every Available Member) to collaborate regarding your patient's treatment, which leads to a better standard of care and patient outcome.

Words of Wisdom

Primary caregivers of patients at high risk for cardiac arrest should be trained in CPR. You should advocate for this as part of your community prevention efforts.

YOU are the Provider — PART 1

At 1435 hours, you are dispatched to a residence at 575 Ranger Drive for a 19-year-old man with a fever. You recognize the address because you have responded to this patient on several occasions. He has quadriplegia and is ventilator dependent because of a spinal injury that occurred 2 years ago. You and your partner proceed to the scene; your response time is 5 minutes.

1. How will your assessment and treatment of this patient differ from a patient who is not dependent on a ventilator?
2. What role do the parents or caregivers of patients with special health care needs have in the prehospital setting?

Intellectual Disability

The term **developmental disability** refers to insufficient development of the brain, resulting in some level of dysfunction or impairment. Developmental disabilities can include intellectual, hearing, or vision impairments that surface during infanthood or childhood.

Intellectual disability results in the inability to learn and socially adapt at a normal developmental rate. An intellectual disability may be caused by genetic factors, congenital infections, complications at birth, malnutrition, or environmental factors. Prenatal drug or alcohol use may also cause intellectual disability, such as fetal alcohol syndrome. Other causes that may occur after birth include traumatic brain injury and poisoning (eg, from lead or other toxins).

A person with a slight intellectual impairment may appear slow to understand or have a limited vocabulary. Such patients will often behave immaturely in comparison with their peers. People with severe intellectual disabilities may not have the ability to care for themselves, communicate, understand, or respond to their surroundings.

Speaking to patients and family members will give you a good idea of how well the patient can understand you and how the patient will interact with you. Family or friends of the patient may also be able to supply additional medical information regarding the patient.

Because patients with intellectual disabilities may have difficulty adjusting to change or a break in routine, an emergency call that generates a roomful of strangers can be overwhelming. A patient may become more difficult to interact with as his or her anxiety level increases. Make every effort to respect the patient's wishes and concerns. Take as much time as necessary to calmly and clearly explain the treatment the patient is about to receive.

Patients with intellectual disabilities are susceptible to the same disease processes as other patients, including diabetes, heart attack, and respiratory difficulties. Assess and treat the patient according to the chief complaint. During transport, keep the patient as calm as possible.

Autism Spectrum Disorder

Autism and **autism spectrum disorder (ASD)** are general terms used to describe a group of complex disorders of brain development that vary greatly in signs and symptoms. Autism is a pervasive developmental disorder characterized by impairment of social interaction. Other characteristics can include severe behavioral problems, repetitive motor activities, and verbal and nonverbal language impairment. Some people with autism may be hyper- or hyposensitive to sensory stimuli. They may also show their pain in unusual ways, such as by humming, singing, and removing clothing. The spectrum of disability is wide. Some children with autism will grow up to be independent, whereas others will be unable to care for themselves.

Patients with autism have difficulty using or understanding nonverbal means of communication, such as gestures. They frequently have difficulty making eye contact and resist encouragement to do so. They may have extreme difficulty with tasks that require many steps and do best with simple, one-step directions, such as "Please roll up your sleeve." Some patients with autism tend to become confused during long conversations and have trouble answering open-ended questions (eg, "What sorts of things do you enjoy doing?"). They may talk in robotic or monotonic speech patterns and sometimes repeat phrases over and over again. Many patients with autism confuse pronouns and will say "you" when they mean "I," as in "You are going to the hospital," when they mean, "I am going to the hospital." A small percentage of patients with autism do not speak at all, but instead rely on pulling parents and caregivers around by the hand to get their needs met.

There is no simple explanation as to why autism exists. According to the Centers for Disease Control and Prevention, approximately 1 in every 68 American children is diagnosed with autism. The prevalence in boys is five times the prevalence in girls. Autism is typically diagnosed by age 3. The parents or caregivers often report repetitive motions (hand flapping, twirling objects) or isolated abnormal behaviors. Many children with autism receive special instruction and care in school-based settings, but this was not always the case in the past. It is likely that some older adults with autism have never been diagnosed and have never received any assistance.

Patients with autism generally have medical needs similar to those of their peers without autism. Rely on parents or caregivers for information and involve them in the treatment of the patient. As with any patient, explain what you are going to do before you do it. Move slowly, stay calm, and perform physical examinations from distal to proximal. Demonstrate the examination on a parent or caregiver first to show the patient with autism what he or she can expect.

Down Syndrome

Down syndrome is characterized by a genetic chromosomal defect resulting in mild to severe intellectual impairment **Figure 36-1**. The normal human somatic cell contains 23 pairs of chromosomes. In most cases, Down syndrome, also known as trisomy 21, occurs when the two 21st chromosomes fail to separate, so that the ovum or sperm contains 24 chromosomes. When fertilization occurs, a triplication ("trisomy") of chromosome 21 occurs. The extra chromosome disrupts the normal course of development.

Figure 36-1 A child with Down syndrome.

Increased maternal age and a family history of Down syndrome are known risk factors for this condition. Various physical abnormalities are associated with Down syndrome—a round head with a flat occiput; an enlarged, protruding tongue; slanted, wide-set eyes; folded skin on either side of the nose, covering the inner corners of the eye; short, wide hands; a small face and features; congenital heart defects; thyroid problems; and hearing and vision problems. People with Down syndrome usually do not have all of these signs, but a diagnosis can be made rapidly at birth because several of the signs can be seen. Depending on their level of intellectual disability, people with Down syndrome may lead independent lives. They may be employed, vote, and get involved in their communities.

Patients with Down syndrome are at increased risk for medical complications, including those that affect the cardiovascular, sensory, endocrine, musculoskeletal, dental, and gastrointestinal systems, as well as neurologic development. As many as 40% of these patients have heart conditions and hearing and vision problems.

Because people with Down syndrome often have large tongues and small oral and nasal cavities, airway management may be difficult. These patients may also have misaligned teeth and other dental problems. The enlarged tongue and dental problems can lead to speech abnormalities as well. In an emergency situation, if airway management is necessary, bag-valve mask (BVM) ventilation can be challenging. In the case of airway obstruction, a jaw-thrust maneuver may be all that is needed to clear the airway. In an unconscious patient, either the jaw-thrust maneuver or a nasopharyngeal airway may be necessary.

Some people with Down syndrome have epilepsy. Most of the seizures are tonic-clonic. Patient management is the same as with other patients with seizures. Chapter 17, *Neurologic Emergencies*, discusses the emergency management of seizures in detail.

According to the National Down Syndrome Society, the atlantoaxial joint—where the first two vertebrae meet—is unstable in approximately 15% of people with Down syndrome. This is termed atlantoaxial instability (AAI). Most patients with AAI do not show symptoms; however, they are at increased risk of complications when they experience trauma. Keep this in mind when you receive a call for a musculoskeletal problem or possible neurologic problem in a patient with Down syndrome. If the atlantoaxial joint becomes dislocated, as may occur with trauma, the patient may experience difficulty walking, neck pain or decreased neck mobility, and sensory deficits. Such a dislocation can even cause spinal cord injury.

AAI is diagnosed with a radiograph of the cervical vertebrae.

Patient Interaction

It is normal to feel uncomfortable when initiating contact with a patient with an intellectual disability, especially if you have not encountered such situations frequently. The best plan of action is to treat the patient as you would any other patient.

Approach the patient in a calm, friendly manner, watching for signs of increased anxiety or fear. Remember, you are a stranger and are approaching with a group of people. The patient may not understand your uniform or realize that you and your team are there to help. It may be helpful to have your team members wait until you can establish a rapport with the patient. You can then introduce the team members and explain what they are going to do as you slowly bring them forward.

You might interact with a patient with an intellectual disability as follows: "Hello, Mr. Pemberton. My name is Jerry Booker." Shake Mr. Pemberton's hand if he will allow it. "We're here to help you. Your sister called us. She says you're not feeling well today, and we're here to help you feel better. My partner, Tina, is going to take your blood pressure. Do you remember having that done before?" Allow Mr. Pemberton to see and touch the blood pressure cuff as your partner moves forward. Move slowly but deliberately. Explain beforehand what you are going to do, just as with any other patient. Watch carefully for signs of fear or reluctance from the patient. Make sure you are at eye level with the patient. If the patient is sitting, kneel or sit down. This is important in communicating with all patients; however, it is even more important in making the patient with special challenges comfortable.

Do your best to soothe the patient's anxiety and discomfort as you work through your assessment and provide treatment. By initially establishing trust and communication, you will have a much better chance for a successful outcome.

Brain Injury

A patient with a prior brain injury may be difficult to assess and treat. Chapter 28, *Head and Spine Injuries*, discusses traumatic brain injuries in detail. Patients with brain injuries may face a complex array of challenges related to the injury. In such cases, gathering a complete medical history from the patient, family, and friends will be helpful. Your interaction with patients with brain injuries should be tailored to their specific abilities. Take the time to speak with the patient and family to establish what is considered normal for the patient; for example, determine whether the patient has cognitive, sensory, communication, motor, behavioral, or psychologic deficits.

When you care for a patient with a prior brain injury, talk in a calm, soothing tone, and watch the patient closely for signs of anxiety or aggression. In some cases, the patient may need to be specially positioned or restrained to ensure your safety and the safety of the patient. Do not expect the patient to walk to the ambulance or stretcher. As always, treat the patient with respect, use his or her name, explain procedures, and reassure the patient throughout the process.

Sensory Disabilities

Visual Impairment

Visual impairments may result from many different causes—a congenital defect; disease; injury; or degeneration of the eyeball, optic nerve, or nerve pathway (eg, with aging). The degree of visual impairment may range from partial to total. Some patients have a loss of peripheral or central vision; others can distinguish light from dark or identify general shapes.

Visual impairments may be difficult to recognize. During your scene size-up, look for signs that indicate the patient is visually impaired, such as the presence of eyeglasses, a cane, or a service animal **Figure 36-2**. Immediately introduce yourself when you enter the room. Have your team members introduce themselves so that the patient can identify their voices and locations. In addition, retrieve any visual aids and give them to your patient to make the interaction more comfortable.

YOU are the Provider **PART 2**

You arrive at the scene and find the patient lying supine in a hospital-style bed in the living room. He immediately looks at you when you approach him but does not talk to you. The patient's mother tells you that he began running a fever earlier in the day. She further advises you that the patient's home health nurse was present earlier and contacted his physician, who requested that EMS transport him to the hospital. While your partner gathers additional information, you perform a primary assessment.

Recording Time: 0 Minutes

Appearance	Eyes open
Level of consciousness	Conscious and alert; this is his baseline mental status
Airway	Tracheostomy tube in place; upper airway clear of secretions and foreign bodies
Breathing	14 breaths/min via mechanical ventilator
Circulation	Increased pulse rate (strong and regular); skin is pink, hot, and moist; no gross bleeding

3. What are some conditions that would cause a patient to become dependent on a mechanical ventilator?
4. How does a tracheotomy tube affect a patient’s ability to communicate? How can you determine if your patient is alert?

Figure 36-2

A service dog may be easily identified by its special harness.

Courtesy of the Guide Dog Foundation for the Blind. Photographed by Christopher Appoldt.

A visually impaired patient may feel vulnerable, especially during the chaos of a crash scene. The patient may have learned to use other senses, such as hearing, touch, and smell, to compensate for the loss of sight, and the sounds and smells of the scene may be disorienting. Remember to tell the patient what is happening, identify noises, and describe the situation and surroundings, especially if you must move the patient.

The patient may use a cane or walker to ambulate safely. Even if the patient will be carried on a gurney, remember to take the patient’s cane or walker. Unless the patient is in critical condition, a service animal can remain with the patient and will provide reassurance for the patient and prevent delays in transport; however, in some cases you may need to make arrangements for the care or accompaniment of the animal. A friend of the patient or an animal control officer can be helpful in this situation.

An ambulatory patient may be led by a light touch on the arm or elbow. You may also allow the patient to rest his or her hand on your shoulder, as this may enhance the patient’s sense of balance and security while moving. You may also ask patients which method they prefer to use. Patients should be gently guided but never pulled or pushed. Obstacles need to be communicated in advance. Statements such as, “You’re approaching the stairs. We’re going to take five steps down,” will allow the patient to anticipate and navigate the obstacles safely.

Words of Wisdom

Service animals are not classified as pets and should, by law, be permitted to accompany the patient unless it is a critical situation or the animal is out of control. Review the Service Animals section in the Americans with Disabilities Act for further information.

Hearing Impairment

Recall from Chapter 4, *Communication and Documentation*, that hearing impairment can range from a slight hearing loss to total deafness. Some hard-of-hearing patients may have difficulty with pitch, volume, and speaking distinctly. Some patients learn to speak even though they have never heard sounds. Other patients may have heard speech and learned to speak, but have since sustained partial or total hearing loss, leading them to speak too loudly. Many older people will have some degree of hearing loss.

The two most common forms of hearing loss are sensorineural deafness and conductive hearing loss. **Sensorineural deafness**, or nerve damage, results from a lesion or damage to the inner ear. **Conductive hearing loss** is caused by a faulty transmission of sound waves, which can occur when a person has an accumulation of wax inside the ear canal or a perforated eardrum.

Words of Wisdom

As with all interventions for barriers to communication, you should document the use of an interpreter. Also remember that conclusions based on the information from interpreters may not be valid. Ask the interpreter to report exactly what the patient signs and not to add any commentary, however well intentioned.

During your scene size-up, look for clues that a person could be hard of hearing, including the presence of hearing aids, poor pronunciation of words, or failure to respond to your presence or questions. Some patients may not have their hearing aids in place. Assist the patient with finding and inserting any hearing aids as appropriate, or ask family members to help you. It may be helpful to communicate by writing until the hearing aids are located. Most hard-of-hearing patients can also read lips to some extent. Therefore, face the patient while you communicate so that he or she can see your mouth; do not exaggerate your lip movements or look away. Position yourself approximately 18 inches (46 cm) in front of the patient. Because hard-of-hearing patients typically have more difficulty hearing higher frequency sounds, never shout; instead, try lowering the pitch of your voice.

Ask the patient, "How would you like to communicate with me?" Some patients may prefer written communication or the use of gestures or pictures. American Sign Language may be the patient's preferred method of communication **Figure 36-3**. An interpreter, family member, or friend may be a valuable teammate. If needed, ask the interpreter to accompany the patient to the hospital because this may decrease the stress of communication on the patient, EMS crew, and the hospital staff. If an interpreter is not readily available, call the receiving facility to request one as soon as you are aware of the need.

Figure 36-3 Consider learning common terms in American Sign Language related to illness and injury. **A.** Sick. **B.** Hurt. **C.** Help.

Here are some helpful hints for working with patients with hearing impairments:

- Speak slowly and distinctly into the less-impaired ear, or position yourself on that side.
- Change speakers. Given that 80% of hearing loss is related to an inability to hear high-pitched sounds, it may be helpful to have a team member with a low-pitched voice communicate with the patient.
- Provide paper and a pencil so that you may write your questions and the patient may write responses.
- Have only one EMT ask interview questions, to avoid confusing the patient.
- Try the "reverse stethoscope" technique: put the earpieces of your stethoscope in the patient's ears and speak softly into the diaphragm of the stethoscope to amplify your voice.

Hearing Aids

A hearing aid is essentially a device that makes sound louder. Hearing aids cannot restore hearing to normal, but they do improve hearing and listening ability. Hearing aids can be either external or internal, depending on the type of hearing damage. Several types of hearing aids are available Figure 36-4:

- **Behind-the-ear.** The working parts are contained in a plastic case that rests behind the ear.
- **Conventional body.** This older style is generally used by people with profound hearing loss.
- **In-the-canal and completely in-the-canal.** These hearing aids are contained in a tiny case that fits partly or completely into the ear canal.
- **In-the-ear.** All parts are contained in a shell that fits in the outer part of the ear.

Implantable hearing aids are also an option for patients with less profound hearing loss. To insert a hearing aid, follow the natural shape of the ear. The device needs to fit snugly without forcing. If you hear a whistling sound, the hearing aid may not be in far enough to create a seal or the volume may be too loud. Try repositioning the hearing aid, or remove it and turn down the volume. If you cannot insert the hearing aid after two tries, put it in its box, take it with you, and document the transport and transfer of hearing aids to hospital personnel. Never try to clean hearing aids, and do not get them wet.

If you are able to insert the hearing aid but it is not working, try troubleshooting the problem. First, make sure the hearing aid is turned on. Try a fresh battery, and check the tubing to make sure it is not twisted or bent. Ensure that the switch is set on M (microphone), not T (telephone). For a conventional body-type aid, try a spare cord; the old one may be broken or shorted. Finally, make sure the ear mold is not clogged with wax.

Figure 36-4 Different types of hearing aids. **A.** Behind-the-ear. **B.** Conventional body. **C.** In-the-canal. **D.** In-the-ear. **E.** Completely in-the-canal.

Words of Wisdom

Many patients with borderline hearing impairments may not be aware of the extent of their problem. The distracting and noisy EMS environment may worsen the situation. If a patient frequently asks you to repeat things, suspect a hearing impairment.

Words of Wisdom

Some patients who are hard of hearing are sensitive to loud noises close to their ears. Remember to use a normal tone of voice when speaking to these patients.

Physical Disabilities

Cerebral Palsy

Cerebral palsy is a term for a group of disorders characterized by poorly controlled body movement **Figure 36-5**. This disorder is a result of damage to the developing fetal brain while in utero, oxygen deprivation at birth, a traumatic brain injury at birth, or infection such as meningitis during early childhood. Patients with cerebral palsy can have symptoms that range from mild to severe, involving poor posture and uncontrolled, spastic movements of the limbs.

Cerebral palsy is also associated with other conditions such as visual and hearing impairments, difficulty communicating, epilepsy (seizures), and intellectual disabilities. A significant majority of patients with cerebral palsy possess some degree of intellectual impairment, whereas others have a normal intelligence level and are able to live independently with minimal support. Patients with cerebral palsy may have an unsteady gait (ataxia) and may require the assistance of a wheelchair or walker. Transport this type of equipment with the patient, provided it can be secured properly in the ambulance.

As with all patients, assessing the ABCs is of the utmost importance when treating a patient with cerebral palsy. Closely observe the airway status of a patient with cerebral palsy because these patients may have increased secretion production and difficulty swallowing (dysphagia), requiring aggressive suctioning to clear the airway.

Figure 36-5 A person with cerebral palsy.

When you care for a patient with cerebral palsy, note the following:

- Do not assume that patients with cerebral palsy have an intellectual disability. Although 75% of patients have some intellectual disability, many people with cerebral palsy have a normal IQ or only slight intellectual impairment.
- Limbs are often underdeveloped and are prone to injury (eg, a fall from a wheelchair).
- Patients who have the ability to walk may have an unsteady gait and be prone to falls.
- If the patient has a specially made pillow or chair (as many pediatric patients do), the patient may prefer to use it during transport. Remember to pad the patient to ensure his or her comfort, and never force a patient's extremities into any position.
- Whenever possible, transport walkers or wheelchairs with the patient.
- Approximately 25% of patients with cerebral palsy have a seizure disorder. Be prepared to address a seizure if one occurs, and keep a suctioning unit available. Consider requesting additional advanced life support (ALS).

Spina Bifida

Spina bifida is a birth defect caused by the incomplete closure of the spinal column during embryonic or fetal development, resulting in an exposed portion of the spinal cord **Figure 36-6**. The opening can be closed surgically, but the child is often left with spinal and neurologic damage. Adequate maternal intake of vitamin B (folic acid) reduces the risk of spina bifida. Most defects occur before the woman knows she is pregnant, so since 1992, the US government has mandated that foods such as breads, cereals, and grains be fortified with vitamin B. This effort has decreased the incidence of spina bifida, but, unfortunately, it is still one of the most common disabling birth defects in the United States. Some patients with spina bifida also have hydrocephalus, which requires the placement of a shunt to drain excessive amounts of cerebrospinal fluid (CSF) from the brain.

Figure 36-6 Spina bifida is one of the most common disabling birth defects in the United States.

Be aware that some patients with spina bifida have partial or full paralysis of the lower extremities, loss of bowel and bladder control, and an extreme allergy to latex products. Latex-free products should be kept on the ambulance to avoid a severe anaphylactic reaction in patients with spina bifida.

Patients with spina bifida will benefit from the same considerations that you offer when you treat a patient with paralysis or a patient who has difficulty moving. Ask patients how it is best to move them before you transport them. It is highly likely that a patient in your community will have spina bifida.

Paralysis

Paralysis is the inability to voluntarily move one or more body parts. It may be caused by stroke, trauma, or birth defects. Paralysis does not always involve a loss of sensation. Some patients will have normal sensation or even hyperesthesia (increased sensitivity), which may cause the patient to experience touch as pain in the affected area. Paralysis of one side of the face may cause communication challenges.

The diaphragm of some paralyzed patients may not function correctly, requiring the use of a ventilator. Patients may also rely on specialized equipment such as urinary catheters, tracheostomy tubes, colostomy bags, or feeding tubes, which are discussed later in this chapter. Some patients may have difficulty swallowing, creating the need for suctioning. Each type of spinal cord paralysis requires its own equipment and may have its own complications.

Patients who have partial or total loss of sensation in a limb cannot tell you when you are injuring them. Always use a gentle touch and take great care when lifting or moving a paralyzed patient. Ask patients how it is best to move them before you transport them.

Bariatric Patients

Obesity is a complex condition in which a person has an excessive amount of body fat. It is the result of an imbalance between calories consumed and calories used. The solution to the obesity problem may sound simple—reestablish the caloric balance—but, unfortunately, the causes of obesity are not fully understood. Many cases of obesity may be attributed to a low metabolic rate or genetic predisposition.

YOU are the Provider — PART 3

The patient's axillary temperature reads 101.2°F (38.4°C). The patient has a gastrostomy tube and his mother tells you that she administered an appropriate dose of acetaminophen through the tube about an hour ago. Your partner assesses the patient's vital signs while you perform a physical examination, which reveals no obvious abnormalities. You note that the patient has a colostomy bag and an indwelling urinary catheter.

Recording Time: 5 Minutes	
Respirations	14 breaths/min; provided by mechanical ventilator
Pulse	110 beats/min; strong and regular
Skin	Pink, hot, and moist
Blood pressure	118/62 mm Hg
Oxygen saturation (Spo_2)	99% (on oxygen)

5. What are some potential complications that may result from your patient's condition? What can you do to prevent them or minimize the risks?
6. What do you suspect is the patient's underlying problem? What specific treatment should you provide to him?

According to the Mayo Clinic, the term *obese* is used when someone is 30% or more over his or her ideal body weight. This is a good general guideline, except in cases where body weight does not correlate to excess fat, for example in very muscular people. In severe obesity (also called extreme or morbid obesity), the person is two or three times over the ideal weight. The person's quality of life is often negatively affected, and the extra weight can cause a variety of problems, such as mobility difficulties, diabetes, hypertension, heart disease, and stroke.

Interaction With Patients With Obesity

People with obesity are often ridiculed publicly and sometimes become targets of discrimination. Patients with obesity may be embarrassed by their condition or fearful of scorn as a result of past experiences. Some of those negative interactions may have occurred with an insensitive health care professional. As with any patient, work hard to put these patients at ease. Establish the patient's chief complaint and then communicate your plan to help. Many patients with severe obesity have a complex and extensive medical history, so mastering the art of conducting a patient interview will serve you well in your patient interactions.

If transport is necessary, plan early for extra help and do not be afraid to call for additional providers and/or specialized equipment if necessary. In particular, send a member of your team to find the easiest and safest exit to use. Remember, everyone's safety is at stake! You do not want to risk dropping the patient or injuring a team member by trying to lift too much weight. Moves, no matter how simple they may seem, become far more complex when handling a patient with obesity.

Interaction With Patients With Morbid Obesity

Morbid obesity affects about 9 million adult Americans. These patients may overcome mobility difficulties by pulling, rocking, or rolling into a position. The constant strain on their body's structures may leave them with chronic joint injuries or osteoarthritis. When you move a patient with morbid obesity, follow these tips:

- Treat the patient with dignity and respect.
- Ask the patient how it is best to move him or her before attempting to do so.
- Avoid lifting the patient by only one limb, which would risk injury to overtaxed joints.
- Coordinate and communicate all moves to all team members prior to starting to lift.
- If the move becomes uncontrolled at any point, stop, reposition, and resume.
- Look for pinch or pressure points from equipment because this could cause significant soft-tissue injuries or deep venous thrombosis.
- Large patients will often have difficulty breathing in a supine position. When safe and appropriate to do so, elevate the head of the stretcher when transporting patients with obesity.
- There are many types of specialized equipment for patients with obesity, and some areas have specially equipped bariatric ambulances for such patients. Become familiar with the resources available in your area.
- Plan egress routes to accommodate large patients, equipment, and the lifting team members. Remember: Do no harm!
- Notify the receiving facility early to allow special arrangements to be made prior to your arrival to accommodate the patient's needs.

Special Populations

As with older adults and pediatric patients, be alert for the possibility of abuse and neglect when treating patients with special challenges.

Signs of abuse include evidence of multiple injuries in various stages of healing, injuries that do not seem to correspond to the history provided by caregivers, and burns associated with a suspicious history. Injuries related to abuse are often inflicted in areas not readily seen. Make the patient as comfortable as possible, then remove his or her clothing to evaluate skin for signs of abuse. Document all findings and report them to the physician at the emergency department (ED) and any mandated reporting agency in your state.

Signs of neglect include poor hygiene, unkempt hair, male patients who are unshaven, frequent sickness, and inappropriate clothing for the weather.

Patients With Medical Technology Assistance

Tracheostomy Tubes

Recall that a **tracheostomy** is a surgical procedure that creates a **stoma**, or opening, through a patient's skin and into an organ or other structure. A tracheal stoma provides a path between the surface of the neck and the trachea. Often, this stoma is kept open by the insertion of a plastic **tracheostomy tube**. The tube, which can be temporary or permanent, passes from the neck directly into the major airways **Figure 36-7**.

Patients who may breathe through a tracheostomy tube include those who depend on home automatic ventilators and those who have chronic pulmonary conditions. Because these tubes are foreign to the respiratory tract, the body reacts by building up secretions in or around the tube. The tubes are prone to obstruction by mucous plugs or foreign bodies. Routine care that is provided by caregivers includes keeping the inner cannula of the tracheostomy tube clean and dry and suctioning any secretions.

An obstruction of the tracheostomy tube is an emergency that requires you to intervene immediately. This type of emergency can be stressful to deal with, so it is imperative to remember the ABCs and airway management. A useful mnemonic in these situations is DOPE **Table 36-1**. The DOPE mnemonic can help you remember the possible causes of an airway obstruction and correct the problem. Failure to clear an obstructed tracheostomy tube could lead to cardiopulmonary arrest.

Figure 36-7

Some patients require a tracheostomy tube to breathe.

Portex® Blue Line® Ultra Tracheostomy courtesy of Smiths Medical.

Table 36-1 DOPE Mnemonic

D	Displaced, dislodged, or damaged tube
O	Obstructed tube (secretions, blood, mucus, vomitus)
P	Pneumothorax
E	Equipment failure (kinked tubing, ventilator malfunction, empty oxygen supply)

There may be bleeding or air leaking around the tube. This is more likely to happen with new tracheostomies. The tube can become loose or dislodged. Occasionally, the opening around the tube may become infected. Your care of a patient with a tracheostomy tube includes maintaining an open airway, maintaining the patient in a position of comfort, administering supplemental oxygen as needed, and providing transport to the hospital.

Some patients with tracheostomy tubes and special health care needs may have muscle contractions that will not allow you to place them in the typical semi-Fowler position; in these cases, suction the patient in a position of comfort. If trauma is involved, protect the cervical spine.

If suctioning of the tracheostomy tube is necessary, first attempt to use the patient's suction device. It is probably already sized correctly and readily available. If the size of the suction catheter is unknown, estimate the size by doubling the inner diameter of the tracheostomy tube. To determine the length of the suction device, ask a family member or measure the length of a spare tracheostomy tube. If the length of the patient's tracheostomy tube cannot be determined, insert the suction device no more than 1 to 2 inches (3 to 6 cm) deep. The suction unit should be set to 100 mm Hg. You may need to instill 2 to 3 mL of saline before suctioning thick tracheal secretions. Do not suction for more than 10 seconds, and do not force the suction catheter into the cannula. Oxygenate before and after the procedure. Call for ALS backup.

Mechanical Ventilators

Patients who are on a mechanical ventilator at home cannot breathe without assistance **Figure 36-8**. Patients requiring a mechanical ventilator may not have an underlying respiratory drive because of a congenital defect or a chronic lung disease process. Other patients may have a traumatic brain injury, muscular dystrophy, or another disease process that weakens their ability to breathe and requires a permanent tracheostomy and mechanical ventilator.

Figure 36-8 A home ventilator.

Remember that patients with tracheostomies typically do not breathe through their mouth and nose; therefore, a face mask or nasal cannula cannot be used to treat them. If the ventilator malfunctions, remove the patient from the ventilator and apply a tracheostomy collar. This oxygen-delivery device is specifically designed to cover the tracheostomy stoma and features a strap that goes around the neck. Tracheostomy collars are usually available in intensive care units, where many patients have tracheostomies, and may not be available in a prehospital setting. If you do not have a tracheostomy collar, you can improvise by placing a face mask over the stoma **Figure 36-9**. Even though the mask is shaped to fit the face, you can usually achieve an adequate fit over the patient's neck by adjusting the strap.

Patients on home mechanical ventilators require assisted ventilation throughout transport. Remember that the patient's caregivers will know how the mechanical ventilator works and can help you attach the bag and valve from a BVM to the tracheostomy tube in preparation for transport.

Words of Wisdom

Several states have adopted laws that require a backup generator or other devices to prevent the loss of electric supply to the homes of families or institutions that have patients using mechanical ventilators.

Figure 36-9 If you do not have a tracheostomy collar, use a face mask instead.

YOU are the Provider — PART 4

You consult with medical control and receive instructions on how to proceed. The mechanical ventilator is too large to fit in your ambulance, so you prepare the BVM, detach the ventilator circuit from the tracheostomy tube, and begin manual ventilations at 12 breaths/min. You carefully move the patient to your stretcher, secure him properly, and load him into the ambulance. Following medical control's direction, you continue to manually ventilate the patient, reassess his vital signs, and begin transport to the hospital.

Recording Time: 15 Minutes	
Level of consciousness	Conscious and alert
Respirations	12 breaths/min; provided by BVM
Pulse	118 beats/min; strong and regular
Skin	Pink, hot, and dry
Blood pressure	120/60 mm Hg
Spo_2	98% (on oxygen)

7. What is the benefit of allowing the patient's mother to accompany her son to the hospital?

Apnea Monitors

While caring for an infant with special challenges, you may come across an apnea monitor. The apnea monitor is typically used when there is a family history of sudden infant death syndrome or when an infant is born prematurely, has severe gastroesophageal reflux that causes choking episodes, or has experienced an apparent life-threatening event. Chapter 34, *Pediatric Emergencies,* discusses sudden infant death syndrome and apparent life-threatening events in detail. Because the central nervous system is not mature in pediatric patients with special challenges, in infants the apnea monitor is used for 2 weeks to 2 months after birth to monitor the respiratory system. A typical episode of apnea may last for approximately 15 to 20 seconds, during periods of sleep. The apnea monitor is designed to sound an alarm if the infant experiences bradycardia or an episode of apnea occurs.

The apnea monitor is attached with electrodes or a belt wrapped around the infant's chest or stomach. A pulse oximeter may also be used. The apnea monitor will provide a pulse oximetry reading that will help you assess the patient's respiratory status.

The parents or caregivers of pediatric patients with special challenges will be a useful resource when obtaining the patient's medical history and a history of the events leading to the call for assistance. Parents and caregivers become knowledgeable regarding the use of apnea monitors and may be able to provide you and your partner with a computerized printout to share with ALS providers or ED personnel. If possible, bring the apnea monitor to the receiving hospital with the pediatric patient so that it may be evaluated and any stored information may be retrieved for further analysis.

Internal Cardiac Pacemakers

An internal cardiac pacemaker is a device implanted under the patient's skin to regulate the heart rate. These devices are typically placed on the nondominant side of the patient's chest so that normal activities are not hindered. In small or extremely thin patients, the device may be implanted in the abdomen. Some pacemakers include an automated implanted cardioverter defibrillator, which monitors the patient's heart rhythm and is able to slow accelerated heart rates.

Never place defibrillator paddles or pacing patches directly over the implanted device. It can be helpful for the hospital staff if you gather information about the cardiac pacemaker while you obtain the patient's history during the patient assessment process. Some patients will have a pacemaker identification card in their wallets that contains information specific to the device Table 36-2.

Table 36-2 Questions for Patients With Pacemakers

- What type of heart disorder do you have?
- How long has this device been implanted?
- What is your normal baseline rhythm and heart rate?
- Is your heart completely dependent on the pacemaker device?
- At what heart rate will the defibrillator fire?
- How many times has the defibrillator shocked you?

Left Ventricular Assist Devices

A left ventricular assist device (LVAD) is a special piece of medical equipment that takes over the function of one or both heart ventricles. These types of devices are typically used as a bridge to heart transplantation while a donor heart is being located or as a permanent solution for patients who do not qualify for a transplant. In addition to the multiple LVAD devices available for adult patients with heart failure, there is one ventricular assist device that has been approved for use in patients aged 5 to 16 years. It may be difficult to palpate a pulse in patients who use an LVAD. In such cases, assess perfusion by noting level of consciousness, skin color, temperature, moisture, and blood pressure.

If you encounter a patient with an LVAD, you will primarily provide support measures and basic care. The parents or caregivers should be knowledgeable about the device, so use them as a resource during transport. The patient should have a "go bag" that must always be transported with him or her. Risk factors associated with the implantation of an LVAD include excessive bleeding following the surgery, infection, blood clots leading to strokes, and acute heart failure. Be prepared to provide cardiopulmonary resuscitation. Keep in mind that the LVAD may be functioning in the absence of a palpable pulse. If you encounter a patient with this device, contact medical control or follow your local protocols. Understand that CPR will likely dislodge the device or its connections. Notify ALS personnel as soon as possible so that other supportive measures may be initiated.

External Defibrillator Vest

This device is a vest with built-in monitoring electrodes and defibrillation pads, which is worn by the patient under his or her clothing. The vest is attached to a monitor that provides alerts and voice prompts when it recognizes a dangerous rhythm and before it delivers a shock. The device uses high-energy shocks similar to an automated external defibrillator (AED), so avoid contact with the patient if the device warns that it is about to deliver a shock.

Words of Wisdom

Special equipment such as an LVAD often includes a 1-800 number to call for information specific to patient care. Patients and family members typically carry identification cards with necessary phone numbers and may be able to share this information with you.

If the patient is in cardiac arrest, the vest should remain in place while you perform CPR unless it interferes with compressions. Any patient who is wearing a device that has already delivered a shock should be transported to an appropriate hospital for further evaluation. See Chapter 16, *Cardiovascular Emergencies*, for further information.

Central Venous Catheter

A central venous catheter, or central line—a catheter that has its tip placed in the vena cava to provide venous access—is used for many types of home care patients, including those receiving chemotherapy, long-term antibiotic therapy, pain management, total parenteral nutrition (TPN), and hemodialysis **Figure 36-10**. Central venous catheters are often located in the chest, upper arm, or subclavicular area.

Problems associated with central venous catheters include broken lines, infections around the lines, clotted lines, and bleeding around the line or from the tubing attached to the line. If bleeding occurs, apply direct pressure to the tubing and provide prompt transport to the hospital.

Gastrostomy Tubes

Gastrostomy tubes, sometimes referred to as gastric tubes or G-tubes, are placed into the stomach of patients who cannot ingest fluids, food, or medication by mouth **Figure 36-11**. These tubes may be inserted through the nose or mouth into the stomach (using a nasogastric or orogastric tube) or inserted surgically directly into the stomach through the abdominal wall. Gastric tubes may become dislodged during the patient's normal daily activities. If such a situation arises, immediately stop the flow of any fluids being infused through the tube, and assess the patient for signs or symptoms of bleeding into the stomach, such as vague abdominal discomfort, nausea, and vomiting (especially emesis with a "coffee-ground" appearance [older blood] or with bright red blood).

Figure 36-10 Patients who require frequent intravenous medications may have a central line in place.

Figure 36-11 Gastric tubes may be placed through the skin into the stomach for children or adults who cannot be fed by mouth.

© DELOCHE/age fotostock.

Patients who have a gastric tube in place may still be at increased risk of aspiration. Always have suction readily available to clear any materials from the patient's mouth. Stop the flow of any fluids if signs of aspiration are present. Patients with gastric tubes who have difficulty breathing should be transported while sitting or lying on the right side with the head elevated 30 degrees to prevent the contents of the stomach from passing into the lungs. Give supplemental oxygen if the patient has any difficulty breathing.

Patients with diabetes who receive insulin and gastric tube feedings may become hypoglycemic quickly if the gastric tube feedings are discontinued for any reason. Be alert for an altered mental status or a change in the baseline behavior of your patient. Unless the tube is dysfunctional, dislodged, or partially dislodged, continue the tube feeding and transport the pump with you.

Shunts

Some patients with chronic neurologic conditions may have shunts in place. For example, a patient with hydrocephalus will have a shunt. **Shunts** are tubes that drain excess CSF from the ventricles of the brain to keep pressure from building up in the brain.

During your assessment of a patient with a shunt, you will likely feel a device beneath the skin on the side of the head, behind the ear. The device is a fluid reservoir, and its presence should alert you to the possibility that the patient has an underlying shunt. There are different types of shunts, including a ventricular peritoneum shunt and a ventricular atrium shunt. A ventricular peritoneum shunt drains excess fluid from the ventricles of the brain into the peritoneum of the abdomen. A ventricular atrium shunt drains excess fluid from the ventricles of the brain into the right atrium of the heart. A shunt may become blocked or an infection may result in the surrounding tissue. Infections as a result of shunt placement may occur within the first 2 months after shunt insertion. A blocked shunt may present as a medical emergency. If the shunt is unable to drain properly, intracranial pressure may increase, affecting the patient's mental status, and respiratory arrest may occur.

The signs that a patient is in distress include a high-pitched cry or bulging fontanels (in infants), headache, projectile vomiting, altered mental status, irritability, fever, nausea, difficulty with coordination (walking), blurred vision, seizures, redness along the shunt track, bradycardia, and heart dysrhythmias. Emergency medical care includes airway management and artificial ventilation during transport.

Vagus Nerve Stimulators

According to the Epilepsy Foundation, approximately 150,000 patients are diagnosed with epilepsy each year in the United States. Vagus nerve stimulation is a form of treatment used for seizures that are not controlled with anti-epileptic medications or if the patient is not a good candidate for brain surgery. Vagus nerve stimulators stimulate the vagus nerve at predetermined intervals to prevent seizure activity. These devices are used in conjunction with medication to reduce the frequency of seizures. They are not meant to replace medications and are not currently used in children under 12 years. Further studies are being done regarding their effectiveness for seizure disorders. The device, which is about the size of a silver dollar, is surgically implanted under the patient's skin. The stimulator can last for up to 6 years or until the battery runs out. If you encounter a patient with this device, contact medical control or follow your local protocols.

Colostomies, Ileostomies, and Urostomies

A **colostomy** or **ileostomy** is a surgical procedure that creates an opening from the small or large intestine to the surface of the body that allows for elimination of waste products. The special opening is referred to as a stoma. Feces are expelled and collected into a clear external bag or pouch, which is emptied or changed frequently.

If you encounter a patient with a colostomy or ileostomy bag, assess for signs and symptoms of dehydration if the patient reports diarrhea or vomiting. The area around the stoma is prone to infection, so patients and caregivers must be diligent with daily hygiene. Signs of infection include redness, warm skin around the stoma, and tenderness with palpation over the colostomy or ileostomy site.

A **urostomy** is a surgical procedure which connects the urinary system to the surface of the skin, allowing urine to drain through a stoma in the abdominal wall instead of through the urethra. For example, a patient who has had his or her bladder removed due to cancer requires a urostomy.

Contact medical control or follow your local protocols for the care of a patient with a colostomy, ileostomy, or urostomy bag.

Patient Assessment Guidelines

Interaction with the parents or caregivers of a child or adult with special challenges will be an important part of the patient assessment process. The parents, caregivers, or home health care staff members have become experts on the illness or disability, and are trained to use and troubleshoot problems with medical equipment on a daily basis. Assess the patient's baseline vital signs, note any allergies (eg, to medications or latex), medications, and other pertinent medical history. You must first determine the patient's normal baseline status before an assessment of the current condition can be made. It is often helpful to ask, "What is different today?"

Home Care

Home care occurs within a patient's home environment. Patients requiring home services represent a spectrum of special health care populations, including infants and older adults, patients with chronic illnesses, and patients with developmental disabilities. These services are commonly needed among patients older than 65 years.

Services offered by home care agencies include, but are not limited to, meal delivery, house cleaning, laundry, yard maintenance, physical therapy, and personal care, including bathing and wound care. Oftentimes, EMS is called to a residence when a home care provider has found the patient injured or has recognized a change in the patient's health status. Home care personnel are an important resource for you when you are obtaining the patient's baseline health status and the history of the present illness or condition. Home care personnel are usually familiar with the patient's surroundings and can obtain any health care documentation or medications that need to be transported with the patient to the hospital.

Hospice Care and Terminally Ill Patients

Unfortunately, not all illnesses can be cured. As health care providers, you and your team may be called on to assist a patient who has a terminal illness. The patient may be receiving hospice care at a hospice facility or at home.

Patients receiving hospice care are terminally ill, commonly with diseases such as cancer, heart and lung failure, end-stage Alzheimer disease, or acquired immunodeficiency syndrome (AIDS). The patient's physician will have determined that the illness is terminal and in most cases has completed a do not resuscitate (DNR) order or given medical orders for the scope of treatment, outlining the care agreed upon by the patient and/or the family. Hospice care provides comfort care, or palliative care (pain medications), during a person's last days. Comfort care improves the patient's quality of life before death and allows the patient to be with family and friends. If you are called to a facility that provides hospice care or a home with a patient receiving hospice care, you will need to follow your local protocols, the patient's wishes, or legal documents such as a DNR order. All necessary documentation must be brought to the hospital if the patient is to be transported to the hospital and must be noted in the patient care report.

If you are called to the home of a terminally ill patient, the care you give will have a lasting impact on the family. This is a time when empathy and sensitivity are most needed. Some homes with patients receiving hospice care may be chaotic. Family members may be having a difficult time coping with the situation, and they may act angry and hostile. Treat everyone with compassion and understanding. Members of your team may be able to separate family members to speak with them privately to defuse intense emotions and restore order.

Some terminally ill patients who are at home may be receiving outpatient care from a hospice or a home health nurse. You may be called to the home because of a delay in the arrival of the regular care provider or for transport so that a physician can address an immediate need, such as increasing pain. Because terminally ill patients may use a complex variety of pain medications, transdermal patches, or self-administered pain management devices, you may need to consult medical control for guidance.

Even if a DNR order is in place, family members may not understand what to do and they may not be ready to face the death of a loved one. In such cases, obtain a thorough history and compassionately discuss the patient's wishes. Ask to review the DNR order, and contact medical control.

Ascertain the family's wishes about having the patient remain in the home or having the patient transported to the hospital. If a family member asks to accompany the patient, he or she should be allowed to do so. If the family wishes the patient to remain at home, this request should be honored provided it is in accordance with your local or state protocol.

Local protocols for handling the death of a patient vary, so be familiar with your local or state regulations. The protocols identify whether the coroner needs to be called to report the death and, if so, who is responsible for contacting the coroner. Also determine whether a pronouncement of death is required and, if so, who is responsible for the determination.

Poverty and Homelessness

According to a US Bureau of the Census report, in 2013, 14.5% of the US population lived in poverty. People who live in poverty are unable to provide for all of their basic needs such as housing, food, child care, health insurance, and medication. An impoverished person or family may have housing but may go without food or medication in order to pay for that housing. Disease prevention strategies such as dental care, good nutrition, and exercise are likely absent, which increases the probability of disease.

Homelessness occurs when people are unable to acquire and/or maintain affordable housing. According to the National Alliance to End Homelessness, about 600,000 people experience homelessness on any given night in the United States. The homeless population includes people with mental illness, prior brain trauma, victims of domestic violence, people with addiction disorders, and impoverished families. You may be called to care for a person who has experienced sexual or physical assault, mental health problems, overdose, respiratory or heat or cold-related illness, and wound or skin infections.

You are an advocate for all patients. Your job is to provide emergency medical care and transport patients to the appropriate facility. Remember that under the Emergency Medical Treatment and Active Labor Act (EMTALA), all health care facilities *must* provide a medical assessment and required treatment, regardless of the patient's ability to pay. You can also be an advocate by becoming familiar with the social services resources within your community so you can refer patients to these lifelines.

The evolution of Mobile Integrated Healthcare and community paramedicine (MIH-CP) will benefit many patient populations, including patients with special challenges. As EMS services around the country continue to implement these new positions, patients with low-acuity (nonemergency) conditions may be able to be assessed and treated on scene without transport. In addition, EMS roles may expand to include providing telephone advice to 9-1-1 callers, preventive care, chronic disease management, and postdischarge follow-up.

YOU are the Provider — PART 5

You call in your radio report to the ED. During your reassessment, you note that the patient is moving his head around and appears to be fighting your attempts to assist ventilations. You also note an acute change in his vital signs. His mother, who is riding in the back of the ambulance with you, asks you if you know what to do.

Recording Time: 25 Minutes	
Level of consciousness	Conscious; moving his head around; mother advises that he is agitated
Respirations	12 breaths/min; provided by BVM
Pulse	130 beats/min; strong and regular
Skin	Pink, hot, and moist
Blood pressure	134/74 mm Hg
Spo_2	87% (on oxygen)

8. What has most likely happened to your patient? What should you do next?

YOU are the Provider — SUMMARY

1. How will your assessment and treatment of this patient differ from a patient who is not dependent on a ventilator?

The principles of patient assessment and treatment are the same, regardless of the patient's special health care needs and any medical equipment that he or she requires to function or live. As with any patient you encounter, your goal is to maintain the ABCs and safely transport the patient to an appropriate medical facility.

2. What role do the parents or caregivers of patients with special health care needs have in the prehospital setting?

When you care for a patient with special health care needs, it is imperative to listen to the people who take care of the patient. The parents or caregivers provide for the medical needs of the patient *every day*; therefore they are aware of the patient's medical and/or surgical history, his or her baseline mental status, and the names and doses of any medications the patient may be taking.

Parents or caregivers of this patient population are also trained and experienced in the use of any special equipment the patient requires. In many cases, the parent or caregiver will have performed certain interventions prior to calling 9-1-1. It is important to determine what interventions were performed, why they were performed, and what effect they had on the patient's condition.

3. What are some conditions that would cause a patient to become dependent on a mechanical ventilator?

When a person has any acute or chronic condition that impairs his or her respiratory muscles or injures the respiratory centers in the brain, he or she will require the use of a mechanical ventilator.

Your patient has quadriplegia secondary to a spinal injury. If the spinal cord is injured above the level of the fourth cervical vertebra (C4), paralysis of the respiratory muscles will also occur. Without a mechanical ventilator, your patient is unable to breathe at all.

Other conditions that often require mechanical ventilation include traumatic brain injury, muscular dystrophy, cystic fibrosis, and spina bifida. Regardless of why a patient requires mechanical ventilation, the most important thing for you to remember is that without it, he or she is unable to breathe!

4. How does a tracheotomy tube affect a patient's ability to communicate? How can you determine if your patient is alert?

Most patients with tracheostomy tubes are unable to speak. This is especially true if the patient requires mechanical ventilation, because he or she will be unable to breathe if the ventilator is detached from the tracheostomy tube. Tracheostomy patients who are not dependent on ventilators may be able to speak—although not as clearly—if they occlude the opening of the tube.

If patients cannot speak, they may communicate in other ways, such as by nodding the head or blinking the eyes. The parent or caregiver should be able to tell you whether the patient is communicating as he or she typically does and whether he or she is responding to questions appropriately. If the patient responds to questions appropriately, it can be said that he or she is alert.

5. **What are some potential complications that may result from your patient's condition? What can you do to prevent them or minimize the risks?**

Patients with quadriplegia who are dependent on a ventilator are typically confined to a bed for prolonged periods. Prolonged immobilization can cause potentially serious complications, including pressure sores and pulmonary embolism.

Patients who are paralyzed are particularly susceptible to urinary tract infections and pneumonia. Urinary tract infections are typically related to indwelling urinary catheters (Foley catheters). Pneumonia often occurs because of decreased or absent cough reflexes and prolonged immobilization, which increases the risk of pulmonary secretions settling in the lungs and becoming infected.

In patients with indwelling urinary catheters, always maintain the catheter collection bag below the level of the bladder; this position will prevent urine from flowing back into the bladder and therefore minimizes the risk of infection.

Thick mucous plugs can develope in the tubes of patients with tracheostomy tubes, such as your patient, which can impair oxygenation and ventilation. Ask the parent or caregiver when the tube was last suctioned and observe for signs that indicate it may need to be suctioned (eg, restlessness, signs of hypoxemia). Many mechanical ventilators will sound an alarm if there is any obstruction in the ventilator circuit, such as a mucous plug in the tracheostomy tube.

After you have transferred the patient to the ambulance stretcher, ensure that there are no wrinkles or lumps in the sheet or blanket under the patient. This simple step can help prevent pressure sores.

6. **What do you suspect is the patient's underlying problem? What specific treatment should you provide to him?**

The presence of fever suggests infection. In this patient, the infection could have several causes. Furthermore, it may be the result of more than one underlying problem.

Fever is often the only presenting sign of pneumonia in paralyzed patients. This is especially true in patients with quadriplegia because their respiratory muscles are also paralyzed; therefore, outward signs of respiratory distress, such as retractions, are not present. Another possibility is a urinary tract infection.

Infection requires antibiotic therapy, which can be administered only in a hospital setting. Treatment of a patient with a possible infection is mainly supportive: monitor the patient's ABCs, observe standard precautions (eg, gloves, mask if necessary), and transport the patient to the hospital.

7. **What is the benefit of allowing the patient's mother to accompany her son to the hospital?**

The patient's mother should be allowed to accompany her son in the ambulance if she wishes. She can continue to be a source of information en route to the hospital, and could alert you to any changes in the patient's status, which may be obvious only to her.

The patient's mother can also bring supplies that the patient needs which you may or may not carry on your ambulance.

You must also consider the emotional needs of the patient. Unnecessarily separating a patient with special health care needs from his or her primary caregiver can be a source of emotional distress for the patient and the caregiver.

If she prefers to follow the ambulance in her own vehicle, assure her that you will take good care of her son.

8. **What has most likely happened to your patient? What should you do next?**

Your patient's clinical condition has changed. He appears to be fighting the ventilator, which is a sign of agitation. Furthermore, his heart rate has increased and his oxygen saturation level has decreased. You should suspect that he is not receiving adequate ventilation.

Tracheostomy tube obstruction is an emergency that requires immediate intervention; suction the tube and reassess the patient for signs of adequate oxygenation and ventilation.

The DOPE mnemonic can be used to troubleshoot acute deterioration in a patient with a tracheostomy tube. It is critical for you to recognize which problems you can correct and which problems require ALS. For example, if the tracheostomy tube has become dislodged, it must be replaced by a paramedic or physician; EMTs are typically not trained or permitted to perform this procedure. If the patient has a pneumothorax, the patient may require a needle chest decompression, which EMTs are not trained to perform. Follow your local protocols and request an ALS ambulance if necessary and available.

Narrative

Medic 53 dispatched to a residence for a 19-year-old man with a fever. On arrival, found the patient lying supine in a hospital-style bed in the living room of his home. The patient has quadriplegia and is ventilator-dependent secondary to a spinal injury he experienced 2 years ago. On presentation, the patient's eyes were open and he acknowledged EMS presence by nodding his head. According to his mother, who is his primary caregiver, his present mental status is consistent with his baseline. The patient has a tracheostomy tube and is receiving mechanical ventilation at 14 breaths/min. According to the patient's mother, he began running a fever earlier in the day, and the last reading was 101.2°F (38.4°C). She administered 500 mg of acetaminophen via his gastrostomy tube about an hour before EMS arrival. The patient's physician, who was contacted by the home health agency who assists the patient's mother in his care, requested transport via ambulance to the ED. Secondary assessment revealed no gross abnormalities. Breath sounds were auscultated and found to be clear and equal bilaterally. Patient also has an indwelling urinary catheter and a colostomy bag. Assessment of these devices revealed no bleeding, redness around the area of the devices, or any other abnormalities. After consulting with medical control, carefully moved the patient to the ambulance stretcher, disconnected him from the mechanical ventilator circuit, and resumed ventilations with a BVM at 12 breaths/min. Moved patient to ambulance, continued BVM ventilations, and reassessed his vital signs. Patient's mother accompanied her son in the back of the ambulance. Began transport to the hospital and continued to monitor the patient en route. Shortly after calling radio report to receiving facility, noted that patient became acutely agitated; his heart rate markedly increased and his oxygen saturation decreased. Suspected obstruction of the tracheostomy tube; provided suctioning one time and reassessed patient. He was now calm and his heart rate and oxygen saturation stabilized. Remainder of transport was uneventful. Delivered patient to ED and gave verbal report to attending physician. Medic 53 cleared the hospital and returned to service at 1523.**End of report**

Prep Kit

Ready for Review

- Medicine and medical technology continue to improve, and the number of children and adults with chronic diseases or injuries who are living at home or in environments outside of the hospital setting continues to grow.
- You may find children and adults who are living at home dependent on mechanical ventilators, intravenous pumps, or other medical devices to maintain their lives.
- Assess and care for patients with special challenges in the same manner as all other patients.
- Intellectual disability is caused by insufficient development of the brain, resulting in the inability to learn and socially adapt at a normal developmental rate.
- People with Down syndrome often have large tongues and small oral and nasal cavities, so intubation of these patients may be difficult.
- Visual impairments may be difficult to recognize. During your scene size-up, look for signs that indicate the patient is visually impaired, such as the presence of eyeglasses, a cane, or a service animal. Immediately introduce yourself when you enter the room, and have your team members introduce themselves so that the patient can identify their locations and voices.
- Hearing impairment may range from a slight hearing loss to total deafness. Clues that a person could be hard of hearing include the presence of hearing aids, poor pronunciation of words, or failure to respond to your presence or questions.
- Cerebral palsy is associated with other conditions such as visual and hearing impairments, difficulty communicating, epilepsy, and intellectual disability. Patients may also have an unsteady gait (ataxia) and may require the assistance of a wheelchair or walker.
- Patients with spina bifida will have either partial or full paralysis of the lower extremities, loss of bowel and bladder control, and an extreme allergy to latex products.
- Patients with obesity may be embarrassed by their condition or fearful of scorn as a result of past experiences. If transport is necessary, plan early for extra help and do not be afraid to call for more providers or special equipment if necessary. In particular, send a member of your team to find the easiest and safest exit.
- Patients who depend on home automatic ventilators or those who have chronic pulmonary medical conditions may breathe through a tracheostomy tube.
- Patients who are on a mechanical ventilator at home cannot breathe without assistance. If the ventilator malfunctions, remove the patient from the mechanical ventilator and begin ventilations with a bag-valve mask (BVM).
- An apnea monitor is typically used when there is a family history of sudden infant death syndrome or when an infant is born prematurely, has severe gastroesophageal reflux that causes episodes of choking, or has experienced an apparent life-threatening event. The apnea monitor is designed to sound an alarm if the infant experiences bradycardia or if apnea occurs.
- An internal cardiac pacemaker is a device implanted under the patient’s skin to regulate the heart rate.
- A left ventricular assist device (LVAD) is a special piece of medical equipment that takes over the function of one or both heart ventricles. These types of devices are used as a bridge to transplantation while a donor heart is being located or as a permanent solution for patients who do not qualify for a transplant.
- Gastrostomy tubes are placed into the stomach for feeding in patients who cannot ingest fluids, food, or medication by mouth. These tubes may be inserted through the nose or mouth or placed through the abdominal wall surgically.
- External defibrillation vests are worn under a patient’s clothing. They monitor the patient’s cardiac rhythm and provide an audible warning before administering a shock to correct the dysrhythmia.
- Shunts are tubes that extend from the ventricles in the brain to the abdomen to drain excess cerebrospinal fluid (CSF) that may accumulate near the brain.
- A colostomy or ileostomy is a surgical procedure that creates an opening from the small or large intestine to the surface of the body to allow for elimination of waste products. Feces are expelled and collected into a clear external bag or pouch, which is emptied or changed frequently. Similarly, a urostomy drains urine.
- You and your team may be called on to assist a patient who is terminally ill. Terminally ill patients may be in a hospice facility or at home.
- Under the Emergency Medical Treatment and Active Labor Act (EMTALA), all health care facilities *must* provide a medical assessment and required treatment, regardless of the patient’s ability to pay.

Vital Vocabulary

autism spectrum disorder (ASD) A group of complex disorders of brain development, characterized by difficulties in social interaction, repetitive behaviors, and verbal and nonverbal communication.

cerebral palsy A group of disorders characterized by poorly controlled body movement.

colostomy A surgical procedure to create an opening (stoma) between the colon and the surface of the body.

conductive hearing loss Hearing loss caused by a faulty transmission of sound waves.

developmental disability Insufficient development of the brain, resulting in some level of dysfunction or impairment.

Down syndrome A genetic chromosomal defect that can occur during fetal development and that results in intellectual impairment as well as certain physical characteristics, such as a round head with a flat occiput and slanted, wide-set eyes.

ileostomy A surgical procedure to create an opening (stoma) between the small intestine and the surface of the body.

obesity A complex condition in which a person has an excessive amount of body fat.

sensorineural deafness A permanent lack of hearing caused by a lesion or damage of the inner ear.

shunts Tubes that drain excess cerebrospinal fluid (CSF) from the brain to another part of the body outside of the brain, such as the abdomen; lowers pressure in the brain.

spina bifida A development defect in which a portion of the spinal cord or meninges may protrude outside of the vertebrae and possibly even outside of the body, usually at the lower third of the spine in the lumbar area.

stoma An opening through the skin and into an organ or other structure.

tracheostomy A surgical procedure to create an opening (stoma) into the trachea; a stoma in the neck connects the trachea directly to the skin.

tracheostomy tube A plastic tube placed within the tracheostomy site (stoma).

urostomy A surgical procedure to create an opening (stoma) which connects the urinary system to the surface of the skin and allows urine to drain through the abdominal wall.

Assessment *in Action*

You and your partner are traveling to headquarters for your monthly in-service training session when you are dispatched to the home of an 18-year-old woman with a high fever. The dispatcher tells you the patient has autism.

1. Upon arrival at the home, what is the first question you should ask the parent or caregiver?

   A. "Could you please leave the room?"
   B. "Can you give me a detailed history of the patient's autism?"
   C. "What can you tell me about the patient's normal functional level? What makes her feel secure?"
   D. "Can you please head to the hospital?"

2. Which of the following techniques should you use when you are communicating with a patient who has autism?

   A. Exaggerate your lip movements.
   B. Speak normally and provide simple, one-step directions.
   C. Speak loudly into the patient's ear.
   D. You and your partner should talk to the patient together.

3. The patient is cautious around new people. How should you proceed with your assessment?

   A. Start at the head.
   B. Start distal to proximal.
   C. Do not perform a patient assessment in this case.
   D. Take the patient's blood pressure first.

4. When asking the patient questions, you should:

   A. ask her open-ended questions.
   B. ask her multiple questions in a row.
   C. ask her simple, direct questions.
   D. direct all questions to the parent or caregiver.

5. If you are having difficulty gaining the patient's trust, you should:

A. look around for a favorite toy or object and ask the patient about it.
B. let the parent or caregiver talk on behalf of the patient.
C. transport the patient without intervention.
D. obtain a signed refusal from the patient.

6. While you are attempting to take the patient's blood pressure, another call comes across your radio. The patient covers her ears and starts to cry. What does this indicate?

A. Tactile sensitivity
B. Auditory sensitivity
C. Poor patient management
D. Abuse

7. If transport is required in this case, you should:

A. move quickly.
B. use restraints to secure the patient to the stretcher.
C. take the patient by the arm to lead her to the ambulance.
D. use gestures the patient can understand and explain what is happening.

8. The patient starts to perform a self-stimulating activity. You should:

A. allow the patient to continue as long as she does not hurt herself.
B. speak loudly and tell her to stop.
C. restrain her.
D. turn on a radio to distract her.

9. Explain what the "reverse stethoscope" technique is and when it is used.

10. Why might airway management be difficult in a patient with Down syndrome?

National EMS Education Standard Competencies

EMS Operations

Knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

Principles of Safely Operating a Ground Ambulance

› Risks and responsibilities of emergency response (pp 1363–1376)
› Risks and responsibilities of transport (pp 1366–1376)

Air Medical

› Safe air medical operations (pp 1376–1381)
› Criteria for utilizing air medical response (pp 1376–1377)

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Infectious Diseases

Awareness of
› How to decontaminate equipment after treating a patient (pp 1367–1368)
› How to decontaminate the ambulance and equipment after treating a patient (pp 1367–1368)

Knowledge Objectives

1. List the nine phases of an ambulance call; include examples of key tasks EMTs perform during each phase. (pp 1353–1368)
2. Name the medical equipment carried on an ambulance; include examples of supplies that are included in each main

category of the ambulance equipment checklist. (pp 1354–1360)
3. Name the safety and operations equipment carried on an ambulance; include examples of how each item might be used by EMTs in an emergency. (pp 1360–1361)
4. Discuss the importance of performing regular vehicle inspections; include the specific parts of an ambulance that should be inspected daily. (pp 1361–1362)
5. List the minimum dispatch information required by EMS to respond to an emergency call. (p 1363)
6. Describe some high-risk situations and hazards during both pretransport and transport that may affect the safety of the ambulance and its passengers. (pp 1363–1366, 1368–1376)
7. Discuss the specific considerations required to ensure scene safety; include personal safety, patient safety, and traffic control. (pp 1363–1366)
8. Describe the key elements that must be included in the written patient report upon patient delivery to the hospital. (pp 1366–1367)
9. Summarize the tasks EMTs must complete in the postrun phase. (pp 1367–1368)
10. Define the terms cleaning, disinfection, high-level disinfection, and sterilization. (p 1367)
11. Discuss the guidelines for safely and defensively driving an ambulance. (pp 1368–1370)
12. Identify key steps EMTs should take to improve safety while en route to the scene, the hospital, and the station. (pp 1368–1376)
13. List the three factors that dictate the use of lights and siren to the scene and to the hospital; include the risk-versus-benefit factors regarding their use. (pp 1370–1371)
14. Describe the specific, limited privileges that are provided to emergency vehicle operators by most state laws and regulations. (pp 1374–1376)
15. Explain the additional risks and special considerations posed by the use of police escorts, and the hazards and special considerations posed by crossing intersections. (pp 1375–1376)
16. Describe the capabilities, protocols, and methods for accessing air ambulances. (pp 1376–1380)
17. Describe key scene safety considerations when preparing for a helicopter medivac, including establishing a landing zone, securing loose objects, reducing onsite hazards, and approaching the aircraft. (pp 1378–1381)

Skills Objectives

1. Demonstrate how to perform a daily inspection of an ambulance. (pp 1361–1362)
2. Demonstrate how to present a verbal report that would be given to receiving personnel at the hospital upon patient transfer. (pp 1366–1367)
3. Demonstrate how to write a written report that includes all pertinent patient information following patient transfer to the hospital. (pp 1366–1367)
4. Demonstrate how to clean and disinfect the ambulance and equipment during the postrun phase. (pp 1367–1368)

Introduction

During the late 1700s, Napoleon Bonaparte commissioned one of the more advanced professional emergency medical patient care systems in the world. At that time, horse-drawn ambulances already were in use in major cities throughout the United States **Figure 37-1**. American hospitals initiated their own professional ambulance services during the late 1860s. Ambulance attendants traveled with limited medical supplies, including brandy, a few tourniquets, several assorted bandages and sponges, basic splinting material, and blankets.

Today's ambulances are stocked with standard medical supplies. Many are equipped with state-of-the-art technology, including defibrillators and monitors that can transmit information directly to the emergency department (ED), blood and oxygen testing equipment, automatic ventilators, automated cardiopulmonary resuscitation (CPR) machines, global positioning systems (GPS), and computer-aided dispatch consoles. Even when following all safety guidelines, the emphasis on rapid response places the EMT in great danger while responding to calls. Although technology can greatly aid in directing the route and mode of response of the ambulance, it is also distracting and, therefore, potentially places the crew at higher risk for crashes. It is very important that the EMT in the passenger's seat operate the mobile data terminal (MDT) and GPS device and does the actual communicating via radio or cell phone, so the driver is freed up to focus solely on the road, particularly when responding on a call. Anything that takes the driver's attention away from the road for even a second greatly increases the risk of a crash.

Figure 37-1 Horse-drawn ambulances were used in major cities throughout the United States during the 1800s.

Safety Tips

We know texting and driving can lead to serious injuries and/or death, but no one thinks about the use of "necessary" distractions in the ambulance. Talking on the radio, looking at the map on an MDT, or any other action that takes your attention away from driving can also be dangerous.

This chapter discusses ambulance design and how to equip and maintain an ambulance. It focuses on the techniques and judgment that you will need to drive an ambulance or ambulance service vehicle, which include parking considerations, emergency vehicle control and operation, the effects of weather on driving, and common hazards that are encountered while driving an ambulance. Finally, the chapter describes how to work safely with air ambulances.

YOU are the Provider — PART 1

At 1730 hours, you are dispatched to 1245 Chance Place for a "fall." It is a bright sunny spring weekday and the traffic is heavy. You have completed an emergency vehicle operator course and have been cleared by your supervisor to drive the ambulance in emergency mode. You and your partner respond to the scene, which is located a short distance away.

1. What attributes should an emergency vehicle operator possess?
2. What factors should you consider before responding to the scene?

Emergency Vehicle Design

An **ambulance** is a vehicle that is used for treating and transporting patients who need emergency medical care to a hospital. The first use of motor-powered ambulances occurred in the late 1800s. For many decades after that, a hearse was the vehicle that was most often used as an ambulance because it was the only vehicle with enough room for a person to lie down. Few supplies were carried on board, and there was little space for attendants.

The hearse-ambulance has gone the way of its horse-drawn predecessor. Ambulance designs today are based on the *NFPA 1917 Standard for Automotive Ambulances* and, in large part, on suggestions from the ambulance industry and from EMS personnel **Figure 37-2**. One of the most significant developments in ambulance design has been the enlargement of the patient compartment. Another development is the use of **first-responder vehicles** **Figure 37-3**, which respond initially to the scene with personnel and equipment to treat the sick and injured until an ambulance can arrive.

The modern ambulance is a vehicle for emergency medical care that has the following features:

- A driver's compartment
- A patient compartment that can accommodate two EMTs and usually two supine patients (one on the stretcher, one on a bench or area designed with swivel seats to accommodate a backboard) positioned so at least one of the patients can receive CPR during transport
- Equipment and supplies to provide emergency medical care at the scene and during transport, to safeguard personnel and patients from hazardous conditions, and to carry out light extrication procedures

Figure 37-2 Ambulances are crash tested by manufacturers while being designed.

Courtesy of AEV. Used with permission.

- Two-way radio communication so ambulance personnel can speak with the dispatcher, the hospital, public safety authorities, and online medical control
- Design and construction that ensure maximum safety and comfort

Each state establishes its own standards for licensing or certifying ambulance operators. Many agencies now use the federal specifications (NFPA 1917) that cover the following three types of basic ambulance designs **Figure 37-4** **Table 37-1**.

Figure 37-3 First responders, such as firefighters **(A)** and law enforcement personnel **(B)**, are often the first to arrive at a scene.

Figure 37-4 **A.** The conventional, truck cab-chassis has a modular ambulance body that can be transferred to a newer chassis (type I). **B.** The standard van ambulance has a forward-control integral cab body (type II). **C.** The specialty van ambulance has a cab that is mounted on a cut-away van chassis (type III).

A: © Jones & Bartlett Learning. Courtesy of MIEMSS; B: Courtesy of Captain David Jackson, Saginaw Township Fire Department; C: © Kevin Norris/ShutterStock.

The six-pointed **Star of Life** emblem **Figure 37-5** identifies vehicles as ambulances. It is often affixed to the sides, rear, and roof of the ambulance. Local or state regulatory authorities determine what emblems may be displayed on the side of a prehospital care ambulance. **Figure 37-6** illustrates some of the required features of a licensed or certified ambulance.

Phases of an Ambulance Call

An ambulance call has nine phases: preparation, dispatch, en route, arrival at scene, transfer of patient to ambulance, en route to receiving facility (transport), at receiving facility (delivery), en route to station, and postrun, as shown in **Table 37-2**. These nine phases address the vehicle and its crew and their roles when responding to a medical emergency. The details of patient care are not included in these nine phases.

The Preparation Phase

Making sure equipment and supplies are in their proper places and ready for use is an important part of preparing for the call. If items are missing or do not work, they are of no use to you or the patient. It is very important that you are trained to use equipment before using it. New equipment should be placed on an ambulance only after proper instruction is given on its use and care, and, additionally, after approval by the medical director.

Table 37-1 Basic Ambulance Designs

Type I	Conventional, truck cab-chassis with a modular ambulance body that can be transferred to a newer chassis as needed
Type II	Standard van, forward-control integral cab-body ambulance
Type III	Specialty van cab with a modular ambulance body that is mounted on a cut-away van chassis

Figure 37-5 The Star of Life.

Figure 37-6 Warning lights and public address systems are necessary on licensed or certified ambulances.

Table 37-2 Phases of an Ambulance Call

1. Preparation for the call
2. Dispatch
3. En route
4. Arrival at scene
5. Transfer of the patient to the ambulance
6. En route to the receiving facility (transport)
7. At the receiving facility (delivery)
8. En route to the station
9. Postrun

Equipment and supplies should be durable and, to the extent possible, standardized. This makes it easy to quickly exchange equipment with other ambulances or with the ED, thus saving time during patient transfer.

Figure 37-7 Store equipment and supplies in the ambulance according to how urgently and how often they are used.

Store equipment and supplies in the ambulance according to how urgently and how often they are used **Figure 37-7**. Give priority to items that are needed to care for life-threatening conditions. These include equipment for airway management, artificial ventilation, and oxygen delivery. Place these items within easy reach, at the head of the primary stretcher. Place items for cardiac care, control of external bleeding, and monitoring blood pressure at the side of the stretcher. Make sure batteries are fresh and equipment is functioning properly. The most common cause of AED malfunction is a dead battery.

Storage cabinets and kits should open easily. They should also close securely so they do not fly open while the ambulance is in motion. The fronts of cabinets and drawers should be transparent so you can quickly identify the contents inside; if they are not, be sure to label each container **Figure 37-8**.

Medical Equipment

As an EMT, you have access to a large variety of medical equipment and supplies, far more than can be described here. Certain items on the ambulance must be available at all times, as dictated by state and jurisdictional requirements.

Figure 37-8 Containers should be placed in cabinets and drawers with transparent fronts for quick identification.

Basic Supplies. Table 37-3 lists the common supplies carried on ambulances. These include basic items such as disposable gloves and sharps, airway and ventilation equipment, basic wound care supplies, splinting supplies, childbirth supplies, an automated external defibrillator, patient transfer equipment, medications, communication equipment, and other regionally appropriate supplies.

Airway and Ventilation Equipment. Airway management equipment that should be carried on ambulances includes the following:

- Oropharyngeal airways for adults, children, and infants
- Nasopharyngeal airways for adults and children
- Equipment for advanced airway procedures if your service is authorized by state regulation and the medical director to perform these

It is important that two portable artificial ventilation devices that operate independently of an oxygen supply are carried on the ambulance: one for use in the ambulance and one for use outside the ambulance or as a spare. These devices include disposable pocket masks and bag-valve masks (BVMs). In addition, BVMs capable of oxygen enrichment and, when attached to an oxygen supply with the oxygen reservoir in place, able to supply almost 100% oxygen should also be carried on the ambulance. Masks for these devices come in a variety of sizes, from neonatal to adult, and are necessary materials to carry on the ambulance. Oxygen-powered devices are also available to provide ventilation to a patient but may quickly deplete available oxygen sources. You should follow local guidelines to identify the specific ventilation equipment carried on the ambulance.

The ambulance should carry portable and mounted suctioning units Figure 37-9. These units must be powerful enough to generate a vacuum of 300 mm Hg when the tube is clamped. The suctioning force must be adjustable for use on infants and children. The units should include large-bore, nonkinking suction tubing with semirigid tips available. The installed unit should include a suction yoke, an unbreakable collection canister, suction catheters, water for rinsing the suction tips, and suction tubing, all easily accessible when you are sitting at the head of the stretcher. The tubing must reach the patient's airway, regardless of the patient's position. All components of the suctioning unit must be disposable or made of material that is easily cleaned and **decontaminated**.

YOU are the Provider — PART 2

Upon arrival you are led to the backyard where a 62-year-old man is lying beside an overturned stepladder, holding his left arm. He tells you he fell from the third step from the bottom and caught himself on his left hand. He has obvious deformity to his left forearm.

Recording Time: 0 Minutes	
Appearance	Appears healthy; holding left arm; grimacing in pain
Level of consciousness	Alert and oriented
Airway	Open; clear of secretions or foreign bodies
Breathing	Normal rate; adequate depth
Circulation	Increased pulse rate, but strong and regular; skin is pink, warm, and dry

3. Based on the mechanism of injury and patient presentation, what equipment do you anticipate needing?

Table 37-3 Ambulance Equipment Checklist

Basic Supplies

Pillows and pillowcases
Sterile sheets
Blankets
Towels
Disposable emesis bags or basins
Boxes of disposable tissue
Bedpan (optional)
Urinals (one each for men and women; optional)
Blood pressure cuffs (pediatric, adult, large adult)
Stethoscope
Disposable drinking cups
Unbreakable container of water
Wet wipes
Chemical cold/hot packs
Sterile irrigation fluid
Restraining devices
Plastic bags for waste or severed parts
Hypoallergenic nitrile, vinyl, or other disposable hypoallergenic gloves (various sizes)
Sharps container
Set of hearing protectors

Airway and Ventilation Equipment

Infection control kits (goggles, masks, waterproof gowns)
Oropharyngeal airways and nasopharyngeal airways of various sizes
Advanced airway supplies, if local protocol permits (laryngeal mask airway, Combitube, King airways), with secondary placement confirmation devices
BVMs (adult, child, and infant)
Mounted suction unit and a portable suction unit
Assorted oxygen delivery devices (adult and pediatric)
Oxygen supply units (both portable and installed)
Disposable humidifier (for mounted oxygen system)

Basic Wound Care Supplies

Trauma shears
Sterile sheets
Sterile burn sheets
Adhesive tape in several widths
Self-adhering, soft roller bandages, 4 in. × 5 yd
Self-adhering, soft roller bandages, 2 in. × 5 yd
Sterile dressings, gauze, 4 in. × 4 in.
Sterile dressings, abdominal or laparotomy pads, usually 6 in. × 9 in. or 8 in. × 10 in.
Sterile universal trauma dressings, usually 10 in. × 36 in., folded into 9 in. × 10 in. packages
Sterile, occlusive, nonadherent dressings (aluminum foil sterilized in original package)
Occlusive dressings, or chest seals
Assortment of adhesive bandages
Tourniquets

Splinting Supplies

Adult-size traction splint
Child-size traction splint
A variety of arm and leg splints, such as inflatable, vacuum, cardboard, plastic, foam-covered wire-ladder or aluminum alloy, or padded board (the number and type of splints should be determined by state regulations and your medical director)
A variety of triangular bandages and roller bandages
Short backboard/short immobilization device
Long backboard
Cervical collars in an adjustable size or a variety of sizes
Head immobilization devices

Childbirth Supplies

Emergency obstetric kit, including:

- Surgical scissors
- Hemostats or special cord clamps
- Umbilical tape or sterilized cord
- Small rubber bulb syringe
- Towels
- Gauze sponges
- Sterile gloves
- Sanitary napkins
- Plastic bag
- Baby blanket
- Baby stocking cap

Automated External Defibrillator

Semiautomated defibrillation equipment

Patient Transfer Equipment

Wheeled ambulance stretcher
Wheeled stair chair
Other devices also carried on ambulances include:
Scoop stretcher
Portable/folding stretcher
Flexible stretcher
Transfer tarp or slide board
Basket stretcher

Medications and Other Supplies

Activated charcoal
Drinkable water and cups
Oral glucose
Oxygen
Supplies for irrigating the skin and eyes
Aspirin and epinephrine (in some areas)
DuoDote or other regional equipment, depending on the area and local protocol
Portable radio or cell phone

Figure 37-9 The ambulance should carry both a mounted suctioning unit **(A)** and a portable unit **(B)**.

The ambulance should carry at least two oxygen supply units: one portable and one installed on board. The portable unit should be located near a door or in the jump kit, for easy use outside the ambulance. It should have a minimum capacity of 500 L of oxygen and be equipped with a yoke, pressure gauge, flow-meter, oxygen supply tubing, nonrebreathing mask, and nasal cannula. This unit must be able to deliver oxygen at a variable rate between 1 and 15 L/min. At least one extra portable 500-L cylinder should be kept on the ambulance. Many services equip the backup cylinder with its own yoke, gauge, regulator, and tubing so it can be used for a second patient.

The mounted oxygen unit should have a capacity of 3,000 L of oxygen **Figure 37-10**. It should also be equipped with visible flowmeters that are capable of delivering 1 to 15 L/min that are accessible when you are at the head of the stretcher. Oxygen masks, with and without nonrebreathing bags, should be transparent, disposable, and in sizes for adults, children, and infants.

Ambulance services that often transport patients on runs lasting longer than 1 hour should consider using a disposable, single-use humidifier for the mounted oxygen system. On runs of less than 1 hour, humidification is not usually necessary. Humidification may increase a patient's risk of infection unless the equipment is disposable and used on a single patient.

Word of Wisdom

Regardless of their location, portable oxygen tanks must always be secured by fixed clasps or housings to prevent accidental damage and to prevent the cylinder from becoming a projectile.

Figure 37-10 An oxygen unit with a capacity of 3,000 L of oxygen should be mounted on the ambulance.

CPR Equipment. A CPR board provides a firm surface under the patient's torso so you can give effective chest compressions **Figure 37-11A**. It also assists in establishing an appropriate degree of head tilt **Figure 37-11B**. Only a few ambulances across the country carry this item. Use a tightly rolled sheet or towel to raise the patient's shoulders 3 to 4 inches; this will also keep the patient’s head in a position of maximum backward tilt and keep the shoulders and chest in a straight position. *Caution:* Do not use this roll to hyperextend the neck if you suspect a spinal injury.

Figure 37-11 **A.** A CPR board may be carried on the ambulance. **B.** A patient on a CPR board has the appropriate degree of head tilt for effective artificial ventilation.

Mechanical devices that operate on compressed gas and deliver chest compressions and ventilations are also available.

Basic Wound Care Supplies. Basic supplies for dressing open wounds should be carried on the ambulance. These include a pair of trauma shears; sterile sheets; sterile burn sheets; adhesive tape in several widths; self-adhering, soft roller bandages; sterile dressings; gauze; abdominal or laparotomy pads; sterile universal trauma dressings; sterile, occlusive, nonadherent dressings (aluminum foil sterilized in original package); an assortment of adhesive bandages; and tourniquets.

Figure 37-12 Supplies for splinting fractures and dislocations should be carried on the ambulance.

Figure 37-13 A sterile emergency obstetric kit must be carried on the ambulance.

© Mark C. Ide.

Splinting Supplies. Examples of supplies for splinting fractures and dislocations that may be carried on ambulances are shown in **Figure 37-12**. These include an adult-size and a child-size traction splint; a variety of arm and leg splints, such as inflatable, vacuum, cardboard, plastic, foam wire-ladder, or padded board; a variety of triangular bandages and roller bandages; a short backboard; a long backboard; head immobilization devices; and cervical collars in an adjustable size or a variety of sizes.

Childbirth Supplies. You must carry at least one sterile emergency obstetric kit **Figure 37-13** that includes the supplies listed in Table 37-3, including a pair of surgical scissors, hemostats or special cord clamps, umbilical tape or sterilized cord, a small rubber bulb syringe, towels, gauze sponges, pairs of sterile gloves, plastic wrap, sanitary napkins, a plastic bag, a baby stocking cap, and a baby blanket.

Automated External Defibrillator. Modern-day EMS was ushered in by the first-ever prehospital use of the defibrillator by a St. Vincent's Hospital ambulance in New York City under the direction of Dr. William Grace in the early 1970s. Now a prehospital standard of care, semiautomated defibrillation equipment or manual monitor/defibrillators that have automated external defibrillation capability, as permitted by regulation and the local medical director, should always be carried on the ambulance **Figure 37-14**.

Patient Transfer Equipment. Each ambulance should carry the following patient transfer equipment:

- A primary wheeled ambulance stretcher
- A wheeled stair chair for use in narrow spaces
- A long backboard
- A short backboard or short immobilization device

You should be able to tilt the head of the stretcher upward to at least a 60-degree angle semisitting position. Stretchers must be provided with fasteners to secure them firmly to the floor or side of the ambulance during transport. Stretcher restraints should be capable of holding the stretcher in place in case the vehicle rolls over. Make certain that the wheeled stretcher is properly locked into position, because injuries can occur to the patient and you if the stretcher becomes loose while the ambulance is in motion **Figure 37-15**. Make sure there are at least three restraining devices for the patient, such as deceleration or stopping straps over the shoulders, to prevent the patient from continuing to move forward in case the ambulance suddenly slows or stops. Regardless of the equipment used, it is important to perform proper lifting techniques to avoid injuries. Chapter 8, *Lifting and Moving,* discusses proper lifting and moving of patients.

Figure 37-14 Every ambulance should carry an automated external defibrillator.

LIFEPAK® 1000 Defibrillator (AED) courtesy of Physio-Control. Used with Permission of Physio-Control, Inc., and according to the Material Release Form provided by Physio-Control.

Other patient transfer devices that can be used include the following:

- A scoop stretcher
- A portable/folding stretcher
- A flexible stretcher
- A basket stretcher

Medications. It is important that the ambulance carry valid and appropriate medications. Keep the telephone number and radio frequency of online medical control or the local poison control center with you on the ambulance. The back of your clipboard is a good place to keep this information.

The Jump Kit. The ambulance must be equipped with a portable, durable, and waterproof jump kit that you can carry to the patient **Figure 37-16**. Think of the **jump kit** as the *5-minute kit,* containing anything you might need in the first 5 minutes with the patient except for the semiautomated external defibrillator, possibly the oxygen cylinder, and portable suctioning unit. The jump kit must be easy to open and secure. **Table 37-4** lists the items that are typically contained in a jump kit.

Figure 37-15 The wheeled ambulance stretcher should be locked into place at an appropriate height.

Courtesy of Rhonda Hunt.

Figure 37-16 A portable jump kit should contain practically anything you will need during the first 5 minutes with the patient.

Table 37-4 Items Carried in a Jump Kit

- Nitrile, vinyl, or other disposable gloves
- Face shield or mask with goggles
- Triangular bandages
- Trauma shears
- Adhesive tape in various widths
- Universal trauma dressings
- Self-adhering soft roller bandages, 4 in. × 5 yd and 2 in. × 5 yd
- Oropharyngeal airways in adult, child, and infant sizes*
- BVM with masks for adults, children, and infants*
- Blood pressure cuff
- Stethoscope
- Penlight
- Sterile gauze dressings, 4 in. × 4 in.
- Sterile dressings (abdominal pads), 6 in. × 9 in. or 8 in. × 10 in.
- Adhesive strips
- Oral glucose
- Activated charcoal
- Other medications allowed by local protocols

*These might be carried in a separate airway kit, along with the portable oxygen cylinder.

Safety and Operations Equipment

In addition to medical equipment, a properly stocked ambulance carries several kinds of equipment for responder safety, rescue operations, and locating emergency scenes. To do the job effectively, your team will need the following equipment:

- Personal protective equipment (PPE)
- Equipment for work areas
- Preplanning/navigation guides

- Extrication equipment

Figure 37-17 The ambulance should have a weatherproof compartment that can be reached from outside the patient compartment. It should hold equipment for safeguarding patients and EMTs, controlling traffic, and illuminating work areas.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Personal Safety Equipment. Along with your ANSI 2 reflective vest, you should always carry PPE that allows you to work safely in a limited variety of hazardous or contaminated situations. These situations include the edges of a structural fire or explosion, vehicle extrication, and in crowds. The equipment should protect you from exposure to blood and other potentially infectious body fluids. You will not be equipped to face all hazardous materials (HazMat) and other exposure situations that you may encounter; this is the job of specially trained HazMat technicians and response teams. Your equipment might include the following:

- Face shields
- Gowns, shoe covers, caps
- Turnout gear
- Helmets with face shields or safety goggles
- Safety shoes or boots

Equipment for Work Areas. A weatherproof compartment that you can reach from outside the patient compartment should hold equipment for safeguarding patients and EMTs, controlling traffic and bystanders, and illuminating work areas **Figure 37-17**. The following items are recommended:

- Warning devices that flash intermittently or have reflectors (Road flares can pose an additional hazard, such as ignition of flammable liquids or gases.)
- Two high-intensity halogen 20,000 candlepower flashlights of the recharging battery-powered, standup type

- Fire extinguisher, type ABC, dry chemical, 5-lb (2.3-kg) minimum
- Hard hats or helmets with face shields or safety goggles
- Portable floodlights

Preplanning and Navigation Equipment. GPS devices and MDTs are standard equipment in modern ambulances. The addresses of area hospitals and nursing homes should be stored for easy access. Enter the location of the hospital into the GPS device before initiating transport to the hospital. If you are alone in the front of the vehicle, you should never turn your attention away from driving to use a device of any type. Make sure you also have detailed street and area maps in the driver's compartment of the ambulance. Familiarize yourself with the roads and traffic patterns in your town or city so you can plan alternative routes to frequent destinations. Pay particular attention to ways around frequently opened bridges, congested traffic, and blocked railroad crossings. Often, switching to an alternative route will save more time than driving faster. Also be familiar with special facilities and locations within your regional operating area, such as other medical facilities, airports, arenas and stadiums, detention facilities, and chemical or research facilities that might pose unusual problems (staging areas may be predefined for emergency operations).

Extrication Equipment. A weatherproof compartment outside the patient compartment should contain equipment that is needed for simple, light extrication, even if an extrication and rescue unit is readily available. Table 37-5 lists the items that may be included in the compartment.

If rescue and extrication services are not readily available, additional equipment may be needed.

Personnel

Every ambulance must be staffed with at least one EMT in the patient compartment whenever a patient is being transported. Certain situations may require more assistance, such as performing CPR. Some EMS systems may allow non-EMT drivers to operate the ambulance when warranted by patient condition with two EMTs in the patient compartment. In these instances the driver is usually a firefighter or law enforcement official who is properly trained to operate the vehicle in emergency situations.

Table 37-5 Extrication Equipment

- 12-in. wrench, adjustable, open-end
- 12-in. screwdriver, standard square bar
- 8-in. screwdriver, Phillips head #2
- Hacksaw with 12-in. carbide wire blades
- Vise-grip pliers, 10-in.
- 5-lb. hammer with 15-in. handle
- Fire ax, butt, 24-in. handle
- Wrecking bar with 24-in. handle. This may be a combination tool with a hammer and ax.
- 51-in. crowbar, pinch point
- Bolt cutter with 1-in. to 1.25-in. jaw opening
- Folding shovel, pointed blade
- Tin snips, double action, 8-in. minimum
- Gauntlets, reinforced, leather covering past midforearm, one pair per crew member
- Rescue blanket
- Ropes, 5,400-lb. (2,449-kg.) tensile strength in 50-ft. lengths in protective bags
- Mastic knife (able to cut seat belt webbing)
- Spring-load center punch
- Roll of duct tape (for window application prior to center punch use)
- Pruning saw
- Heavy-duty 2-in. × 4-in. and 4-in. × 4-in. shoring (cribbing) blocks, various lengths

Daily Inspections

Being fully prepared means you and your team must inspect both the ambulance and equipment daily to ensure all items are in proper working order. The ambulance inspection should include the following:

- Fuel level
- Oil level
- Transmission fluid level

- Engine cooling system and fluid levels
- Batteries
- Brake fluid
- Engine belts
- Wheels and tires, including the spare, if there is one. Check inflation pressure and look for signs of unusual or uneven wear.
- All interior and exterior lights
- Windshield wipers and fluid
- Horn
- Siren
- Air conditioners and heaters
- Ventilating system
- Doors. Make sure they open, close, latch, and lock properly.
- Communication systems, vehicle and portable
- All windows and mirrors. Check for cleanliness and position.

Check all medical equipment and supplies daily, including all the oxygen supplies, the jump kit, splints, dressings and bandages, backboards and other immobilization equipment, and the emergency obstetrics kit. Is the equipment functioning properly? Are the supplies clean? Are there enough of them? All battery-operated equipment, including the defibrillator, should be operated and checked each day **Figure 37-18**. Rotate the batteries according to an established schedule.

Safety Precautions

A final part of the preparation phase is reviewing safety precautions. These precautions, which include standard traffic safety rules and regulations, should be followed on every call. Check safety devices, such as seat belts (in the cab and patient compartment), to ensure they are in proper working order. Regardless of their location, portable oxygen tanks must always be secured by fixed clasps or housings. Never attempt to secure a tank to the stretcher or bench, unless you are using a commercially manufactured device specifically designed for this purpose; tanks may become projectiles if the ambulance is involved in a motor vehicle crash. In fact, all equipment in the cab, the rear, and in compartments needs to be secured appropriately.

Words of Wisdom

Because mechanical aspects of emergency work such as driving and moving patients strongly impact your safety and that of others, your service should have specific procedures for daily inspections. Following them protects you physically, and documenting your compliance is an important legal protection. Procedures should call for dating and either signing or initialing the check sheets and for storing them where they can be found later if needed.

Figure 37-18 Always check the defibrillator at the beginning of each day.

YOU are the Provider — PART 3

After assessing the patient you determine he is hemodynamically stable. He did not have a loss of consciousness. He has deformity and crepitus to his left forearm with severe pain on palpation. He has a history of hypertension and is allergic to wasp stings and iodine. Even though he does not have neck or back pain, and his mechanism of injury (MOI) is not significant, he agrees to spinal immobilization as a precautionary measure.

Recording Time: 5 Minutes	
Respirations	20 breaths/min; adequate depth
Pulse	98 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	138/86 mm Hg
Oxygen saturation (Spo_2)	99% (on room air)

4. What assessment and treatment should be performed on scene and what should be delayed until you are in the ambulance and en route to the hospital?
5. How would you determine whether to use lights and sirens during transport of this patient?

The Dispatch Phase

Dispatch must be easy to access and in service 24 hours a day **Figure 37-19**. It may be operated by the local EMS or by a shared service that also covers law enforcement and the fire department. The dispatch center might serve only one jurisdiction, such as a single city or town, or it might be an area or regional center serving several communities or an entire county. In either case, it should be staffed by trained personnel who are familiar with the agencies they are dispatching and the geography of the service area. For every emergency request, the dispatcher should gather and record the following minimum information:

- The nature of the call
- The name, present location, and call-back telephone number of the caller
- The location of the patient(s)
- The number of patients and some idea of the severity of their conditions
- Any other special problems or pertinent information about hazards or weather conditions

Many areas implement emergency medical dispatching, which provides the caller with prearrival instructions for patient care before the ambulance arrives. The emergency medical dispatcher follows a set of guidelines to determine the type of information given and then guides the caller through basic care such as bleeding control.

Figure 37-19 The dispatcher is the key communications link throughout all phases of the ambulance run.

En Route to the Scene

In many ways, the en route or response phase of the call is the most dangerous for responders. Crashes between motor vehicles and emergency vehicles cause many serious injuries among EMS personnel. As you and your partner prepare to respond to the scene, make sure you fasten your seat belts and shoulder harnesses before you move the ambulance. You should inform dispatch that your unit is responding and confirm the nature and location of the call. This is also an excellent time to ask for any other available information about the location. For example, you might learn that the patient is on the third floor or that the best door to use is around the side of the house.

While en route to the call, the team should prepare to assess and care for the patient. Review dispatch information about the nature of the call and the location of the patient. Assign specific initial duties and scene management tasks to each team member, and decide what type of equipment to take initially. Depending on your operating procedures, you may also decide which stretcher to take to the patient. Arriving at the scene safely and safely transporting the patient are two of the most challenging aspects of being an EMT. Refer to the defensive ambulance driving section discussed later in this chapter for techniques on safely driving and operating an ambulance.

Arrival at the Scene

On arrival at the incident, you will perform a scene size-up. After you complete your size-up, report to dispatch the nature of the incident if this is part of your local protocol. If other units are en route, provide dispatch with your size-up information to help determine whether the units should continue to the scene. For example, if your size-up determines that the patient is potentially violent, the police unit should continue to the incident scene.

If you are the first to arrive on the scene of a mass-casualty incident, you should inform dispatch that you have arrived and give a brief report of what you see. Also report any unexpected situations, such as the need for additional units, a heavy rescue unit, or a HazMat team **Figure 37-20**. Do not enter the scene if there are any hazards to you. If there are hazards at the scene, the patient should be moved somewhere safe before you begin care. The patient may have to be moved by others if you are not appropriately equipped.

Immediately size up the scene by using the following guidelines:

- Look for safety hazards to yourself, your partner, bystanders, and your patient(s).

Figure 37-20 If you are the first to arrive on the scene of a mass-casualty incident, you should report to dispatch and ask for additional units, such as rescue, or HazMat units as needed.

- Evaluate the need for additional units or other assistance.

- Determine the MOI in trauma patients or the nature of the illness on medical calls.
- Evaluate the need to immobilize the spine.
- Follow standard precautions. The type of care that you expect to give will dictate the personal protective equipment you should wear.

If you are the first EMT at the scene of a mass-casualty incident, quickly estimate the number of patients, and communicate with the incident commander **Figure 37-21**. Inform dispatch that additional units are needed at the scene. Mass-casualty incidents involve complex organization of personnel under the incident command system (see Chapter 38, *Incident Management*). In this system, individual EMTs may be assigned roles, for example, to begin the triage process, assist in treating patients, and load patients for transportation to a hospital.

Safe Parking

In assessing the situation, you must decide where to park the ambulance. Pick a position that will allow for efficient traffic control and flow around a crash scene. Do not park alongside the scene, as you may block the movement of other emergency vehicles. Instead, park in front of or behind the scene, depending on whether other responders have arrived. If other vehicles such as firefighters or law enforcement officers are on scene, they should position their vehicles before the scene, while the EMS vehicle is parked about 100 feet beyond the scene.

Figure 37-21 At a mass-casualty incident, follow instructions from the incident commander assigning your roles, which may include assisting with triage, treating patients, or loading patients for transportation to the hospital.

The first vehicle to arrive on scene should park about 100 feet before the scene on the same side of the road **Figure 37-22**. The first vehicle should create a barrier between the scene and oncoming traffic; if other responders have not arrived on scene, the ambulance can be positioned to block the scene to prevent oncoming traffic from getting too close to the scene or emergency personnel rather than to leave yourself and the scene exposed. It is best to park uphill and/or upwind of the scene if smoke or hazardous materials are present. Always leave on your warning lights or devices, and use extra caution if you must park on the backside of a hill or curve. Do the same when parking at night. When you park, always provide a cushion of space between your vehicle and operations at the scene. Assume someone may collide with your vehicle and strike personnel on the scene **Figure 37-23**.

Safety Tips

When parking at a scene at night you should leave on warning lights but turn off your headlights. This prevents you from blinding oncoming traffic and creating further hazards. Parking lights may also be utilized.

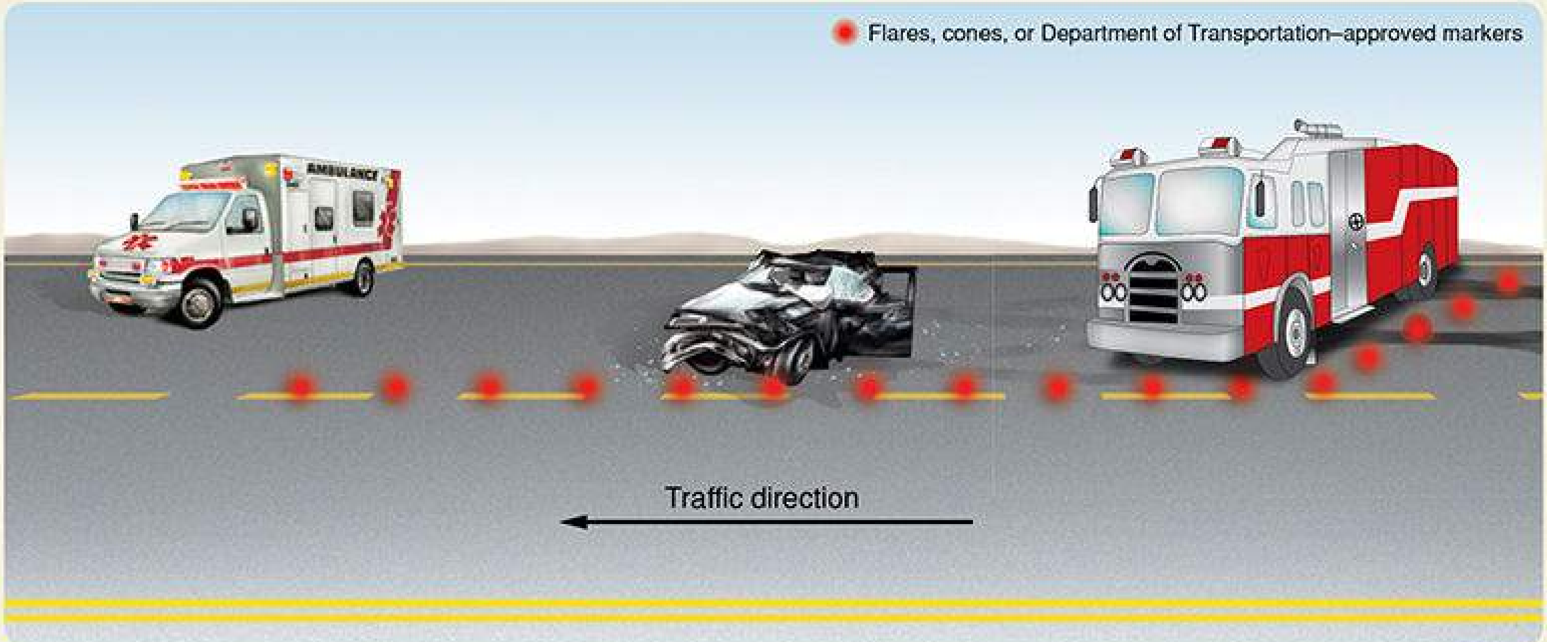

Figure 37-22 Park the ambulance about 100 feet past the scene on the same side of the road.

Figure 37-23 Unsafe parking of an ambulance can result in a crash with other vehicles and injury of personnel.

Stay away from any fires, explosive hazards, downed wires, and structures that might collapse. Be sure to set the parking brake. If your vehicle is blocking part of the roadway, leave on the emergency warning lights. Some motorists tend to drive toward emergency vehicles with flashing red or red and white lights. Turn off headlights to prevent impairing the vision of oncoming traffic. Within these safety guidelines, you should try to park your ambulance as close to the scene as possible to facilitate emergency medical care. If necessary, you can temporarily block traffic to unload equipment and to load patients quickly and safely. If you must do this, try to do it quickly so traffic is not blocked any longer than necessary. Also, you should park in a location that does not hamper leaving the scene. Remember to lock all doors when leaving the ambulance and ensure the designated driver has the keys.

Traffic Control

After you ensure your safety, your first responsibility at a crash scene is to care for the patients. Only after all the patients have been treated and the emergency situation is under control should you be concerned with restoring the flow of traffic. If the police are slow to arrive at the scene, you might then need to take action to control the scene and limit access by other vehicles.

The purposes of traffic control are to ensure an orderly traffic flow and to prevent another crash. Under ordinary circumstances, traffic control is difficult. A crash or disaster scene presents serious additional problems. Passing motorists often slow down and stare, paying little attention to the roadway in front of them. Some curiosity seekers may park down the road and return on foot, creating additional hazards. As soon as possible, place appropriate warning devices, such as reflectors, on both sides of the crash. Remember, the main objectives in directing traffic are to warn other drivers, to prevent additional crashes, and to keep vehicles moving in an orderly manner so care of injured people is not interrupted.

▶ The Transfer Phase

Many patients have said one of the most frightening parts of being suddenly ill or injured is the ambulance ride to the hospital. Already anxious, a patient may be made more so by a fast, bumpy ride with a siren blaring. Sometimes, such a ride is truly lifesaving. However, in most cases, excessive speed is unnecessary and dangerous and may prevent the provider in the back of the ambulance from rendering appropriate care. What is necessary is that the patient be safely transported to an appropriate medical care facility in the shortest practical time. This takes common sense and defensive driving techniques. Speed is no substitute for these qualities. In almost every case, you will provide lifesaving care right where you find the patient, before moving the patient to the ambulance. You may then begin less critical measures, such as bandaging and splinting. Next, you must package the patient for transport, securing him or her to a device such as a backboard, a scoop stretcher, or the wheeled ambulance stretcher. Then move to the ambulance, and properly lift the patient into the patient compartment.

No matter how careful the ambulance driver may be, riding to the hospital while lying down on a stretcher can be uncomfortable and even dangerous. So be sure to secure the patient with at least three straps across the body Figure 37-24. Use deceleration or stopping straps over the shoulders to prevent the patient from continuing to move forward in case the ambulance suddenly slows or stops. This is especially important if the patient is lying flat or secured to a backboard.

Figure 37-24 Secure the patient appropriately for protection during transport.

The Transport Phase

Inform dispatch when you are ready to leave with the patient. Report the number of patients you have, the name of the receiving hospital, and, in some jurisdictions, the beginning mileage of the ambulance. In most cases, even though you have already assessed and treated the patient, you should continue to monitor the patient's condition en route. These ongoing assessments may reveal changes in the patient's vital signs and overall condition. Recheck the patient's vital signs en route. The frequency of checking vital signs depends on the situation, but checking them every 15 minutes for a stable patient and every 5 minutes for an unstable patient is a practice that many services use. In addition, it is important that you continually reassess the patient's clinical situation and record and address new problems and the patient's responses to earlier treatment.

At this time, contact the receiving hospital. Inform online medical control about the patient(s) and the nature of the problem(s). Depending on the number of EMTs and how much care the patient needs, you might also want to begin working on your written report while en route.

Most important, do not abandon the patient emotionally. Do not become so involved in paperwork and ongoing assessments that you ignore the patient's fears. You are there to help the patient, so use this time to reassure him or her.

Some patients, such as very young or older people, may benefit from added attention during transport. Be aware of your patient's level of need.

The Delivery Phase

Inform dispatch as soon as you arrive at the hospital and, depending on your jurisdiction, your ending mileage as well. Then follow these steps to transfer the patient to the receiving hospital:

1. Report your arrival to the triage nurse or other arrival personnel.
2. Physically transfer the patient from the stretcher to the bed directed for your patient.
3. Present a complete verbal report at the bedside to the nurse or physician who is taking over the patient's care.
4. Complete a detailed report, obtain the required signatures, and leave a copy with an appropriate staff member. Electronic reports are commonly used. Your service should have a method for printing or sending electronic reports as well as obtaining electronic signatures.

Figure 37-25 After transferring the patient and relating patient information to the hospital staff, you should restock any items that were used during the run.

The patient care report (PCR) should include a summary of the history of the patient's current illness or injury with pertinent positives and negatives, MOI, and findings on your arrival. In addition, list vital signs and briefly mention relevant past medical or surgical history, as well as information regarding medication and allergies. Also, be sure to include any treatment and its effect during the prehospital setting.

While at the hospital, you may be able to restock any items that were used during the call, such as oxygen masks or dressings and bandages **Figure 37-25**. Remember that your priority is transfer of the patient and patient information to the hospital staff; restocking the ambulance comes second.

En Route to the Station

Once you leave the hospital, inform dispatch whether you are in service and where you are going. As soon as you are back at the station, you should do the following:

- Clean and disinfect the ambulance and any equipment that was used, if you did not do so before leaving the hospital **Figure 37-26**.
- Restock any supplies you did not get at the hospital.

The Postrun Phase

During the postrun phase, complete and file any additional reports and again inform dispatch of the unit status, location, and availability.

Each crew member is responsible for maintaining the ambulance so it is safe and available on a moment's notice. This means you should perform routine inspections and refuel the vehicle. Use a written checklist to document needed repairs or replacement of equipment and supplies.

Figure 37-26 Clean and disinfect the ambulance and equipment at the station if you did not do so at the hospital.

You should know the meanings of the terms "cleaning," "disinfection," "high-level disinfection," and "sterilization," as follows:

- **Cleaning**. The process of removing dirt, dust, blood, or other visible contaminants from a surface or equipment.
- **Disinfection**. The killing of pathogenic agents by directly applying a chemical made for that purpose to a surface or equipment.
- **High-level disinfection**. The killing of pathogenic agents by the use of potent means of disinfection.
- **Sterilization**. A process, such as the use of heat, which removes all microbial contamination.

A basic rule is to do the following after every call:

1. Immediately strip used linens from the stretcher after use, and place them in a plastic bag or in the designated receptacle in the ED.
2. Discard in an appropriate receptacle all disposable equipment used for care of the patient that meets your state's definition of medical waste. Most items will be considered general trash. Discard disposable equipment that is bloody or

contaminated by body fluids in an OSHA-approved biohazard container. Discard noncontaminated disposable equipment used for care of the patient following OSHA and local guidelines.

3. Wash contaminated areas with soap and water. For disinfection to be effective, cleaning must be done first.
4. Disinfect all nondisposable equipment used in the care of the patient. For example, properly clean and disinfect stethoscopes, nondisposable blood pressure cuffs, pulse oximetry probes, and other reusable equipment.
5. Clean the stretcher with an EPA-registered germicidal/virucidal solution or bleach and water at 1:100 dilution.
6. Clean up any spillage or other contamination that occurred in the ambulance, with the same germicidal/virucidal or bleach/water solution.
7. Create a schedule for routine full cleaning for the vehicle.
8. Have a written policy/procedure for cleaning each piece of equipment. Refer to the manufacturer's recommendations as a guide.

Words of Wisdom

Complete your daily duties, such as cleaning quarters, after the ambulance has been checked, cleaned, and restocked. Once these tasks are completed there is usually down time between calls. This is an excellent time to review local protocols and standing orders. Many EMTs also use this time to study for upcoming skills assessments or other courses required for recertification.

Defensive Ambulance Driving Techniques

According to the National Highway Traffic Safety Administration, between 1992 and 2011 (20 years), there were approximately 4,500 motor vehicle traffic crashes involving an ambulance each year. Of these, 65% resulted in damage to property only, 34% resulted in one or more injuries, and 1% (or 45 per year) resulted in one or more fatalities. These statistics show the impact of these crashes on pedestrians, motorists, ambulance passengers, and EMS personnel **Figure 37-27**. Learning how to properly operate your vehicle is just as important as learning how to care for patients when you arrive on the scene. An ambulance that is involved in a crash delays patient care, at a minimum, and may take the lives of the EMTs, or other motorists, or pedestrians, at worst. The following section is provided to introduce you to safe driving techniques; however, you cannot become a proficient and safe ambulance driver without specialized training and practice. You are strongly encouraged to participate in a certified defensive driving program, such as those offered through your EMS organization, before attempting to operate an emergency vehicle.

Figure 37-27 Each year, ambulance crashes are the cause of thousands of injuries to pedestrians, motorists, ambulance passengers, and EMS personnel.

Driver Characteristics

Not everyone who drives a motor vehicle is qualified to drive an emergency vehicle. In some states, you must successfully complete an approved emergency vehicle operations course before you are allowed to drive the ambulance on emergency calls. In any state, due diligence and caution are important characteristics, as are a positive attitude about your ability and tolerance of other drivers.

Many crashes occur as a result of physical impairment of the driver. Do not drive if you are taking medications that may cause drowsiness or slow your reaction time. These include cold remedies, analgesics, and tranquilizers, among others. And, of course, you should never drive or provide medical care after drinking alcohol. While most employers have guidelines that require an employee to stop drinking at least 10 to 12 hours prior to the start of his or her shift, many factors affect the rate of alcohol metabolism, so it is possible to stop drinking for this period of time and still be impaired.

Working long shifts or multiple consecutive shifts also puts drivers at risk for delayed reaction time and/ or falling asleep behind the wheel. While many services have regulations against working beyond a specific number of hours, most do not consider EMTs who may work for more than one service. It is your responsibility to notify your employer if you have previously worked a shift and feel unable to safely operate an emergency vehicle.

Words of Wisdom

Driving an ambulance does not automatically give you the authority to ignore basic traffic laws or operate the vehicle without due regard for the safety of others. The good judgment needed to drive an ambulance requires practice—even for the best drivers.

Another requirement is emotional fitness. Emotions should not be taken lightly. A person's personality often changes once he or she gets behind a steering wheel. Emotional maturity and stability are closely related to the ability to operate under stress. In addition to knowing exactly what to do, you must be able to do it under difficult conditions.

Having the proper attitude is very important for the driver of an ambulance. Never get behind the wheel of an emergency vehicle thinking you can drive in any manner that pleases you simply because you have on lights and siren. You must operate the vehicle with due regard for the safety of others and preservation of property. A greater responsibility is placed on the driver of an ambulance, and generally a lower burden of proof is needed to find that an EMT has caused a crash. As a rule, whenever lights and siren are used on an emergency call and there is a crash, the actions of the emergency vehicle operator fall under the most scrutiny.

Words of Wisdom

Ambulance crashes that kill EMTs, patients, or occupants of other vehicles are disturbingly common. Most of them could have been prevented by the driver of the ambulance. Thoroughly attending to your own driving skills, driving according to established standards, and addressing any obvious lack of skills in your partner's driving are all crucial to your safety on the job.

Safe Driving Practices

The first rule of safe driving in an emergency vehicle is that speed does not save lives; good care does. The second rule is that the driver and all passengers must wear seat belts and shoulder restraints at all times. These are the most important safety equipment items on every ambulance. You should wear restraints en route to the scene and whenever you are not performing direct patient care. Patients should also be properly restrained. Studies show fewer than half of all EMTs wear seat belts while the vehicle is in emergency mode, and few wear lap belts in the rear compartment while patient care is being rendered. If you must remove your seat belt to care for the patient, fasten the belt again as soon as possible. Also, unrestrained or improperly restrained patients and medical equipment (especially portable oxygen tanks) may become airborne during a crash and place you and your patient at an additional risk. All equipment and cabinets must be secured, as well as the patient and any passengers accompanying the patient.

YOU are the Provider — PART 4

The hospital you are transporting to is 12 miles away. The patient's vital signs are normal and he states his pain is a "5" on a 1 to 10 scale. After traveling approximately 5 miles, you realize the ambulance is slowing down. Your partner tells you he has just heard on the radio that there is a motor vehicle crash a couple of miles ahead, and traffic is at a standstill. He says he can turn on the lights and siren and try to get through.

Recording Time: 12 Minutes	
Level of consciousness	Alert and oriented
Respirations	18 breaths/min; adequate depth
Pulse	98 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	136/88 mm Hg
Spo_2	100% (at room air)

6. What should you consider when deciding whether it is appropriate to turn on the lights and siren to maneuver through traffic?
7. If you are in an unfamiliar area and do not know an alternate route, what are your options?

Learn how your vehicle accelerates, corners, sways, and stops. Understand exactly how each particular vehicle will respond to steering, braking, and accelerating under various conditions.

Getting a feel for the proper brake pressure comes with experience and practice. Each vehicle has a different braking action. For example, the brakes on types I and III vehicles have a heavier feel than the brakes on a type II vehicle. The braking system on a diesel-powered unit will be different from the braking system on an identically equipped gasoline-powered unit. Certain heavy vehicles use air brakes, which have yet another feel. Get to know each vehicle you drive, and be sure you understand its braking characteristics and the best downshifting techniques.

When driving an ambulance on a multilane highway, you should usually stay in the extreme left-hand (fast) lane. This allows other motorists to move over to the right when they see or hear the ambulance approach.

Table 37-6 lists further guidelines to follow when en route to a call.

Words of Wisdom

Centrifugal force is the tendency for objects to be pulled outward when rotating around a center. Vehicles are subject to this force when making a turn. If you must brake on a turn, brake gently while making the turn.

Siren Risk-Benefit Analysis

Whether responding to a call or transporting a patient from the scene to the hospital, the decision to activate the emergency lights and siren will depend on several factors such as local protocols, patient condition, and the anticipated clinical outcome of the patient. Some local protocols require that all responses to the scene use emergency lights and siren, whereas other systems incorporate response modes based on the information received from dispatch. Regardless of your jurisdictional requirements, as the driver of the ambulance, you need to evaluate the risk versus benefit of your response mode. Numerous studies have been conducted to determine whether the use emergency lights and siren save time getting to the patient or getting the patient from the scene to the hospital. The findings of these studies show that while time is saved, the time that you do save is minimal.

As an EMT, you will also need to consider the patient's condition before activating emergency lights and siren. For example, patients who have experienced a seizure may have another seizure as a result of the rapid flash pattern of the emergency lighting. In cases such as this, it may be better to transport your patient without lights and siren activated to minimize external stimuli and to prevent making your patient's condition worse.

Table 37-6 Guidelines for Safe Ambulance Driving

1. Select the shortest and least congested route to the scene at the time of the dispatch.
2. Avoid routes with heavy traffic congestion; know alternative routes to each hospital during rush hours.
3. Avoid one-way streets; they may become clogged. Do not go against the flow of traffic on a one-way street, unless absolutely necessary.
4. Watch carefully for bystanders as you approach the scene. Curiosity seekers rarely move out of the way.
5. Park the ambulance in a safe place once you arrive at the scene. If you park facing into traffic, turn off your headlights so they do not blind oncoming motorists unless they are needed to illuminate the scene. If the vehicle is blocking part of the road, keep on your warning lights to alert oncoming motorists.
6. Drive within the speed limit while transporting patients, except in the rare extreme emergency.
7. Go with the flow of the traffic.
8. Always drive defensively.
9. Always maintain a safe following distance. Use the "4-second rule": stay at least 4 seconds behind another vehicle in the same lane.
10. Maintain an open space or cushion in the lane next to you as an escape route in case the vehicle in front of you stops suddenly.
11. Use your siren if you turn on the emergency lights.
12. Always assume other drivers will not hear the siren or see your emergency lights.
13. Always exercise due regard for person and property.

Driver Anticipation

Always assume that motorists around your vehicle do not hear your siren/public address (PA) system or see your vehicle until proven otherwise by their actions. Drivers of ambulances often make the mistake of assuming that motorists and pedestrians will do what is expected of them when an emergency vehicle is in the area. Motorists may indeed pull over to the right and stop or drive as close to the curb as possible, but you cannot take this behavior for granted. At any time, a motorist might stop suddenly in front of the ambulance or pull to the left. Both of these motorist responses may result in a crash. Aggressive ambulance driving may have an opposite effect on motorists, as you may not allow enough time for motorists to respond to your vehicle, or they may become nervous and not react in a rational manner. Whenever a motorist yields the right-of-way, the emergency vehicle operator should attempt to establish eye contact with the other driver. When anticipating how motorists may respond to your lights and siren, always assume that they will react in a manner that may cause a crash. You can also look at the direction of the other vehicle's front tires to get an early indication of which way the vehicle will turn.

It is often quite difficult for motorists to hear instructions called out over the ambulance's PA system, especially when their windows are rolled up. The PA system may actually make the situation worse because motorists may hesitate or make unexpected moves in the attempt to hear or follow instructions. Moreover, when the driver of the ambulance is shouting to motorists and pedestrians over the PA system, he or she is now distracted from the business of driving and forced to handle the microphone when both hands should be on the steering wheel. You should avoid using the ambulance's PA system during emergency driving.

Most important, you must always drive defensively. Never rely on what another motorist will do unless you get a clear visual signal. Even then, you must be prepared to take defensive action in the case of a misunderstanding, panic, or careless driving on the part of the other driver.

The Cushion of Safety

To safely operate an emergency vehicle, you must maintain a safe following distance from the vehicles in front of you and avoid being tailgated from behind. You also must ensure the **blind spots** in your vehicle's rearview and side mirrors do not prevent you from seeing vehicles or pedestrians on either side of the ambulance. Keeping a safe distance between your vehicle and the one in front of you, checking for tailgaters behind your ambulance, and keeping aware of vehicles potentially hiding in your mirrors' blind spots are considered maintaining a **cushion of safety**. To ensure you have enough reaction time and stopping distance from the vehicle in front of you, follow at a safe distance, allowing the motorist enough time to move over to the right. If the motorist does not move, you will need to allow for enough time to avoid the vehicle. This means driving about 4 or 5 seconds behind a vehicle traveling at an average speed.

While operating in emergency mode, tailgaters may follow your vehicle dangerously close in congested areas simply to use your ambulance to get through traffic. This poses a threat to the crew and patient. If the ambulance stops suddenly to avoid a crash (which should not happen if a cushion of safety was maintained), the tailgating vehicle could smash into the rear of the ambulance, possibly causing you to lose control and strike other vehicles or pedestrians. Always scan your rearview and side mirrors for vehicles following too closely. Instruct your partner to stay alert for such vehicles while he or she is in the rear compartment rendering care and to inform you about any tailgaters.

If you are being tailgated, never speed up to create more distance. The tailgater may, in turn, increase his or her speed to continue to follow you through traffic, thereby decreasing your cushion of safety and reaction time and increasing the time and distance needed to avoid a crash. Slamming on your brakes to scare the other driver usually does not work either and may also cause a crash. The best method for distancing yourself from the vehicle is to slow down. Generally tailgaters are impatient and will speed up past you. You can also have your dispatcher contact the local police to let them know that someone is driving recklessly behind you.

Never, under any circumstance, get out of the ambulance to confront a driver. This will only delay your response or transport of the patient and can lead to a dangerous situation. It is also unprofessional for you to become involved in a verbal argument with any member of the public and may lead to disciplinary actions or termination, depending on your service's conduct regulations.

Finally, there are three blind spots around the ambulance that you cannot see with side or rearview mirrors:

- The rearview mirror creates a blind spot, obstructing the view ahead and preventing the driver from seeing objects such as a pedestrian or vehicle. Many new ambulance drivers will not be used to the larger mirrors on ambulances, which create a special hazard that the driver should be aware of. To eliminate this blind spot, you should lean forward in your seat so the mirror does not obstruct the view, especially when making turns at intersections.
- The rear of the vehicle cannot be seen fully through the mirror and is therefore a blind spot. Because of the configuration of today's ambulances and the relative height of the vehicle, the rearview mirror generally gives the driver only a view of the patient compartment and is not intended to be used for alerting the driver of a vehicle behind the ambulance. Because of this blind spot, many crashes occur when the ambulance driver is backing up. It is highly recommended, and required in many jurisdictions, that a **spotter** be used to help you back up the vehicle. Rear-facing cameras are also helpful and much more common; however, they do not replace the use of a spotter if one is available.
- The side of the vehicle often cannot be seen through the side view mirrors at a certain angle. Entire vehicles may not be seen in the mirror, even though they are right next to the ambulance. To eliminate this problem, many EMS systems place small rounded mirrors on the side mirrors to assist you in visualizing this blind spot. However, if these mirrors are not available, you need to lean forward or backward in the seat to help eliminate the blind spot. This is an especially important technique to use when shifting lanes or making turns. Remember, just because you are turning from the

appropriate lane does not mean that another motorist will not try to cut in beside the ambulance or that there is not a bicyclist riding on the side of the road next to you.

Scan your mirrors frequently for any new hazards, so you maintain your cushion of safety; however, keep in mind that your mirrors can give you a misleading view and may block people or vehicles. Adjust your position in the driver's seat to avoid blind spots in your mirrors. Always use a spotter whom you can see from the driver's side mirror and agreed on hand signals when backing up the ambulance.

The Problem of Excessive Speed

Even in extreme life-and-death emergencies, excessive speed is not indicated. In most cases, if you properly assess and render appropriate treatments at the scene, speeding during transport is unnecessary and undesirable. No matter what the situation, you should never travel at a speed that is unsafe for the given road conditions.

Excessive speeds, in addition to being unnecessary, do not increase a patient's chance of survival. More often, using excessive speed while driving to and from the scene has resulted in crashes in which the EMT, the patient, and occupants of other vehicles are killed. It also makes it very difficult for the EMT attending to the patient to be able to provide care because of the rough ride typically created by the excessive speed and maneuvering. Excessive speed also cuts down on the driver's reaction time and increases the time and distance needed to stop the ambulance. While many state laws allow emergency vehicles to travel beyond the posted speed limits in emergencies, they offer little or no protection against prosecution should the driver become involved in a motor vehicle crash. The legal ramifications of driving an emergency vehicle will be covered later in this section.

Recognition of Siren Syndrome

The siren may have a psychological effect on EMS providers as well as on other drivers. Recognizing that the siren may increase the anxiety of other drivers will help you become aware of your or other drivers' tendencies to drive faster in the presence of sirens. Although a siren signifies a request for drivers to yield the right-of-way, drivers do not always do so. The adrenaline rush you experience may cause you to have limited focus and also interfere with your ability to judge distance or the potential actions of others. One of the biggest mistakes you can make as an EMT is to assume motorists will hear the siren and take proper action.

Vehicle Size and Distance Judgment

Vehicle length and width are critical factors when maneuvering, driving, and parking an emergency vehicle. They are especially important with types I and III vehicles, which are wider than they look from behind the steering wheel. To brake and pass effectively, you must know the width and length of your vehicle. Crashes often occur when the driver is backing up the vehicle. Always use someone outside the ambulance as a ground guide when you are backing up to avoid any incidents. Vehicle size and weight greatly influence braking and stopping distances. Good peripheral vision and depth perception will help you judge distances, but they are no substitute for intensive training, experience, and frequent evaluation of the vehicle.

Road Positioning and Cornering

Road position means the position of the vehicle on the roadway relative to the inside or outside edge of the paved surface. To corner efficiently, you must know the vehicle's present position and its projected path. The aim is to take the corner at the speed that will put you in the proper road position as you exit the curve **Figure 37-28**. Whereas the fastest path through a curve is to enter high in the lane (positioned to the outside of the lane), apex low in the lane (to the inside of the lane), and exit high, these actions can result in misjudgment of speed and position, creating the danger of ending up in the opposing lane or off the road if you are traveling too fast. The safest path is to enter high in the lane (to the outside), and exit low (to the inside). This allows room for error if you enter the turn too fast.

Weather and Road Conditions

Whereas most ambulance crashes occur on clear days with dry roads, there are certain conditions that can limit your ability to control your vehicle. Ambulances do not handle the same as motor vehicles. Ambulances have a longer braking time and stopping distance. In addition, the weight of the ambulance is unevenly distributed, which makes it more prone to roll over. These factors, in addition to bad environmental conditions, greatly increase the chance that a crash may occur. Therefore, you should be alert to changing weather, road, and driving conditions **Figure 37-29**. Whether traveling to or from an emergency, you must modify your speed according to road conditions. Take warnings of ice or hazardous conditions seriously, and be prepared to take an alternative route, if necessary. During a major disaster, all public safety and emergency services should be coordinated. If you run into unexpected traffic congestion, notify the dispatcher so other emergency vehicles can select alternative routes.

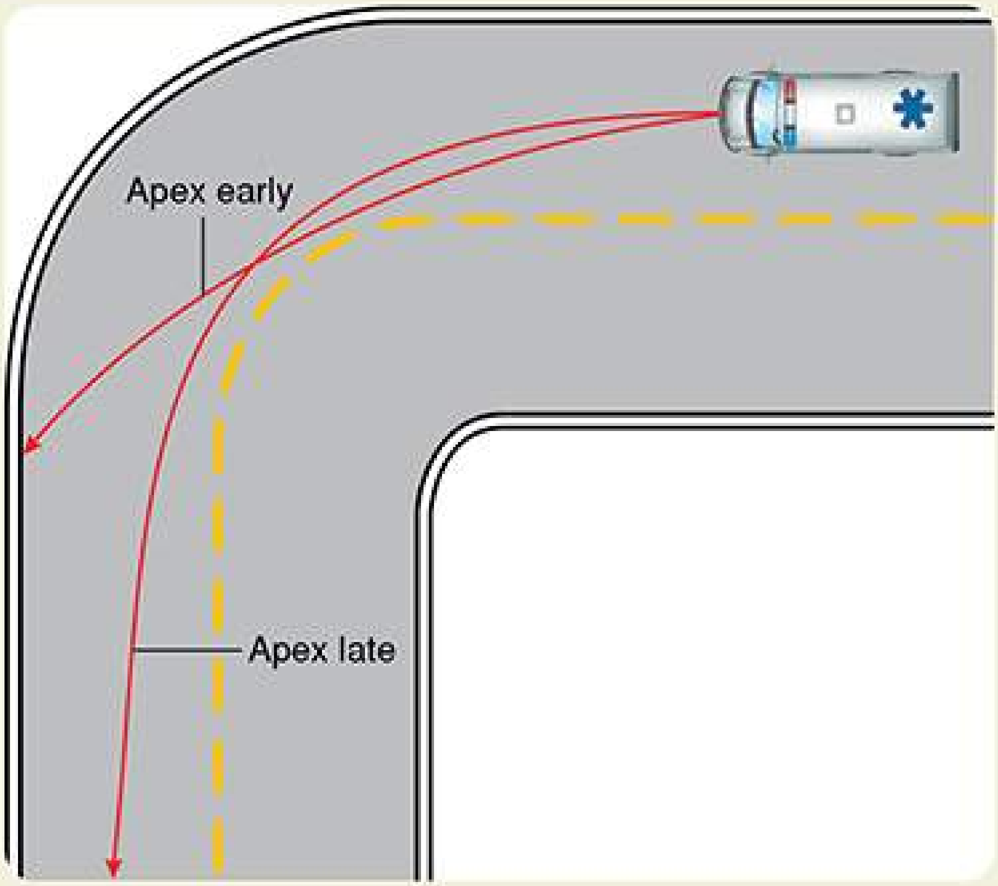

Figure 37-28 To keep the ambulance in the proper lane on a curve, you must know the vehicle's present position and projected path and take the corner at the correct speed.

Even the most careful drivers will occasionally run into unexpected situations that may require special driving skills. However, if you drive at a speed that is appropriate for the weather and road conditions and maintain an adequate cushion of safety, you will minimize these situations. Therefore, it is safer if you decrease your speed in bad weather conditions such as fog, rain, snow, or ice. The following are examples of conditions that require the emergency vehicle operator to decrease speed, increase following distance, and be alert.

Hydroplaning. On a wet road surface, tires are designed to move the water out of the way and stay in direct contact with the road. However, at speeds of greater than 30 mph, tires may be lifted off the road as water "piles up" underneath; the vehicle may then feel as if it is floating. This problem is known as **hydroplaning**. At higher speeds on wet roadways, the front wheels may actually be riding on a sheet of water, robbing the driver of control of the vehicle. If hydroplaning occurs, you should gradually slow down without jamming on the brakes.

Figure 37-29 Modify your speed according to changing weather, road, and driving conditions.

Water on the Roadway. Wet brakes will not slow the vehicle as efficiently as dry brakes, and the vehicle may pull to one side or the other. If at all possible, avoid driving through large pools of standing water; often, you cannot tell how deep they are. If you must drive through standing water, slow down and turn on the windshield wipers. After driving out of the water, lightly tap the brakes several times until they are dry. If the vehicle is equipped with antilock brakes, apply a steady, light pressure to dry the brakes. Driving through moving water should be avoided at all times.

Decreased Visibility. In areas where there is fog, smog, snow, or heavy rain, slow down after warning vehicles behind you by turning your emergency lights on. At night, use only low headlight beams for maximum visibility without reflection. You should always use headlights during the day to increase your visibility to other drivers. Also, watch carefully for stopped or slow-moving vehicles.

Ice and Slippery Surfaces. A light mist on an oily, dusty road can be just as slippery as a patch of ice. Good all-weather tires and an appropriate speed will significantly reduce traction problems. If you are in an area that often has snowy or icy conditions, consider using studded snow tires or tire chains, if they are permitted by law. You should be especially careful on bridges and overpasses when temperatures are close to freezing. These road surfaces will freeze much faster than surrounding road surfaces because they lack the warming effect of the ground underneath.

Words of Wisdom

Although preventing skids and sliding is ideal, you are likely to skid or slide occasionally, especially if you live in climates with ice and snow.

Your training should include the technique for correcting slides during turns. If you are likely to drive on ice and snow, practice control maneuvers until they become automatic—at low speeds in an area where there is no danger of crashes. Remember that four-wheel-drive and front-wheel-drive vehicles behave differently than rear-wheel-drive vehicles when sliding. It is also important to remember that although four-wheel-drive vehicles have better traction for acceleration in slippery conditions, they do not stop any faster than two-wheel-drive vehicles.

Laws and Regulations

Regulations regarding vehicle operations vary by state and by city, but some regulations are the same regardless of location. Drivers of emergency vehicles have certain limited privileges in every state. However, these privileges do not lessen their liability in a crash. In fact, in most cases, the driver is presumed to be guilty if a crash occurs while the ambulance is operating with warning lights and a siren. Motor vehicle crashes comprise a large number of lawsuits against EMS personnel and services.

While on an emergency call, emergency vehicles typically are exempt from normal vehicle operations. If you are on an emergency call and you are using your warning lights and siren, you may be allowed to do the following:

- Park or stand in an otherwise illegal location
- Proceed through a red traffic light or stop sign, but never without stopping first.
- Drive faster than the posted speed limit
- Drive against the flow of traffic on a one-way street or make a turn that is normally illegal
- Travel left of center to make an otherwise illegal pass

Remember that these exemptions vary by state and local jurisdiction. Therefore, you should check your local statutes for regulations in your area.

An emergency vehicle is *never* allowed to pass a school bus that has stopped to load or unload children and is displaying its flashing red lights or extended “stop arm.” If you approach a school bus that has its lights flashing, you should stop before reaching the bus and turn off your siren. Next, you should wait for the bus driver to make sure the children are safe, close the bus door, and turn off the flashing lights. Only then may you carefully proceed past the stopped school bus.

Use of Warning Lights and Siren. Three basic principles govern the use of warning lights and siren on an ambulance:

1. The unit, to the best of your knowledge, must be on a true emergency call.
2. Audible and visual warning devices must be used simultaneously.
3. The unit must be operated with due regard for the safety of all others, on and off the roadway.

Carefully consider when to use or not use your siren. In general, the siren does not help you as you drive, nor does it really help other motorists. Motorists who drive at the speed limit with the windows up, the radio on, and the air conditioner or heater set on high may not hear the siren until the ambulance is very close. If the radio is loud, they may not hear the siren at all.

If you do have to turn on the siren, tell the patient before you do. Be especially mindful not to increase the speed of the ambulance just because the siren is in use. Always travel at a speed that allows you to stop safely at all times, especially so you are prepared for drivers who do not give you the right-of-way. Never assume that warning lights and siren will allow you to drive through a congested area without stopping or slowing down. Slow down to ensure all drivers are stopping as you approach an intersection, and proceed with caution. Remember, the siren is a request that other drivers give you the right-of-way: it does not magically clear traffic. However, driving through a busy intersection against a directional signal without using the siren may also be dangerous and may violate your state law. In these high-risk situations, use all tools at your disposal to ensure nearby traffic is aware of your presence and that the danger is decreased to the greatest degree possible.

Some ambulance headlights are equipped with a high-beam flasher unit. These are very visible, effective warning devices for clearing traffic in front of the vehicle.

Right-of-Way Privileges. State motor vehicle statutes or codes often grant an emergency vehicle, such as an ambulance, the right to disregard the rules of the road when responding to an emergency. However, in doing so, the operator of an emergency vehicle must not endanger people or property under any circumstances.

Consider this case: An ambulance is approaching an intersection that is controlled by a four-way stop sign. The ambulance, with lights and siren turned on, proceeds through the intersection without slowing or stopping and crashes into a vehicle coming from its right. Did the operator of the ambulance act appropriately by going through the intersection in this manner?

Right-of-way privileges for ambulances vary by state. Some states allow you to proceed through a red light or stop sign after you stop and make sure it is safe to go on. Other states allow you to proceed through a controlled intersection "with due regard," using flashing lights and siren. This means you may proceed only if you consider the safety of all people who are using the highway. If you fail to use due regard, your service may be sued. If you are found to be at fault, you may personally have to pay punitive damages or face civil and criminal sanctions.

Get to know your local right-of-way privileges. Exercise them only when it is absolutely necessary for the patient's well-being. The use of lights and audible warning devices is a matter of state and local practice and protocol.

Use of Escorts. Using a police escort is an extremely dangerous practice. When other motorists hear a siren and see a police vehicle passing, they might assume the police vehicle is the only emergency vehicle and not see the ambulance. The only time an escort is justified is when you are in an unfamiliar area and truly need a guide more than an escort. In such cases, vehicles using warning lights or siren should use different tones to alert other motorists and be prepared to stop if needed. If you are being guided, follow at a safe distance. Assume nearby traffic will not be aware of your presence.

Intersection Hazards. Intersection crashes are the most common and usually the most serious type of crash that ambulances are involved in. Always be alert and careful when approaching an intersection. If you are on an urgent call and cannot wait for traffic lights to change, you should still come to a brief stop at the light; look around for other motorists and pedestrians before proceeding into the intersection.

Motorists who "time the traffic lights" present a serious hazard. You may arrive at an intersection while the light is green. At the same time, a motorist who is timing the lights on the cross street arrives at the intersection. The motorist has a red light but knows it is about to turn green and is expecting to go through. This creates the possibility for a serious crash to occur.

Another common intersection hazard occurs when the driver of one emergency vehicle follows another emergency vehicle through an intersection without carefully assessing the situation. A motorist who has yielded the right-of-way to the first vehicle may proceed into the intersection without expecting a second vehicle. You should exercise extreme caution in these situations. To signal motorists that a second unit is approaching, use a siren tone that is different from that of the first vehicle.

Highways. When you are responding to an emergency call and you must travel on the highway, you should turn off your emergency lights and siren until you have reached the far left lane. Turning off your emergency devices minimizes the possibility that other drivers will get confused and not know what to do or where to go.

When driving on a highway with your emergency devices activated, you should always travel in the far left-hand lane. Also known as the "passing lane," this allows the ambulance to safely pass vehicles, while still leaving a safety corridor on the left side of the ambulance in case of emergency or unexpected obstacles.

When you exit the highway, you should follow the same procedures as when you entered the highway: turn off all emergency devices, move onto the off-ramp, and then turn on the emergency lights and siren if necessary.

Unpaved Roadways. When you are required to drive the ambulance on an unpaved roadway, special care must be taken. Unpaved roadways often have uneven surfaces, as well as large potholes. While responding on this type of roadway, you must operate the vehicle at a lower speed and maintain a firm grip on the steering wheel to maintain complete control of the ambulance at all times.

School Zones. When you respond through a school zone with your emergency lights turned on, it is important to remember that lights and sirens tend to attract children to the roadway and create a potential hazard. In many states, it is unlawful for an emergency vehicle to exceed the speed limit in school zones regardless of the condition of the patient.

Distractions

As technology progresses, so will the distractions you will face while operating the ambulance. While MDTs and GPS devices are necessary to assist EMTs in determining the location of the call, these devices, along with using the vehicle's mounted mobile radio, listening to the stereo, talking on your cell phone, and eating/drinking, create additional driving hazards. While the ambulance is in motion, you should focus on driving and anticipate roadway hazards. Your partner should operate the MDT, GPS device, and portable radios or turn on the siren. Minimizing distractions allows for a safer response and minimizes the potential for mishaps.

Driving Alone

Although driving alone is not a standard practice or even allowable in certain systems, there may be an occasion when you need to respond to a scene by yourself in the ambulance and meet your partner on the scene. When presented with this situation, you have additional duties and responsibilities, such as figuring out the safest route to the call, operating the radios and emergency warning devices, and mentally preparing for the call. Situations such as these demand your complete attention and focus.

Fatigue

Fatigue has many causes, such as stress, working the night shift, and lack of quality sleep in accordance with your body's circadian rhythms. As a result of these causes of fatigue, operating a large vehicle, such as an ambulance, creates a high risk. You must be able to recognize when you are fatigued. Do not be ashamed to admit it to yourself, your partner, or your supervisor. If you feel fatigued, you should be placed out of service for the remainder of the shift or until the fatigue has passed and you feel capable of safely operating the vehicle.

Air Medical Operations

Air ambulances are used to evacuate medical and trauma patients. They land at or near the scene and transport patients to trauma facilities every day in many areas. There are two basic types of air medical units: fixed-wing and rotary-wing, otherwise known as helicopters **Figure 37-30**. Fixed-wing aircraft generally are used for interhospital patient transfers over distances greater than 100 to 150 miles. For shorter distances, ground transport or rotary-wing aircraft are more efficient.

Specially trained medical flight crews accompany all air ambulance flights. Your role in fixed-wing aircraft transfers probably will be limited to providing ground transport for the patient and medical flight crew between the hospital and the airport.

Rotary-wing aircraft have become an important tool in providing emergency medical care. Trauma patient survival is directly related to the time that elapses between injury and definitive treatment. Most helicopters that are used for emergency medical operations fly well in excess of 100 mph in a straight line, without road or traffic hazards, straight to a hospital helipad. The crew may include flight paramedics, flight nurses, specialty providers such as respiratory therapists, and/or physicians.

Familiarize yourself with the capabilities, protocols, and methods for accessing helicopters in your area. Helicopter services provide training for EMS systems, fire services, and first responders in ground operations and safety. The following discussion is an introduction to safe operations and is not intended to be substituted for the more extensive courses available locally.

Figure 37-30 **A.** Fixed-wing aircraft are generally used to transfer patients from one hospital to another over distances greater than 100 to 150 miles. **B.** A rotary-wing aircraft, or helicopter, is used to help provide emergency medical care to patients who need to be transported quickly over shorter distances.

Helicopter Medical Evacuation Operations

A medical evacuation is commonly known as a **medivac** and is generally performed exclusively by helicopters. Most rural and suburban EMS jurisdictions and many urban systems have the capability to perform helicopter medivacs or have a mutual aid agreement with another agency such as police or hospital-based medivac service to provide such service. Familiarize yourself with the medivac capabilities, protocols, and procedures of your particular EMS system because they vary by agency. The following are some general guidelines that you should be familiar with when considering whether to initiate a medivac operation.

Calling for a Medivac

Every agency has specific criteria for the type of patient who may receive medical evacuation and how and when to call for a medivac. These basic guidelines will help you understand the process better.

- **Why call for a medivac?** The transport time to the hospital by ground ambulance is too long considering the patient's condition. Road, traffic, or environmental conditions limit or completely prohibit the use of a ground ambulance. The patient requires advanced care that you are unable to provide, such as administering pain medications or other specialized medications and inserting advanced airways. There are multiple patients who will overwhelm resources at the hospital reachable by ground transport. The helicopter may respond directly to the scene or it may be called to the hospital to transfer a patient to a facility with the capacity to provide definitive care for the patient's condition.
- **Who receives a medivac?** Medical evacuations should be used for patients with time-dependent injuries or illnesses. Patients suspected of having a stroke, heart attack, or serious spinal cord injury, such as injuries sustained in a motor vehicle crash or while diving into a swimming pool or horseback riding, often require medivac service. Serious conditions that may require the use of helicopter medivacs may be found in remote areas and involve scuba diving accidents, near drownings, or skiing and wilderness accidents. Other patients who may require medical evacuation are trauma patients, candidates for limb replantation (for amputations), and patients requiring air transport to a burn center, a hyperbaric chamber center, or a venomous bite center. Because specific criteria vary by service, familiarize yourself with the criteria in your system used to call for this lifesaving service.
- **Whom do you call?** Generally, your dispatcher must be notified first. In some regions, after the medivac has been initiated, the ground EMS crew may be able to access the flight crew on a specially designated radio frequency for one-on-one communications. If available, it is important to keep this frequency clear of chatter and lengthy communications. You may be asked to give a brief presentation or update on the patient's condition. In this case, you should gather your thoughts and speak clearly and concisely, avoiding information that is not pertinent. Another important topic of communication between the ground and flight EMS crews will be where to land the helicopter. This will be covered in the next section.

Safety Tips

The most dangerous phases of air transport are the takeoff and landing. It is very important that at least one person is dedicated to these tasks. This person should not have patient care responsibilities.

Establishing a Landing Zone

Although a helicopter can fly straight up and down, this is the most dangerous mode of operation. The safest and most effective way to land and take off is similar to that used by fixed-wing aircraft. Landing at a slight angle allows for safer operations. Takeoff combines a gradual lift and forward motion to travel up and out on a slight angle.

An important part of conducting a medivac is choosing the best location. Establishing a landing zone is the responsibility of the ground EMS crew. It involves more than simply looking for a clear space. You must be prepared to take action to ensure the flight crew is able to land and take off safely. Things to do and consider when selecting and establishing a landing zone include the following:

- Ensure the area is a hard or grassy level surface that measures 100 feet × 100 feet (recommended) and no less than 60 feet × 60 feet **Figure 37-31**. If the site is not level, notify the flight crew of the steepness and direction of the slope.
- Ensure the area is clear of any loose debris that could become airborne and strike the helicopter or the patient and crew. This includes branches, trash bins, flares, caution tape, and medical equipment and supplies.
- Examine the immediate area for any overhead or tall hazards such as power lines or telephone cables, antennas, and tall

or leaning trees. If you see any of these hazards, immediately inform the flight crew because an alternative landing site may be required. The flight crew may request that the hazard be marked or illuminated by weighted cones or that an emergency vehicle with its lights turned on be positioned next to or under the potential hazard.

- To mark the landing site, use weighted cones or position emergency vehicles at the corners of the landing zone with the headlights facing inward to form an ×. This procedure is essential during night landings as well. It is common for fire suppression personnel to help mark the landing site since they are often called to the scene to stand by. Never use caution tape or ask people to mark the site. You also should not use flares because not only can they become airborne, but they also have the potential to start a fire or cause an explosion.
- Move all nonessential people and vehicles to a safe distance outside of the landing zone.
- If the wind is strong, radio to the flight crew the direction of the wind. They may request that you create some form of wind directional device to aid their approach.

Figure 37-31 A landing area should be a level surface measuring 100 feet × 100 feet.

Landing Zone Safety and Patient Transfer

Helicopter safety is a combination of using good sense and a constant awareness of the need for personal safety. You should stay away from the helicopter and go only where the pilot or crew member directs you. The most important rule is to keep a safe distance from the aircraft whenever it is on the ground and "hot," which means when the helicopter blades are spinning. The rotor blades will usually remain running because the flight crew does not generally expect to remain on the ground for a long time. This means all EMTs should stay outside the landing zone perimeter unless directed to come to the aircraft by the pilot or a member of the flight crew. Usually, the flight crew will come to the EMTs carrying their own equipment and do not require any assistance inside the landing zone. If you are asked to enter the landing zone, stay away from the tail rotor; the tips of its blades move so rapidly that they appear invisible. With the possible exception of a rear-loading aircraft, always approach a helicopter from the front, even if it is not running, and you should approach only after the pilot signals it is clear to do so. If you imagine the front of the helicopter as the number 12 on a clock, then you should enter only the area between the ten o'clock and two o'clock positions. If you must move from one side of the helicopter to another, go around the front. Never duck under the body, the tail boom, or the rear section of the helicopter. The pilot cannot see you in these areas.

Another area of concern is the height of the main rotor blade. On many aircraft, it is flexible and may dip as low as 4 feet off the ground **Figure 37-32**. When you approach the aircraft, walk in a crouched position. Wind gusts can alter the blade height without warning, so protect your equipment as you carry it under the blades. Air turbulence created by the rotor blades can blow off hats and loose equipment. These objects, in turn, can become a danger to the aircraft and personnel in the area.

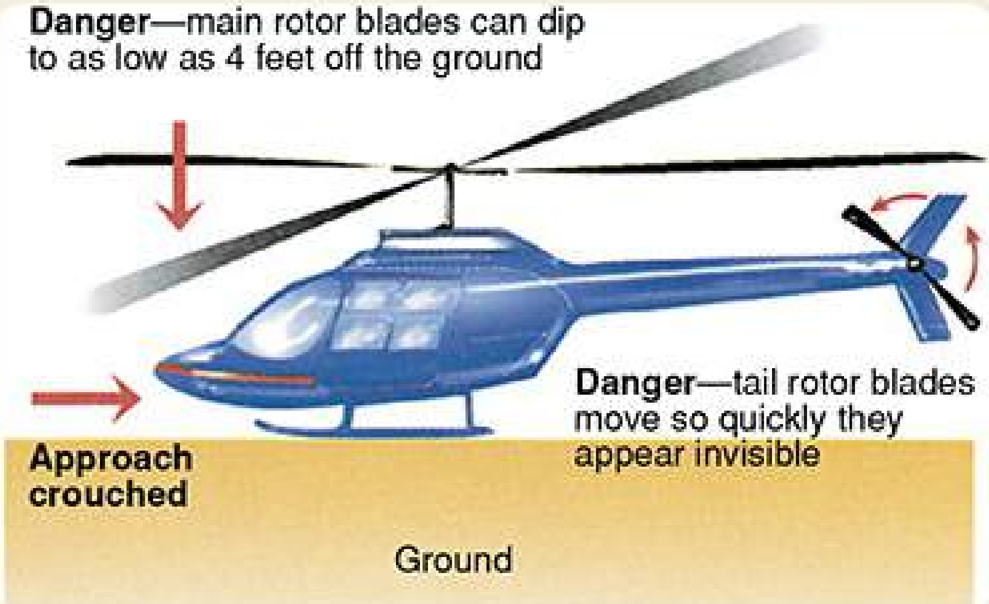

Figure 37-32 The main rotor blade of the helicopter is flexible and may dip as low as 4 feet off the ground.

When accompanying a flight crew member, you must follow directions exactly. Never open any aircraft door or move equipment unless instructed by a crew member. When told to approach the aircraft, use extreme caution and pay constant attention to hazards.

YOU are the Provider — PART 5

After turning around and determining a new route, your partner advises you there is now a 25-minute transport time. Your partner also warns that you are rapidly approaching a stopped school bus with its stop sign out, and children are exiting the bus.

Recording Time: 22 Minutes	
Level of consciousness	Alert and oriented
Respirations	20 breaths/min; adequate depth
Pulse	104 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	142/90 mm Hg
Spo_2	97% (at room air)

8. When traveling in the emergency mode, how do you respond to a stopped school bus?
9. Where do most serious ambulance crashes occur, and what should you do to help avoid a crash?

Keep the following guidelines in mind when operating at a landing zone:

- Familiarize yourself with helicopter hand signals used within your jurisdiction **Figure 37-33**.

- Do not approach the helicopter unless instructed and accompanied by flight crew.
- Ensure all patient care equipment is properly secured to the stretcher and that the patient is fastened as well. This includes oxygen tanks, cervical collars, and head stabilizers. Any loose articles or belongings such as hats, coats, or bags that belong to the patient or crew should not be brought into the landing zone and will likely need to be transported to the hospital by ground.
- Be aware some helicopters may load patients from the side, whereas others have rear-loading doors. Regardless of where the patient is being loaded, always approach the aircraft from the front unless otherwise instructed by the flight crew. It is very important that the pilot be able to see anyone who comes under the rotors. Always take the same path when exiting away from the helicopter, moving the patient headfirst.
- Smoking, open flames, and flares are prohibited within 50 feet of the aircraft at all times.
- Wear eye protection during approach and take off.

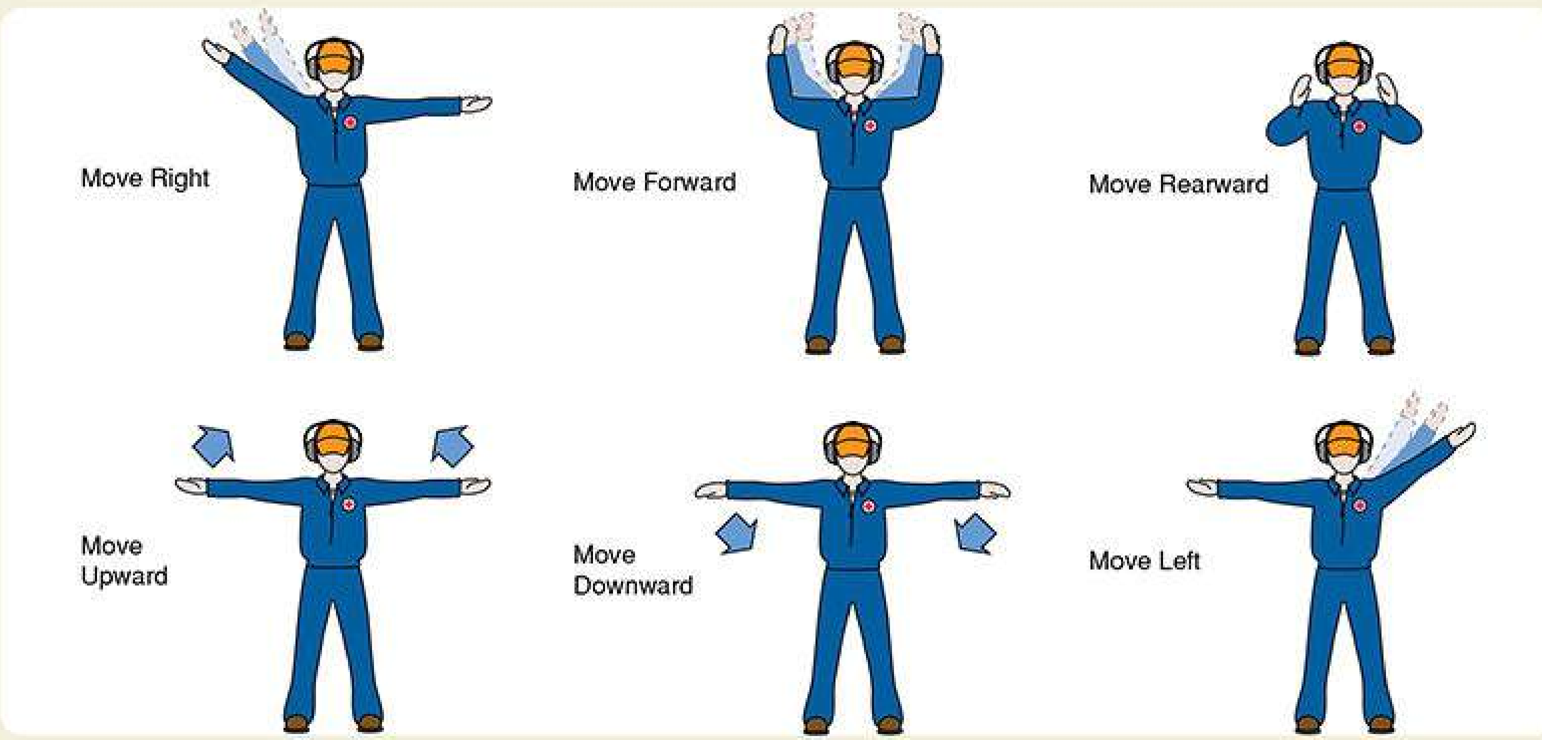

Figure 37-33 Some examples of helicopter hand signals. Be familiar with those used within your jurisdiction.

Communication Issues

When interacting with other agencies, there is always the possibility of communication issues. Medivacs are no exception. While the typical EMS system has its specific and well-defined jurisdiction, medivacs respond to service requests throughout a large, multijurisdictional area. Because of this large area with numerous jurisdictions, the medivac interacts with many services on a multitude of different radio frequencies.

To prevent any miscommunication, when the request is made for a medivac response, the request should include a ground contact radio channel (typically a preestablished mutual aid channel), as well as a call sign of the unit that the medivac should make contact with.

Special Considerations

Night Landings

Nighttime operations are considerably more hazardous than daytime operations because of the darkness. The pilot will generally fly over the area at least twice at varying altitudes with the helicopter's lights on in order to identify potential obstacles and overhead wires, which can be hard to see. Do not shine spotlights, flashlights, or any other lights in the air to help the pilot; they may temporarily blind the pilot. Instead, direct low-intensity headlights or lanterns toward the ground at the landing site from opposite corners to form an × at the center of the landing zone. Turn off all headlights or lanterns that are facing in the direction of the aircraft once it has landed; after the helicopter has landed, you should not aim lights near the aircraft. Always make certain the flight crew is aware of any overhead hazards or obstructions, and illuminate these if possible.

Landing on Uneven Ground

If the helicopter must land on a grade (uneven surface), extra caution is advised. The main rotor blade will be closer to the ground on the uphill side. In this situation, approach the aircraft only from the downhill side or as directed by the flight crew **Figure 37-34**. Do not move the patient to the helicopter until the crew has signaled that they are ready to receive you.

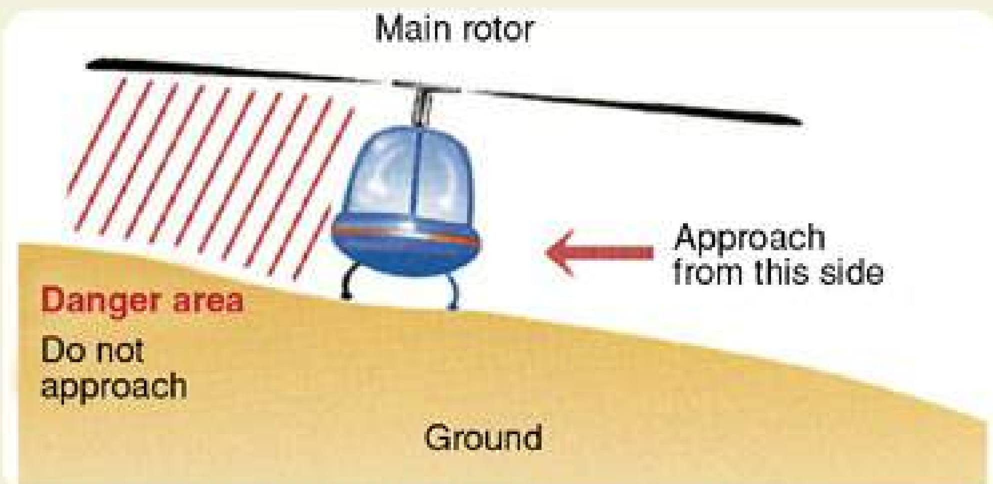

Figure 37-34 Approach a helicopter only on a grade from the downhill side.

Medivacs at Hazardous Materials Incidents

Notify the flight crew immediately of the presence of HazMat at the scene. The aircraft generates tremendous wind and may easily spread any HazMat vapors present. Always consult the flight crew and incident commander about the best approach and distance from the scene for a medivac. The landing zone should be established upwind and uphill from the HazMat scene. Any patients who have been exposed to a HazMat must be properly decontaminated before you load them into the aircraft. For proper procedures at HazMat incidents, refer to Chapter 38, *Incident Management*.

▶ Medivac Issues

While making the decision to request medivac, several important factors need to be taken into consideration. These factors are weather, the environment/ terrain, altitude, airspeed limitations, cabin size, and cost. Typically, helicopters are unable to operate in severe weather conditions such as thunderstorms, blizzards, and heavy rain. The environment may pose a risk as well. In mountainous or desert terrain, there may be too many hazards in the immediate vicinity to safely land the helicopter in the desired location.

As the elevation increases, the air thins, which makes it more difficult for pilots and patients to breathe. Because of this danger, helicopters have a maximum limit on flight elevations. Most helicopter services are limited to flying at 10,000 feet above sea level. This could create a problem if your patient is located at 13,500 feet above sea level. Remember that medivac helicopters are not jets, so it takes time for them to arrive on the scene, because of limitations in airspeed. Typically medivac helicopters fly between 130 and 150 mph.

Because of the helicopter cabin's confined space, helicopters are limited in the number of patients that can be safely transported and by the size of the patient that they can safely transport. Although a helicopter may be able to safely lift off with a 500-lb (227-kg) patient, because of his or her size and girth, it may be impossible to safely fit and secure the patient into the cabin area.

Typical medivac flights are extremely expensive compared to ambulance transports; however, the level of care may be higher and the overall transport time may be much shorter in the helicopter. The decision to request a medivac should not be based on the perceived ability of the patient to pay the bill, but rather on the medical necessity.

YOU are the Provider — SUMMARY

1. What attributes should an emergency vehicle operator possess?

Clearly, not everyone who drives a motor vehicle is qualified to operate an emergency vehicle. In many states, EMTs are required to successfully complete an emergency vehicle operator course before they are allowed to drive the ambulance in emergency mode. Many EMS systems require completion of an emergency vehicle operator course as well as clearance by a supervisor or field training officer.

All the training in the world cannot replace reasonable judgment and common sense; these are the most crucial attributes that any vehicle operator must possess, not just an emergency vehicle operator.

Regardless of your systems' requirements for operating an emergency vehicle, constant care and caution are important qualities for all operators of emergency vehicles, as are a positive attitude about your driving abilities and tolerance of other motorists.

2. What factors should you consider before responding to the scene?

Before you depart your station, you need to consider a number of factors that will ensure an easy, quick, and safe response. First, regardless of what method you use to navigate to the location, you must know exactly where you are going and then notify the dispatcher that you are en route. If there is any question or confusion regarding the location of the call, ask the dispatcher for confirmation. Ask if there is a cross street that you can use as a point of reference. Choose the shortest and least congested route to the scene, considering the time of day. In this case, it is 1730 hours, the traffic is heavy, and it is rush hour on a weekday; therefore, the most obvious route to the scene may not be the quickest and safest.

Another factor to consider before you respond is the weather. Although you must go into "safety mode" prior to responding—regardless of the weather conditions—you must use extra caution during bad weather.

There are numerous other factors to consider before responding—some of which may be unique to your location. However, if safety is at the forefront of your mind, your ability to get to the scene *quickly and safely* will be maximized.

3. Based on the mechanism of injury and patient presentation, what equipment do you anticipate needing?

For this patient you would need the jump kit, which should contain anything you might need within the first 5 minutes after making contact with any patient, including splinting and bandaging supplies. In addition, spinal immobilization requires a backboard, an appropriately sized cervical collar, and some type of cervical immobilization device. If he were unstable, splinting and bandaging should be delayed until you are en route, and all other necessary assessments and treatments are completed.

4. What assessment and treatment should be performed on scene and what should be delayed until you are in the ambulance and en route to the hospital?

This patient is stable with only an isolated injury. There was not a loss of consciousness and vital signs are within normal limits. Since this is not a priority load and go patient, you should complete your secondary assessment on scene and take the time to splint his arm. Apply a spinal immobilization device, if indicated, prior to moving the patient.

Once you are en route to the hospital, repeat the primary assessment, including taking vital signs, and reassess the effectiveness of any interventions. Now would also be the time to manage any minor secondary injuries. Remember that stable patients should be reassessed every 15 minutes, and critical or unstable patients should be reassessed every 5 minutes.

5. How would you determine whether to use lights and siren during transport of this patient?

The transport mode (eg, lights and siren [emergency mode] versus no lights and siren [nonemergency mode]) is determined by the patient's present condition and his or her anticipated clinical outcome. In this case, the patient is stable; he is alert and oriented, his vital signs are stable, and he has no life-threatening conditions (eg, airway problems, uncontrolled bleeding); therefore, the use of lights and siren during transport is not indicated.

6. What should you consider when deciding whether it is appropriate to turn on the lights and siren to maneuver through traffic?

Regulations regarding vehicle operations vary by state and by city, but some regulations are the same regardless of location. Emergency vehicle operators have certain limited privileges in every state. However, these privileges do not lessen your liability in a crash.

Three basic principles govern the use of warning lights and siren on an ambulance:

1. The unit must be, to the best of your knowledge, on a true emergency call.
2. Audible and visual warning devices must be used simultaneously.
3. The unit must be operated with due regard for the safety of all others, on and off the roadway.

In this situation, the patient's condition does not warrant the use of lights and siren. If you choose to use an emergency transport you will put yourself, your partner, your patient, and other motorists at risk. You could also face possible litigation. You have time to take an alternate route and avoid creating more hazards as other drivers try to move out of the way.

7. If you are in an unfamiliar area and do not know an alternate route, what are your options?

The best option would be to use a GPS device to navigate through an unfamiliar area. Another option is to call the dispatcher via radio and ask for street by street directions. As a last resort, a police escort may be requested.

8. When traveling in the emergency mode, how do you respond to a stopped school bus?

Although state motor vehicle statutes or codes often grant an emergency vehicle certain privileges when responding to an emergency, special privileges are not given to emergency vehicles when driving through a school zone or approaching a stopped school bus that is loading or unloading children. In these situations, the emergency vehicle operator is required to obey the law like any other motorist.

An emergency vehicle operator is never allowed to pass a school bus that has stopped to load or unload children and is displaying its red warning lights and extended "stop arm." If you approach a school bus that is loading or unloading children, you should stop before you reach the bus and turn off your siren. Wait for the bus driver to make sure the children are safe, the bus door has been closed, and its red warning lights are turned off. *Only then may you cautiously proceed past the stopped school bus*.

9. Where do most serious ambulance crashes occur, and what should you do to help avoid a crash?

Intersection crashes are the most common—and usually the most serious—type of crash involving ambulances. Therefore, the emergency vehicle operator must be especially careful and alert when approaching an intersection. If you are operating the vehicle in emergency mode and cannot wait for traffic lights to change, you should still come to a complete stop, look around for other motorists and pedestrians, and then cautiously proceed. The same applies if you approach an intersection with stop signs.

Narrative

Dispatched to a residence for a "fall." Arrived on scene to find a 62-year-old man who had fallen approximately 3 feet from a ladder, landing on his outstretched left hand. The patient is alert and oriented and denies any loss of consciousness. Patient reports isolated left arm pain with crepitus and deformity to the left forearm. Vital signs are within normal limits, and secondary assessment was normal. Patient has good pulse, movement, and sensation in left wrist. Breath sounds are clear and equal bilaterally, and pupils are equal and reactive to light. Although patient denies any neck or back pain, he agrees to full spinal immobilization as a precautionary measure due to the mechanism of injury in the context of a distracting injury to the forearm. Splinted left forearm, immobilizing the elbow and wrist, and reassessed pulse, motor, and sensory functions. Patient was also immobilized on a backboard with cervical collar and head blocks with tape. Patient was then placed on stretcher and loaded into the ambulance. En route monitored vital signs and level of consciousness. Prior to reaching the destination, Medic unit was forced to detour due to a motor vehicle crash, and transport time was extended by 25 minutes. Closely monitored the patient's ABCs for the duration of the transport and provided emotional support as needed. His condition remained unchanged. Arrived at the hospital, gave verbal report to the staff nurse, and transferred patient care.**End of report**

Prep Kit

Ready for Review

- Today's ambulances are designed according to strict government regulations based on national standards.
- The six-pointed Star of Life emblem identifies vehicles that meet federal specifications as licensed or certified ambulances.
- An ambulance call has nine phases:
  - Preparation for the call
  - Dispatch
  - En route
  - Arrival at scene
  - Transfer of the patient to the ambulance
  - En route to the receiving facility (transport)
  - At the receiving facility (delivery)
  - En route to the station
  - Postrun
- Certain items, like sterile gloves, must be available on the ambulance at all times, as dictated by state and jurisdictional requirements.
- Every ambulance must be staffed with at least one EMT in the patient compartment whenever a patient is being transported. However, two EMTs are strongly recommended. Some services may operate with a non-EMT driver and a single EMT in the patient compartment.
- Check all medical equipment and supplies daily, including all the oxygen supplies, the jump kit, splints, dressings and bandages, backboards and other immobilization equipment, and the emergency obstetric kit.
- During the postrun phase, you should complete and file any additional written reports and inform dispatch of your status, location, and availability. Perform a routine inspection to ensure the ambulance is ready to respond to the next call.
- Learning how to properly operate your vehicle is just as important as learning how to care for patients when you arrive on the scene.
  - The first rule of safe driving in an emergency vehicle is that speed does not save lives; good care does.
  - The second rule is that the operator and all passengers must wear seat belts and shoulder restraints at all times.
- Air ambulances are used to evacuate medical and trauma patients.
  - There are two basic types of air medical units: fixed-wing and rotary-wing, otherwise known as helicopters.
  - A medical evacuation is commonly known as a medivac and is generally performed exclusively by helicopters.

Vital Vocabulary

air ambulances Fixed-wing and rotary-wing (known as helicopters) aircrafts that have been modified for medical care; used to evacuate and transport patients with life-threatening injuries to treatment facilities.

ambulance A specialized vehicle for treating and transporting sick and injured patients.

blind spots Areas of the road that are blocked from your view by your vehicle or mirrors.

cleaning The process of removing dirt, dust, blood, or other visible contaminants from a surface.

CPR board A device that provides a firm surface under the patient's torso.

cushion of safety Keeping a safe distance between your vehicle and any vehicles around you.

decontaminate To remove or neutralize radiation, chemical, or other hazardous material from clothing, equipment, vehicles, and personnel.

disinfection The killing of pathogenic agents by direct application of chemicals.

first-responder vehicles Specialized vehicles used to transport EMS equipment and personnel to the scenes of medical emergencies.

high-level disinfection The killing of pathogenic agents by using potent means of disinfection.

hydroplaning Occurs when the tires of a vehicle are lifted off the road surface as a result of water "piling up" underneath them, making the vehicle feel as though it is floating.

jump kit A portable kit containing items that are used in the initial care of the patient.

medivac Medical evacuation of a patient by helicopter.

spotter A person who assists a driver in backing up an ambulance to help adjust for blind spots at the back of the vehicle.

Star of Life The six-pointed star emblem that identifies vehicles that meet federal specifications as licensed or certified ambulances.

sterilization A process, such as heating, that removes microbial contamination.

Assessment *in Action*

© Jones & Bartlett Learning. Courtesy of MIEMSS.

It is time for your annual competency assessment. This test includes knowledge and skills assessments. You refer to your EMT textbook to prepare by answering sample questions provided.

1. The features found in a modern ambulance are defined by which of the following agencies?

   A. Department of Transportation
   B. National Association of EMS Directors
   C. American Ambulance Association
   D. National Research Council of the National Academy of Sciences

2. If you are on an emergency call with your warning lights and siren turned on, you may be allowed to do which of the following?

   A. Proceed through a red traffic light or stop sign without stopping.
   B. Drive faster than the posted speed limit.

C. Drive against the flow of traffic on an interstate in the left lane.
D. Pass a stopped school bus with the stop sign out.

3. Keeping a safe distance between your vehicle and the one in front of you, checking for tailgaters behind your ambulance, and being aware of objects in your mirror's blind spots are considered maintaining a(n):

A. buffer zone.
B. open space.
C. cushion of safety.
D. evasion area.

4. Which of the following is a cause of fatigue?

A. Family interaction
B. Working during the day
C. Sleeping only 6 hours
D. Stress

5. During the _____ phase of an ambulance call, the crew should review dispatch information about the nature of the call and the location of the patient.

A. preparation
B. dispatch
C. en route
D. postrun

6. If you arrive on the scene of a mass-casualty incident, what is the first thing you should do?

A. Declare the area a crime scene.
B. Direct traffic until law enforcement arrives.
C. Ask for additional resources.
D. Begin treating patients.

7. To ensure you have enough reaction time to avoid hitting a motorist who does not move over, you should drive, at minimum, about _____ seconds behind vehicles traveling at an average speed.

A. 2
B. 4
C. 6
D. 8

8. When responding to a scene where smoke or possible hazardous materials are present it is best to park:

A. uphill and upwind.
B. uphill and downwind.
C. downhill and downwind.
D. downhill and upwind.

9. You are treating a 45-year-old woman who is has chest pain. Her blood pressure is 92/40 mm Hg; pulse rate, 132 beats/min and irregular; and respirations, 24 breaths/ min and labored. Should you use lights and siren when transporting this patient? Justify your answer.

10. You respond to a motor vehicle crash with massive damage to the front of the vehicle where it struck a tree head on. The only occupant is a young man, who is unrestrained, unresponsive, and entrapped. Fire rescue is on scene preparing for extrication, and a responding paramedic unit is attending the patient. The supervisor informs you he has requested a helicopter to respond and has asked you and your partner to prepare a landing zone. What should your considerations be when establishing a landing zone?

CHAPTER 38

Vehicle Extrication and Special Rescue

National EMS Education Standard Competencies

EMS Operations

Knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

Vehicle Extrication

› Safe vehicle extrication (pp 1389-1398)
› Use of simple hand tools (p 1396)

Knowledge Objectives

1. Explain the responsibilities of an EMT in patient rescue and vehicle extrication. (p 1389)
2. Discuss how to ensure safety at the scene of a rescue incident, including scene size-up and the selection of the proper personal protective equipment and additional necessary gear. (pp 1389, 1391–1395)
3. Describe examples of vehicle safety components that may be hazardous to both EMTs and patients following a collision and how to mitigate their dangers. (pp 1389–1390)
4. Define the terms extrication and entrapment. (p 1390)
5. Describe the ten phases of vehicle extrication and the role of the EMT during each one. (pp 1391–1398)
6. Discuss the various factors related to ensuring situational safety at the site of a vehicle extrication, including controlling traffic flow, performing a 360-degree assessment, stabilizing the vehicle, dealing with unique hazards, and evaluating the need for additional resources. (pp 1391–1395)
7. Describe the special precautions the EMT should follow to protect the patient during a vehicle extrication. (pp 1395–1396)
8. Explain the different factors that must be considered before attempting to gain access to the patient during an incident that requires extrication. (pp 1391–1395)
9. Explain the difference between simple access and complex access in vehicle extrication. (pp 1396–1397)
10. Discuss patient care considerations related to assisting with rapid extrication, providing emergency care to a trapped patient, and removing and transferring a patient. (pp 1397–1398)

11. Describe examples of situations that would require special technical rescue teams and the EMT's role in these situations. (pp 1399–1403)

Skills Objectives

There are no skills objectives for this chapter.

Introduction

As an EMT, you will usually not be responsible for rescue, though you may assist with extrication. Rescue involves many different processes and environments, including vehicle, water, and wilderness rescue. These incidents require training beyond the level of the EMT. You must understand the basic concepts of extrication in order to function effectively as part of a team during a rescue incident. In some cases, you may be the first emergency unit to arrive at the scene, and your initial actions may determine how efficiently the rescue is completed.

The chapter begins with a discussion of safety at the scene of a rescue incident, followed by the 10 phases of extrication. This includes how to gain access to patients and how to keep yourself, your partner, patients, and bystanders safe in the process. In most cases, once you have reached the patient, extrication will occur around you and the patient. Communication between you and the personnel performing the extrication is vital.

Safety

You must always be prepared, mentally and physically, for any incident that requires rescue or extrication. Your priority as an EMT is to provide patient care. However, your personal safety and the safety of your team are paramount and must be addressed before patient care is initiated. Safety begins with the proper mind-set and the proper protective equipment.

The equipment that you use and the gear that you wear will depend on the hazards you expect to encounter, as well as what you observe during your scene size-up **Figure 38-1**. Such protective gear may include turnout gear, a helmet, hearing protection, and a fire extinguisher. However, the importance of wearing blood- and fluid-impermeable gloves at all times during patient contact cannot be over emphasized. If you will be involved with extrication, wear a pair of leather gloves over your disposable gloves to protect you from injury when handling ropes, tools, broken glass, hot or cold objects, or sharp metal.

Figure 38-1 Proper protective equipment varies depending on the anticipated hazards.

Vehicle Safety Systems

A variety of safety systems are used in modern vehicles. Although many of these devices are useful when the vehicle is in motion, they can become hazards after the vehicle has been involved in a crash.

YOU are the Provider — PART 1

It is 1622 hours and your unit is dispatched to a small private airport for a single-engine plane crash involving two passengers. The plane was coming in to refuel and crashed just prior to landing. It is a two-seater aircraft. Upon arrival, a fire rescue team member advises you that a 360-degree assessment of the scene has been performed and it is safe. The pilot has massive head and facial trauma that is incompatible with life. Rescue personnel are attempting to access a woman trapped in the passenger seat located behind the pilot.

1. What information is obtained from a 360-degree assessment of a plane crash?
2. How would your approach change if leaking fuel were present?

Shock-absorbing bumpers provide vehicle protection from low-speed impact. Following a front or rear-end crash, the shock absorbers within these bumpers may be compressed or “loaded.” Avoid standing directly in front of such bumpers, and always approach vehicles from the side, because the shock absorbers can release and injure your knees and legs.

Manufacturers are now mandated to incorporate supplemental restraint systems, or air bags, into their vehicles. These air bags fill with a nonharmful gas on impact and quickly deflate after the crash. Air bags are located in the steering wheel and the dashboard in front of the passenger, and they deploy when the vehicle is struck from the front or rear. Side-impact air bags may be present to protect the driver and passengers from side impacts; these may be located in the doors or seats.

Air bags should normally deploy and deflate before your arrival on the scene. However, air bags that have not deployed may spontaneously inflate while you provide patient care, causing injury to you. Use caution when working in damaged vehicles in which air bags have not inflated. Generally, you should maintain at least a 5-inch (13-cm) clearance around side-impact air bags, a 10-inch (25-cm) clearance around driver-side air bags, and a 20-inch (51-cm) clearance around passenger-side air bags.

Words of Wisdom

A vehicle crash scene can present many hazards to emergency responders and patients, including fuel spills that pose fire and explosion risks, downed power lines that pose electric hazards, broken glass and torn metal, and exposure to potentially infectious body fluids. Your safety at every type of emergency scene begins with, and depends on, your scene size-up. What you see at the scene helps you determine which personal protective equipment to use and whether to call for additional or specialized assistance.

You may notice a haze similar to smoke inside vehicles in which air bags have deployed. This haze is caused by the cornstarch or talcum powder that manufacturers used to place on the air bags to prevent minor skin irritations by reducing the friction between the occupant's skin and the airbag. Appropriate protective gear, including eye protection, will reduce the risk of eye or lung irritation from this substance.

Fundamentals of Extrication

As an EMT, your primary concern during all phases of a rescue is safety, and your primary roles are to provide emergency medical care and prevent further injury to the patient. You will provide care to the patient as extrication goes on around you unless this proves to be too dangerous for you or the patient. **Extrication** is the removal from entrapment or from a dangerous situation or position (also called disentanglement).

Entrapment is a condition in which a person is caught within a closed area with no way out or has a limb or other body part trapped. In the context of this chapter, extrication means removal of a patient from a wrecked vehicle. However, the same principles and concepts apply to other situations, such as a collapsed building.

Words of Wisdom

Extended entrapment of a limb or other body part can lead to crush syndrome in a patient. Crush syndrome requires specific and specialized care that is discussed in greater detail in Chapter 26, *Soft-Tissue Injuries.*

Each emergency responder has a distinct role at a vehicle extrication scene. EMS providers assess patients, provide immediate medical care, triage and package patients, provide additional assessment and care as needed once patients are removed, and provide transport to the emergency department.

The rescue team secures and stabilizes the vehicle, provides safe entrance and **access** to the patients (the ability to reach the patients), safely extricates patients, and provides adequate room so that patients can be removed properly.

Law enforcement officers control traffic, maintain order at the scene, establish and maintain a perimeter so that bystanders are kept at a safe distance, and ultimately investigate the crash or crime scene. Firefighters extinguish fire, prevent additional ignition, ensure that the scene is safe, and remove spilled fuel **Figure 38-2**.

Roles and responsibilities often vary based on jurisdiction and the available agencies. For example, the fire department may take primary responsibility for traffic control in certain situations. An incident commander (discussed later in the chapter) should take command of the scene and coordinate the response, ensuring the agencies work seamlessly together. Good communication among team members and clear leadership are essential to safe, efficient provision of proper emergency care.

Figure 38-2 EMS providers, the rescue team, law enforcement officers, and firefighters have distinct responsibilities at a rescue scene and must cooperate to manage the incident.

There are 10 phases to the extrication process Table 38-1. Many are similar to the phases of an ambulance call (discussed in Chapter 37, *Transport Operations*). Each will be discussed, with emphasis on the phases in which you will participate.

Words of Wisdom

The scene of an extrication is dynamic—it constantly changes. Be alert to new dangers and plan an escape route.

Table 38-1 Ten Phases of Extrication

1. Preparation
2. En route to the scene
3. Arrival and scene size-up
4. Hazard control
5. Support operations
6. Gaining access
7. Emergency care
8. Removal of the patient
9. Transfer of the patient
10. Termination

Safety Tips

Just as in patient care, the first priority in rescue is *personal safety*.

Preparation

Preparing for an incident requiring extrication involves pre-incident training with rescue personnel for the various types of rescue situations to which you might respond. On a daily basis, just as you must check the equipment carried on the ambulance, rescue personnel must also check the extrication tools and their response vehicles to ensure proper operation. Such preparations reduce the possibility of equipment failure at an emergency scene.

En Route to the Scene

The procedures and safety precautions similar to those discussed in the phases of an ambulance call are used when responding to a rescue incident.

Arrival and Scene Size-up

If you are the first unit to arrive on the scene, position the ambulance to block the scene from oncoming traffic. Use only essential warning lights, because too many lights tend to distract or confuse motorists. Many emergency responders have been injured on scenes when they were struck by passing vehicles. (In some locales, policies indicate that emergency lighting can be reduced or turned off after the scene is secured; this may reduce the risk of a secondary crash.) If you are not the first to arrive, choose a location that will allow safe access to the scene while leaving yourself a way out. Do not park in an area where you will be blocked in. If law enforcement or fire units have blocked the roadway, position your unit so that the back of the ambulance is pointing toward the scene to facilitate patient transport.

Avoid adding a hazard to the scene by parking alongside the incident on an active roadway; this could increase the risk of your vehicle or responders being struck. Sometimes the scene at a crash is complicated by the presence of **hazardous materials**. A hazardous material is any substance that is toxic, poisonous, radioactive, flammable, or explosive and can cause injury or death with exposure. Therefore, always park uphill and upwind from the hazard.

Before exiting your vehicle at an emergency scene, put on proper protective gear. Be alert for any vehicles that might cause injury to you. Do not assume that motorists will always heed the warning lights.

Figure 38-3 The scene of a crash should be marked properly, and traffic should be diverted so that responders have enough room to work.

Before proceeding, make sure that the scene is properly marked and protected. Request assistance from law enforcement and/or fire personnel **Figure 38-3**, who should close the road or divert traffic safely around the scene with cones, flares, or barricade tape. Remember, your job is to provide patient care. You may be forced to direct traffic until other units arrive, but ultimately, traffic control is usually handled by other public safety units.

Words of Wisdom

When responding to incidents at night, use your headlights and spotlights to illuminate the scene. Wear a high visibility reflective safety vest so that you will be seen by fellow emergency responders and motorists.

Size-up is the ongoing process of information gathering and scene evaluation to determine appropriate strategies and tactics to manage an emergency, while paying attention to hazards such as downed power lines, leaking fluids, fire, and broken glass. One of the important responsibilities of scene size-up is to determine what, if any, additional resources will be needed. If you are first on the scene, you may need to initiate a rescue response or call for additional EMS units, law enforcement, utility departments, or specialized crews such as Hazardous Materials (HazMat).

Words of Wisdom

Practice situational awareness. Situational awareness is the ability to understand and react to the threats around you. Remember that scenes are dynamic, and be alert for changing situations. Consider weather and environmental conditions, and always be aware of traffic, patients, and bystanders.

A 360-degree walk around the scene will allow you to evaluate the hazards and potential injuries and determine the number of patients. If there is a large group of patients, implement local mass-casualty incident protocols as necessary. During your walk, look for the following:

- The mechanism of injury
- Downed power lines
- Leaking fuels or fluids
- Smoke or fire
- Broken glass
- Trapped or ejected patients
- The number of patients and vehicles involved

On the scene of a motor vehicle crash, it is important to note the physical damage to the structure of the vehicle(s). A bent steering wheel is a mechanism of injury for significant face and/or thoracic trauma. Imprints in the dashboard, which are usually the result of the knees striking it, indicate the potential for serious lower extremity injuries such as hip dislocations and fractures. Always lift deployed air bags to see if there is deformity to the steering wheel or dashboard, which indicates that the patient struck the structure after the airbag deflated. Determine if the patient was restrained or not. An unrestrained patient may have contact injuries as well as secondary injuries. If the unrestrained patient is thrown forward, he or she may strike the windshield with the head, resulting in a spider web pattern of shattered glass and possible head, face, or neck injuries. Include any findings in your documentation and maintain a high index of suspicion, even if the patient does not present with significant obvious injuries. For a detailed discussion on the kinematics of trauma, see Chapter 24, *Trauma Overview*.

Use the information you have gathered to evaluate the need for additional resources such as:

- Extrication equipment
- Fire department
- Law enforcement
- HazMat unit
- Utility company
- Advanced life support unit(s)
- Air transport

Look for spilled fuel and other flammable substances. Motor vehicles carry a variety of fuels and lubricants that pose a fire hazard. Sometimes post-crash fires are started when sparks created during the crash ignite spilled fuel. A short in a vehicle's electric system or a damaged battery may also cause a postcrash fire. These fires may trap the occupants of the vehicle and require fire suppression.

Environmental conditions can lead to unique hazards at a crash scene. Crashes that occur in rain, sleet, or snow, for example, present an added hazard for rescue personnel and patients. Crashes that occur on hills are harder to handle than those that occur on level ground. Uneven terrain increases the potential for the vehicle to roll over, requiring stabilization of the vehicle prior to gaining access. Remember that the conditions responsible for the crash may also cause other motorists to lose control of their vehicles and injure you.

Some crash scenes may present threats of violence if the vehicle's occupants are intoxicated or upset with other motorists. This may pose a threat to you or to others on the scene. Be alert for weapons that are carried in civilian vehicles.

You will need to coordinate your efforts with the rescue teams and with law enforcement officials. If you respect their jobs, they will respect yours. You should communicate with members of the rescue team throughout the extrication process. Report to the incident commander as soon as you arrive at the scene. Under the incident command system (described in Chapter 39, *Incident Management*), rescue operations are integrated as a separate group. You become a member of this group and will enter the vehicle and provide care for the patient(s) when approved by the incident commander.

YOU are the Provider — PART 2

The entire passenger compartment is badly damaged and the aircraft doors cannot be opened manually. There is no window next to the patient; the only window is the windshield in front of the pilot. Next to the passenger's seat are bars rather than a window. A rescue team member is able to cut through the bars with bolt cutters and use a hydraulic cutter to allow better access to the patient. Your partner is able to reach through the bars and manually stabilize the patient's head. You access the patient through the opposite side and perform a primary assessment. The woman is approximately 55 years old and is unresponsive but breathing. Her legs are pinned by the wreckage, and she has large lacerations to her left temple and right arm. The bones at the elbow are exposed.

Recording Time: 0 Minutes	
Appearance	Unresponsive with snoring respirations
Level of consciousness	Unresponsive
Airway	Open with a modified jaw thrust; clear of secretions or foreign bodies
Breathing	Decreased rate; shallow depth
Circulation	Radial pulses, weak and rapid; skin is cool, clammy, and pale; laceration to the forehead from the temple through the left orbit with minimal bleeding; laceration to right arm with the bones of the elbow exposed and bleeding controlled

Because of the mechanism of injury, the patient's clinical condition, and the possibility of a prolonged extrication, you request air transport to respond to the scene and transport her to a trauma center located 35 miles away. You apply high-flow oxygen via nonrebreathing mask, cover the laceration on her forehead, apply a cervical collar, and attempt to shield the patient from debris during the extrication process.

3. How should you initially attempt to gain access to a crash victim?
4. What treatment should you provide to a patient who is entrapped in wreckage?

Hazard Control

A variety of hazards may be present at the extrication scene. Downed power lines are a common example. Never attempt to move downed power lines. If power lines are touching or located in proximity to a vehicle involved in the crash, patients should be instructed to remain in the vehicle until power is shut off by a utility company representative.

If you are not the first on scene, in most incidents, there will be an area designated as the **safe zone**. You and the ambulance should remain in that area, outside of the danger zone **Figure 38-4**. A **danger zone (hot zone)** is an area where people can be exposed to sharp metal edges, broken glass, toxic substances, radiation, or explosion of hazardous materials.

Bystanders and family members can also create hazards. If they are allowed to get too close, they are at risk of injury and may also interfere with the overall management of the incident. For these reasons, the danger zone is off-limits to bystanders **Figure 38-5**. You should help to set up and enforce this zone. If you arrive before the rescue team, coordinate crowd control with law enforcement officials.

The vehicle itself can be a hazard. A vehicle that came to rest on its side or roof is unstable and can be dangerous to you. Rescue personnel can stabilize the vehicle with a variety of jacks or cribbing (wooden blocks). Prior to attempting to gain access to the vehicle, the vehicle should be in "park" with the parking brake set and the ignition turned off. Both battery cables should be disconnected, negative side first, to minimize the possibility of sparks or fire.

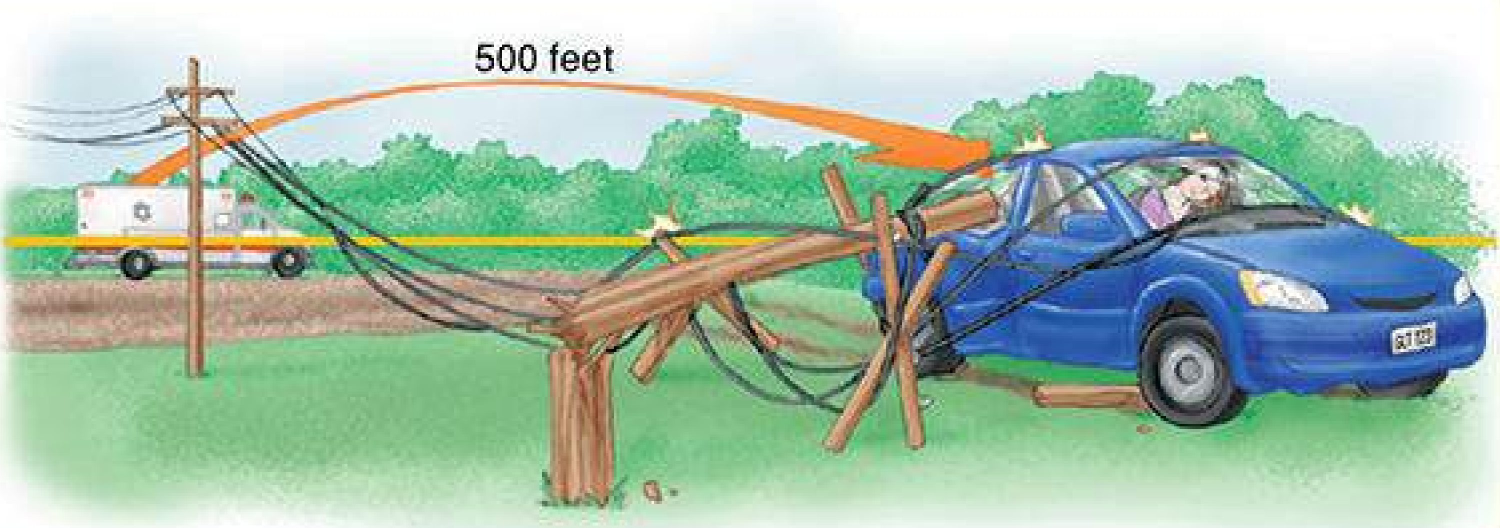

Figure 38-4 Remain outside the danger zone (hot zone).

Figure 38-5 Establish a danger zone to prevent bystanders from entering the incident area.

Safety Tips

Always assume that oncoming traffic cannot see you, and take appropriate steps to keep yourself safe. "Rubberneckers" are gawking at the crash, not looking at you!

Alternative Fuel Vehicles

Today, with advances in automotive technology, some vehicles on the road use alternative fuel. Vehicles may be powered by electricity or electricity/gasoline hybrids, or fuels such as propane, natural gas, methanol, or hydrogen. One feature is common throughout all alternative vehicles—the need for rescue personnel to disconnect the battery to prevent further fire or explosion. In more than 40% of today's alternative fuel vehicles, the batteries are not located in the engine compartment, but in other areas, such as the trunk or under the seats. Furthermore, there may be more than one battery present. You must remain vigilant when presented with alternative vehicles and be aware of their inherent dangers. For example, hybrid batteries have a higher voltage than traditional automotive batteries, and it may take up to 10 minutes for a high voltage system to de-energize after the main battery is turned off. Avoid contact with high-voltage cables (typically orange) and components throughout the rescue. Damaged high-voltage batteries may also give off toxic fumes. Do not approach the vehicle if you detect an unusual odor, and retreat if you experience burning in your eyes or throat until the scene is safe. If not previously notified, call dispatch to request additional assistance from the fire department and/or HazMat team.

Support Operations

Support operations include lighting the scene, establishing tool and equipment staging areas, and marking helicopter landing zones. Fire and rescue personnel will work together on these functions.

Gaining Access

A critical phase of extrication is gaining access to the patient. Remember, do not attempt to gain access to the patient or enter the vehicle until you are sure that the vehicle is stable and that any hazards have been identified and properly controlled or eliminated. When an incident commander is present, you will be authorized to enter the scene or the vehicle only when these conditions have been met.

The safest, most efficient way to reach the patient(s) depends on the situation. It is up to you and the team to identify the best way to gain access. Darkness, uneven terrain, tall grass, shrubbery, and wreckage may make patients hard to find **Figure 38-6**. Multiple vehicles with multiple patients may be involved. If this is the situation, you should locate and rapidly triage each patient to determine who needs urgent care before you proceed with any treatment and patient packaging. Triage is discussed in Chapter 39, *Incident Management.*

Figure 38-6 The exact way to gain access depends on many factors, including the terrain, the way in which the vehicle is situated, and the weather.

Words of Wisdom

Remember that scene size-up is a dynamic and ongoing process, because the situation often changes. As a result, you may need to change your plans for gaining access and providing treatment.

To determine the exact location and position of the patient, consider the following questions:

- Is the patient in a vehicle or in some other structure?
- Is the vehicle or structure severely damaged?
- What hazards exist that pose a risk to the patient and responders?
- In what position is the vehicle? On what type of surface? Is the vehicle stable or is it likely to roll over?

You must also consider the patient's injuries and their severity, and change your course of action as you learn more about the patient's condition. What if you have to quickly remove a patient from a vehicle because the environment is threatening or you need to perform cardiopulmonary resuscitation? Chest compressions and airway management are ineffective when the patient is in a sitting position. Depending on the patient's condition and scene safety, you and your team may have to use the rapid extrication technique (discussed in Chapter 8, *Lifting and Moving Patients*) to move a patient who is not entrapped from a sitting position inside a vehicle to a supine position on a long backboard. A team of experienced EMTs should be able to perform rapid extrication in 1 minute or less.

During the access and extrication phases, make sure that the patient remains safe. For example, cover the patient with a heavy, fire-resistant blanket or place a backboard between the windshield and the patient to protect him or her from breaking glass, flying particles, tools, or other hazards. In addition, maintain good communication with the patient. Reassure the patient that everything possible is being done to remove him or her from the situation. Always describe what you are going to do before you do it and as you are doing it, even if you think the patient is unresponsive **Figure 38-7**.

In many cases, you or your partner may need to provide cervical spine immobilization or other care during extrication.

The rescue team should try to keep heat, noise, and force to a minimum and use only what is necessary to extricate the patient safely.

Figure 38-7 Always explain to the patient why you are there and what you are doing.

Simple Access

The first step is **simple access**, trying to get to the patient as quickly and simply as possible without using any tools or force. Motor vehicles are built for easy entry and exit; however, it may be necessary to use forcible entry methods. The rescue team is responsible for providing the entrance you need to gain access to the patient. In situations where the rescue team has not yet arrived and delayed access to the patient could be life threatening, simple hand tools, such as hammers, center punches (to break side or rear windows), pry bars, and hacksaws, are usually stored on the ambulance for you to use. Whenever possible, you should first try to unlock the doors (or ask the patient to unlock them) or roll down the windows. Try to open every door using the door handles to gain access before breaking any windows or using other methods of forced entry **Figure 38-8**.

> **Safety Tips**
>
> Always try before you pry.

Complex Access

Complex access requires the use of special tools, such as pneumatic and/or hydraulic devices, special training that includes breaking the wind-shield or removing the roof **Figure 38-9**. These advanced skills are typically performed by a specialized team rather than EMS providers and are listed in **Table 38-2**.

Figure 38-8 Get to the patient as quickly and simply as possible by opening the door without using tools or breaking any glass.

Figure 38-9 Complex access requires the use of pneumatic and/or hydraulic devices.

Emergency Care

Providing medical care to a patient who is trapped in a vehicle is essentially the same as for any other patient. Unless there is an immediate threat of fire, explosion, or other danger, once entrance and access to the patient have been provided and the scene is safe, you should perform a primary assessment and provide care before further extrication begins, as follows:

Table 38-2 Vehicle Extrication Techniques (Complex Access)

- Brake and gas pedal displacement
- Dashboard roll-up
- Door removal
- Roof opening and removal
- Seat displacement
- Steering column displacement
- Steering wheel cutting

1. Provide manual stabilization to protect the cervical spine, as needed.
2. Open the airway.
3. Provide high-flow oxygen.
4. Assist or provide for adequate ventilation.
5. Control any significant external bleeding.
6. Treat all critical injuries.

If the patient has obvious, life-threatening external hemorrhage, address it first (even before airway and breathing) and control it quickly.

Removal of the Patient

In the case of a vehicle extrication, work with rescue personnel to determine the best route for removal. Whereas one crash may require removal of the patient through the driver's door, a similar crash may require complete removal of the vehicle's roof. Removal of a patient from a motor vehicle is a multistep process that is intensive in terms of the number of rescue personnel involved, the equipment used, and the effort required to prevent further injury or harm.

As a part of your assessment, participate in the preparation for patient removal. Determine how urgently the patient must be extricated, where you should be positioned to best protect the patient during extrication, and, once the patient has been freed, how you will best move the patient from within the vehicle onto the backboard and onto the stretcher. Carefully examine the exposed area of the limb or other part of the patient that is trapped to determine the extent of injury and whether there is a possibility of hidden bleeding. If possible, evaluate sensation in the trapped area so that you will know whether increased pain indicates that an object is pressing on or impaled in the patient during extrication.

During this time, the rescue team assesses exactly how the patient is trapped and determines the safest, easiest way to extricate him or her. Your input is essential so that the rescue team plans an extrication that protects the patient from further harm. Reevaluate whether the patient needs to be immediately removed by using manual stabilization and the rapid extrication technique, or whether a spinal immobilization device (such as a vest-style extrication device or short backboard) can be applied before he or she is moved further. In most cases, it is impractical and difficult to properly apply extremity splints within the vehicle. Extremity injuries can generally be rapidly supported and stabilized while the patient is being removed by securing an injured arm to the body and, if a leg is injured, securing one leg to the other. This will be adequate until the patient is placed on the immobilization device or until time permits a more detailed assessment and splinting of each injury.

YOU are the Provider — PART 3

As your partner continues to manually stabilize the patient's head, she begins to respond to voice and moans loudly. As the rescue team prepares to remove enough wreckage to allow her to be pulled free, you quickly assess the patient's vital signs.

Recording Time: 7 Minutes	
Respirations	15 breaths/min; shallow
Pulse	138 beats/min; weak at the radial artery
Skin	Cool, clammy, and pale
Blood pressure	98/40 mm Hg
Oxygen saturation (Spo_2)	93% (on oxygen)

A rescue team member informs you that the medical helicopter will arrive in approximately 4 minutes. A landing zone has been established about 500 yards away.

5. Is it appropriate to obtain the vital signs of a patient who is entrapped? Why or why not?
6. What should you do as the patient is being extricated from the wreckage?

Once the extrication plan has been devised and everyone understands what will be done, determine how best to protect the patient. Often, you or your partner will be placed in the vehicle alongside the patient to monitor his or her condition as the vehicle is being forcibly cut, bent, or disassembled. Be sure to wear proper protective clothing.

Remember, your safety and that of the patient are paramount during this process. Extrication is often extremely noisy, and appropriate hearing protection should be worn by you and the patient. Be sure that you can communicate effectively with the patient and the rescue team so that you can instantly let the rescue personnel know if they need to stop.

Transfer of the Patient

Once the patient has been freed, rapidly assess any other patients who were previously inaccessible, and then perform a complete primary assessment. Provide critical interventions, if required. Make sure that the patient's spine is manually stabilized, and apply a cervical collar if this was not previously done Figure 38-10.

To avoid injuring yourself, your team members, or the patient, ensure that each EMT is positioned so that he or she can lift and carry properly at all times. Move the patient in a series of smooth, slow, controlled steps, with designated stops to allow for repositioning and adjustments. Make sure that sufficient team members are available for the move. One EMT should be in charge; he or she will plan and verbalize the exact steps that you will follow to move the patient from a sitting position in the vehicle to lying supine on the backboard or stretcher. Choose a path that requires the least manipulation of the patient and equipment. Once you are sure that everyone understands the steps and is ready, you can transfer the patient safely. Move only on the team leader's command and move the patient as a unit. While transferring the patient, continue to protect the patient from any hazards.

Figure 38-10 Once the patient has been accessed, rapidly assess the patient and make sure that the spine is manually stabilized. Apply a cervical collar if this was not previously done.

Once the patient has been placed on the stretcher, continue with any additional assessment and treatment that was deferred. If it is extremely cold or hot, raining, or snowing, load the stretcher and patient into the climate-controlled ambulance before continuing assessment and treatment. If the patient's condition requires immediate transport, provide only the additional care that is necessary to package the patient. Perform the remaining steps en route to the hospital.

Termination

Termination involves returning the emergency units to service. For rescue units, this process may be time-consuming. All equipment used on the scene, including hydraulic, electric, and hand tools, must be checked before reloading them on the vehicle.

You will also be required to check the ambulance thoroughly, replacing used supplies and decontaminating the unit as required by bloodborne pathogen standards.

Finally, rescue units and medical units will be required to complete all necessary reports.

Specialized Rescue Situations

On most calls, you can drive the ambulance to or within a short distance of the patient's location. However, in some situations, the patient can be reached only by teams trained in special technical rescues. Specialized skills of these teams include the following:

- Cave rescue
- Confined space rescue
- Cross-field and trail rescue (park rangers)
- Dive rescue
- Missing person search and rescue

- Mine rescue
- Mountain-, rock-, and ice-climbing rescue
- Ski slope and cross-country or trail snow rescue (ski patrol)
- Structural collapse rescue
- Special weapons and tactics (SWAT)
- Technical rope rescue (low- and high-angle rescue)
- Trench rescue
- Water and small craft rescue
- White water rescue

Technical Rescue Situations

A **technical rescue situation** requires specialized skills and equipment to safely enter and move around. These situations may contain hidden dangers, and it is unsafe to include personnel who do not have the necessary training and experience. A **technical rescue group** is made up of people from one or more departments in a region who are trained and on call for certain types of technical rescues. Many members of a technical rescue group are also trained as emergency medical responders (EMRs) or EMTs so that they can provide the necessary immediate care when they safely reach the patient. Even when the technical rescue group includes a paramedic or physician, generally only essential care is provided until the group members can bring the patient to the nearest safe and stable setting, known as the staging area.

If a technical rescue group is necessary but is not present when you arrive, immediately check with the **incident commander** to make sure that the group has been summoned and is en route to your location. The incident commander is the individual who has overall command of the scene in the field **Figure 38-11**. Although every team member's input at the scene is important, one person must be clearly in charge. A lack of identifiable leadership at the scene hinders the rescue effort and patient care. The incident commander's assessment of the patient and the scene will dictate how medical care, packaging, and transport will proceed. Usually, the senior medical official is responsible for this role. If no incident commander is present, follow local guidelines. (Chapter 39, *Incident Management*, discusses this in more detail.)

YOU are the Provider — PART 4

The side of the plane has been peeled down, and the patient's seat has been cut to allow access. The patient's legs are freed by moving the back of the seat. You remove the patient from the wreckage using the rapid extrication technique and perform a rapid secondary assessment as your partner reassesses her vital signs.

Recording Time: 18 Minutes	
Level of consciousness	Responsive to voice
Respirations	14 breaths/min; shallow
Pulse	148 beats/min; weak radial pulses
Skin	Cool, clammy, and pale
Blood pressure	80/58 mm Hg
Spo_2	94% (on oxygen)

You note a large, open wound just distal to her right knee with angulation of the tibia. After providing spinal immobilization, you cover the patient with a blanket.

7. How does the rapid extrication technique differ from other methods of patient removal? When is it indicated?

Figure 38-11 The incident commander is the individual who has overall command of the scene.

When you arrive at a scene where a technical rescue is in progress, you will usually be met by a member of the technical rescue group and directed or led to the staging area. If the staging area is some distance from the road, you may need to leave the ambulance on the road. The use of the ambulance stretcher is impractical in these situations; instead take a backboard and/or basket stretcher (or similar rescue stretcher) to carry the patient back to the ambulance. Be sure that you take all of the jump kits and other equipment you may need to treat and immobilize the patient at the staging area.

When you arrive at the rescue site, identify the designated staging area and set up your equipment there. As soon as the technical rescue group brings the patient to the staging area, perform a primary assessment and, after providing the treatment indicated, package the patient without delay. Although you are responsible for the patient's care, it usually requires a cooperative effort by the technical rescue group and the EMTs to carry the patient to the waiting ambulance. Consider using air transport if the patient will need to be carried or transported an extensive distance.

Safety Tips

Treat all downed wires as if they are energized (live) until you receive specific clearance from the electric company. Even if the lights are out along the street where the wires are down, never assume that the wires are de-energized. Be especially alert for downed wires after a storm that has blown down trees or tree limbs.

Search and Rescue

When someone is missing outdoors and a search effort is initiated, an ambulance is usually summoned to the incident **command post** (location of the incident commander) or staging area. Each search team will be organized to include a member who is trained at the EMR or EMT level and who carries the essential equipment to provide essential, immediate care. Your role, and that of the other EMTs who arrive with the ambulance, is to stand by at the command post until the missing person or people have been found.

As soon as you arrive at the scene and have been briefed on the situation, you should isolate and prepare the equipment you will need to carry to the patient's location; this will save time once the patient has been found or if a member of the search team is injured. The carry-in equipment, including a backboard and other devices you will need to immobilize the patient, should be left in the back of the ambulance until it is needed, so that it is protected from the weather. In addition, if the ambulance should need to be relocated, the equipment will not need to be reloaded and will not be left behind. You will usually be given a portable radio that is tuned to the search frequency so that you can monitor the progress of the search and communicate with those in charge of the search operation.

Sometimes, you may be asked to stay with relatives of the missing individual who are at the scene. Find out from relatives whether the missing person has any medical history that may need to be addressed, and pass this information on to those who are in charge of the search. Unless you have been instructed otherwise, only the incident commander should communicate any news or progress of the search to the family. For this reason, be sure that your radio is set at a discreet volume.

Once the missing person has been found, you will be guided by search personnel to that location or to a prearranged meeting point where the patient will be carried, which allows you to begin treatment more quickly. Consider relocating the ambulance or, if one is available, using a four-wheel drive, all-terrain vehicle (ATV), or snowmobile to decrease the time and effort needed to reach and carry out the patient. Be sure that equipment is evenly distributed among personnel and that the pace is such that all can stay together easily. Remember that although EMS will assume the responsibility for patient care once they are at the patient's side, a cooperative effort between the EMS and search teams is necessary to safely carry the patient to the staging area and waiting ambulance.

Trench Rescue

Owing to the physical forces involved, many cave-ins and trench collapses have poor outcomes for victims. Collapses usually involve large areas of falling dirt that weigh approximately 100 pounds per cubic foot (16 kg per cubic meter). Victims with thousands of pounds of dirt resting on their chests cannot fully expand their lungs and may become hypoxic.

The risk of a secondary collapse during the rescue operation is a concern for rescue personnel and EMTs. Safety measures can reduce the potential for injury from this and other hazards. When arriving on the scene of a cave-in or trench collapse, response vehicles should park at least 500 feet from the scene. Because vibration is a primary cause of secondary collapse, all vehicles, including on-scene construction equipment, should be turned off. In addition, all road traffic should be diverted from the 500-foot safety area. Other hazards include exposed or downed electric wires and broken gas or water lines. In addition, construction equipment at the collapse may be unstable and could fall into the cave-in or trench site.

Identify any witnesses to the incident. They may provide valuable information on the number of victims and their location within the collapsed area. Assist any nontrapped people from the area. At no time should medical or rescue personnel enter a trench deeper than 4 feet (1 m) without proper shoring (temporary supports to prevent collapse) in place.

During the extrication of any survivors from a cave-in or trench collapse site, trained medical personnel will provide most medical care. Be prepared to receive patients once they have been extricated from the site.

Tactical Emergency Medical Support

A steady increase in violence throughout the country has resulted in EMTs taking precautions to ensure personal safety. Normally, when the potential for violence exists—as in shootings, stabbings, and attempted suicides—responding units should wait until the scene is secured by law enforcement officers. However, some incidents pose an increased risk to emergency responders. Hostage incidents, barricaded subjects, and snipers require the use of specialized law enforcement tactical units or the **special weapons and tactics team (SWAT)**.

YOU are the Provider — PART 5

A rescue team member drives the ambulance to the landing zone as your partner applies a rigid splint to the patient's right leg and you reassess her vital signs.

Recording Time: 40 Minutes	
Level of consciousness	Responsive to voice
Respirations	16 breaths/min; adequate
Pulse	128 beats/min; weak radial pulse
Skin	Cool, clammy, and pale
Blood pressure	84/60 mm Hg
Spo_2	96% (on oxygen)

The medical helicopter is waiting, and you give a verbal report to the flight paramedic. You assist in the loading of the patient onto the helicopter. You then return to the scene to retrieve any equipment you may have left and to assist with removal of the pilot's body from the wreckage.

8. What are your considerations when calling for air transport?

Words of Wisdom

Physical dangers such as fire, infectious disease, and electricity are not the only risks to your safety during emergency responses. Some calls involve the possibility of deliberate violence against EMTs. Formal tactical situations are obvious examples, but "simple" calls involving assaults, possible alcohol or drug use, and domestic disputes can be just as dangerous. Your training, your attitude when responding to calls, and your routine daily procedures should all help you take these risks into account. Never let your guard down, and continually reassess your surroundings.

Owing to the high potential for injuries at these volatile incidents, many communities have incorporated specially trained EMTs, paramedics, nurses, and even physicians into their SWAT units. These EMS providers provide a special level of care to the sick and injured, and their training goes well beyond the practices seen in standard emergency medical care. Thus, the techniques used may seem inappropriate or inadequate. For example, spinal immobilization is not used within an unsecured area where gunfire is a risk. The time and manpower necessary to completely secure a victim to a backboard may expose EMS providers and SWAT officers to injury or death from gunfire **Figure 38-12**. Such altered standards of care are similar to those used by military EMS providers on the battlefield and are *not* used in the standard situations you will encounter as an EMT.

When called to the scene of a law enforcement **tactical situation**, determine the location of the command post and report to the incident commander for instructions. Lights and siren should be turned off when nearing the scene, and outside radio speakers should not be used. The command post is usually located in an area that cannot be seen by the suspect and is out of range of possible gunfire. Remain in this area and do not roam beyond this site. Nearby areas may be visible to the suspect, and you could be injured.

A number of planning measures will reduce the potential for chaos should a mass-casualty incident occur at the scene. First, have the incident commander identify the specific location of the incident, including the street address and the side of the street on which the house or building is located. The incident commander should determine a safe location (staging area) where you can meet SWAT team members or tactical EMS providers should an injury occur. The incident commander should also determine a safe route to this point. Tactical EMS providers or officers will remove the patient to this area for continued treatment and transport to a medical facility.

Figure 38-12 Tactical EMS providers move a downed officer; only the most basic medical care is provided in an unsecured area.

Words of Wisdom

The topic of active shooter and mass-casualty incidents has received a great deal of attention in recent years. In response, some EMS providers are being trained to enter the area directly around the hazard (the "warm zone") with appropriate law enforcement cover. Their role is to identify patients, provide targeted lifesaving interventions, and perform extraction. Since it is impractical for EMS providers to carry large bags or heavy equipment, they generally provide only essential, specific care including bleeding control, maintaining an open airway, and applying tourniquets.

Such policies should only be implemented in collaboration with local law enforcement and must include appropriate training. Traditional continuing education that focuses on high-quality CPR and other skills that have the greatest potential to save lives should receive the highest emphasis. However, training related to shooting incidents is an excellent resource for you; take advantage of these opportunities.

Words of Wisdom

F-A-I-L-U-R-E:

The reasons for rescue failure can be summarized by the mnemonic FAILURE:

F Failure to understand the environment or underestimating it
A Additional medical problems not considered
I Inadequate rescue skills
L Lack of teamwork or experience
U Underestimating the logistics of the incident
R Rescue versus recovery mode not considered
E Equipment not mastered

To save valuable time in critical situations, designate primary and secondary helicopter landing zones if your region uses aeromedical evacuation. The closest hospital, burn center, and trauma center should be identified. The route of travel to these facilities should also be noted. Many of these measures are incorporated into the operational plan used by tactical EMS providers. If tactical EMS providers are used in your jurisdiction, coordinate with them on your arrival at the command post.

Structure Fires

In most areas, an ambulance is dispatched with the fire department to any **structure fire**, whether or not injuries are reported. A fire in a house or other building is considered a structure fire. When responding to a major fire scene, determine whether any special route will be necessary to reach the scene. Once you arrive at the scene, ask the incident commander where the ambulance should be staged. It is essential that the ambulance be parked far enough from the fire to be safe from the fire itself or a collapsing building. You must also ensure that the ambulance will not block or hinder other arriving units or be blocked in by other equipment or hose lines. However, you must also make sure that the ambulance will be close enough to be visible and that patients can be brought to it easily. The fire officer who is the incident commander will determine this location.

Your next step is to determine whether there are any injured patients at the scene or whether you have been called to stand by. A number of ambulances may be dispatched to a major fire to ensure that one or more units will always remain immediately available at the scene if others leave to transport the injured.

As with other specialized rescue situations, search and rescue in a burning building requires special training and equipment. Search and rescue operations are performed by teams of firefighters wearing full turnout gear and **self-contained breathing apparatus (SCBA)** and carrying tools and fully charged hose lines. These teams will bring patients out of the burning building to the area where the ambulance is staged. Therefore, unless otherwise ordered, you should always stay with the ambulance. Do not leave the scene even after the fire is out because you may need to treat a firefighter who has been injured during salvage and overhaul. The ambulance should leave the scene only if transporting a patient or if the incident commander has released it.

Sometimes the scene at a fire is complicated by the presence of hazardous materials. In addition to posing a threat to you and others at the immediate scene, hazardous materials may pose a threat to a larger population. Whenever there is a possibility that a hazardous material is involved, you will have to follow a number of additional special procedures. Chapter 39, *Incident Management*, covers the specifics of hazardous material procedures.

YOU are the Provider — SUMMARY

1. What information is obtained from a 360-degree assessment of a plane crash?

The 360-degree assessment of a plane crash focuses on hazards unique to this type of incident. Common safety hazards include downed power lines, leaking fuels or other fluids, smoke or fire, broken glass, and aircraft instability. Safety issues must be addressed by the appropriate personnel before anyone attempts to gain access to the patient(s).

Other information obtained during the 360-degree assessment of a plane crash includes the mechanism of injury, the position of the patient(s) in the aircraft, and whether the patient(s) are entrapped or have been ejected.

2. How would your approach change if leaking fuel were present?

A scene with leaking fuel cannot be made 100% safe unless the plane's fuel tank can be emptied. It is imperative that you understand the capabilities of the fire department and rescue team, and coordinate your efforts accordingly. Plan an exit route in the event the scene becomes more unstable. If the fuel spills onto the patient, he or she will have to be decontaminated prior to transport. Fuel spills must also be handled appropriately by qualified personnel.

3. How should you initially attempt to gain access to a crash victim?

Do not attempt to gain access to the patient or enter the wreckage until you are sure that it is stable and that any hazards have been identified and properly controlled or eliminated. The incident commander will inform you when it is safe to gain access to the patient.

Whenever possible, you should use simple access techniques to get to the patient. Try to unlock and open all of the doors, starting with the least damaged door. If the patient's condition requires immediate care and you cannot access the passenger compartment, attempt to provide basic care as the extrication is performed. Be on constant alert for dangers to yourself, your partner, and the patient.

If you must break a window to gain access, try to break one that is farthest away from the patient. If the patient's condition warrants immediate entry (ie, airway compromise, severe bleeding), however, do not hesitate to break the closest window. If you cannot gain access to the patient by opening a door or breaking a window, pneumatic and/or hydraulic rescue tools will be necessary to gain access to the patient.

4. What treatment should you provide to a patient who is entrapped in wreckage?

Unless there is an immediate threat of fire, explosion, or other danger, once entry and access to the patient have been provided, perform a primary assessment and begin immediate emergency care before the process of extrication begins. Focus on identifying and correcting immediate life threats. A lengthy, detailed assessment is inappropriate because this delays the process of patient extrication. Pass on any information that you obtain about the type or degree of entrapment to the extrication team.

In the case of this patient, you can only access her head, torso, and upper extremities. Her legs are pinned by the wreckage. Your partner is manually stabilizing the patient's head and maintaining an open airway with a modified jaw thrust. The airway is clear, and she is breathing, although the rate is a little slow and shallow. There is not enough room to ventilate the patient with a bag-valve mask, but you can apply a nonrebreathing mask to facilitate oxygenation until you have full access to her airway. You have already determined that her pulse is weak and rapid, and her skin is cool, clammy, and pale. You note lacerations to her forehead and right arm.

On the basis of your findings, you should apply high-flow oxygen, control the bleeding from her forehead and arm, and control any other bleeding to the areas of her body that you can access. It would be appropriate to apply a cervical collar—after assessing the back of the neck for any deformities—to help maintain cervical spine immobilization. Cover as much of the patient as you can with a blanket to preserve body heat.

The patient is showing signs of shock; therefore, after correcting problems with airway, breathing, and circulation, she must be extricated so that you can complete your assessment and provide additional treatment.

5. Is it appropriate to obtain the vital signs of a patient who is entrapped? Why or why not?

It is not always appropriate or practical to obtain a complete set of vital signs while a patient is entrapped. Your primary focus should be to provide immediate lifesaving care and then have the patient extricated as quickly and safely as possible.

In some cases, there may be a delay in extricating the patient. If this is the case, obtain a baseline set of vital signs; doing so will provide you with additional information about the patient's condition. However, make sure that you have identified and corrected all immediate life threats *first*.

Do not delay extrication to assess the patient's vital signs. The longer the patient remains trapped in the vehicle, the longer the delay to definitive care.

6. What should you do as the patient is being extricated from the wreckage?

During the coordinated extrication process, your input is essential. Once a plan has been devised and all team members understand what will be done, you have a role in protecting the patient. When possible, position yourself alongside the patient to monitor his or her condition as the wreckage is being cut, bent, or disassembled. In the case of this patient, you and your partner are positioned on opposite sides of the aircraft. Your partner should continue to provide manual stabilization of the cervical spine if it can be managed safely.

Be sure that you are both wearing the appropriate protective clothing (ie, a bunker coat, heavy-duty gloves [over your exam gloves], a rescue helmet, and hearing protection).

Communicate with the patient to let him or her know what is happening. Also communicate with the rescue team. If the patient suddenly screams in pain, instruct the rescue team to stop extrication while you determine where the patient is hurting; it may be necessary for the rescue team to take a different extrication approach.

7. How does the rapid extrication technique differ from other methods of patient removal? When is it indicated?

The main difference between the rapid extrication technique and other methods of patient removal (ie, short backboard, vest-style extrication device) is that it is fast and requires minimal preparation of the patient in the vehicle before he or she is removed. For example, it takes between 6 and 8 minutes—and in some cases, even longer—to properly apply a spinal immobilization device. This is clearly too long when your patient is critically injured and needs immediate treatment and transport. Rapid extrication technique can be performed in 1 minute or less.

8. What are your considerations when calling for air transport?

If your region uses aeromedical evacuation, air transport is an excellent option when a patient is critical and time is a factor. Medical helicopters can quickly access remote locations and provide rapid transport to definitive care. You must locate an area that is large enough and obstacle-free to allow for a landing zone. If the rescue site is not accessible as a landing zone, identify the nearest safe, stable setting (staging area) and transport the patient by ambulance to the alternative location.

To save valuable time in critical situations, designate primary and secondary helicopter landing zones. Identify the closest hospital, burn center, and trauma center, and the most efficient route of travel to these facilities. Many of these measures are incorporated into the operational plan used by tactical EMS providers. If tactical EMS providers are used in your jurisdiction, coordinate with them on your arrival at the command post.

Narrative

EMS was dispatched to private airport for a single-engine plane crash involving two passengers. Upon arrival fire rescue on scene advised that the scene was safe. The aircraft was stabilized, and fire personnel were preparing equipment for extrication. A 360-degree assessment of the victims showed that the pilot had massive head and facial trauma incompatible with life. An unresponsive female passenger, approximately 55 years, occupied the second seat. There were no windows in aircraft, only the windshield in front of the pilot. The patient's upper body was accessible through bars along the portion of the plane next to the patient, but lower extremities were not visible under wreckage. Cervical spine immobilization was established, and the patient's airway opened manually. Respirations were shallow, radial pulses were present but weak, and skin was pale, cool, and diaphoretic. Unable to use BVM to ventilate the patient because of space restrictions so she was placed on NRB mask @ 15 L/min. Patient had a large laceration superior to left orbit with bleeding controlled and a large laceration to right arm with muscle and bone exposed at elbow. Both wounds were bandaged, and the patient was covered with a blanket to preserve heat and provide protection. Window bars were removed, and the side flap was created by rescue team to allow access to the patient. Patient responding to voice at this time. Seat was disassembled, and the patient was extricated onto a backboard. The patient's clothing was removed, and she was covered with blankets. Patient fully immobilized and moved to ambulance for transport to helicopter landing zone. Reassessed vital signs and splinted fracture of right lower extremity. Transferred to air transport, and gave verbal report to flight paramedic. Medic 8 returned to service at 1735.**End of report**

Prep Kit

Ready for Review

- You must always be prepared, mentally and physically, for any incident that requires rescue or extrication.
- As an EMT, your first priority in a rescue incident is personal safety.
- EMS personnel are responsible for the assessment, care, triage, packaging, and transport of patients.
- The rescue team secures and stabilizes the vehicle, provides safe access to patients, and safely extricates patients.
- Law enforcement officers control traffic, maintain order at the scene, establish and maintain a perimeter, and ultimately investigate the crash or crime scene.
- Firefighters extinguish fire, prevent additional ignition, ensure scene safety, and remove spilled fuel. Variations in responsibilities are possible, depending on jurisdictional protocols.
- Vehicle safety systems, such as shock-absorbing bumpers and air bags, protect your patients but also have the potential to injure you.
- Simple access is easily achieved without the use of tools or force. Complex access requires heavy-duty tools and special training.
- The 10 phases of extrication are:
  - Preparation
  - En route to the scene
  - Arrival and scene size-up
  - Hazard control
  - Support operations
  - Gaining access
  - Emergency care
  - Removal of the patient
  - Transfer of the patient
  - Termination
- In some situations, the patient can only be reached by teams trained in special technical rescues. Situations requiring specialized teams include:
  - Cave rescue
  - Confined space rescue
  - Cross-field and trail rescue (park rangers)
  - Dive rescue
  - Missing person search and rescue
  - Mine rescue
  - Mountain-, rock-, and ice-climbing rescue
  - Ski slope and cross-country or trail snow rescue (ski patrol)
  - Structural collapse rescue
  - Special weapons and tactics (SWAT)
  - Technical rope rescue (low- and high-angle rescue)
  - Trench rescue
  - Water and small craft rescue
  - White water rescue

Vital Vocabulary

access Gaining entry to an enclosed area and reaching a patient.

command post The location of the incident commander at the scene of an emergency and where command, coordination, control, and communication are centralized.

complex access Entry that requires special tools and training and includes the use of force.

danger zone (hot zone) An area where people can be exposed to hazards such as electric wires, sharp metal edges, broken glass, toxic substances, radiation, or fire.

entrapment To be caught (trapped) within a vehicle, room, or container with no way out or to have a limb or other body part trapped.

extrication Removal of a patient from entrapment or a dangerous situation or position, such as removal from a wrecked vehicle, industrial incident, or collapsed building.

hazardous materials Any substances that are toxic, poisonous, radioactive, flammable, or explosive and cause injury or death with exposure.

incident commander The individual who has overall command of the incident in the field.

safe zone An area of protection providing safety from the danger zone (hot zone).

self-contained breathing apparatus (SCBA) Respirator with independent air supply used by firefighters to enter toxic and otherwise dangerous atmospheres.

simple access Access that is easily achieved without the use of tools or force.

size-up The ongoing process of information gathering and scene evaluation to determine appropriate strategies and tactics to manage an emergency.

special weapons and tactics team (SWAT) A specialized law enforcement tactical unit.

structure fire A fire in a house, apartment building, office, school, plant, warehouse, or other building.

tactical situation A hostage, robbery, or other situation in which armed conflict is threatened or shots have been fired and the threat of violence remains.

technical rescue group A team of emergency responders from one or more departments in a region who are trained and on call for certain types of technical rescue.

technical rescue situation A rescue that requires special technical skills and equipment in one of many specialized rescue areas, such as technical rope rescue, cave rescue, and dive rescue.

Assessment *in Action*

© Jones & Bartlett Learning. Courtesy of MIEMSS.

You are dispatched to the scene of a motor vehicle crash where a gasoline tanker truck has struck a small passenger van. The truck has come to rest in the center of the intersection. The van is situated against a power pole and you note downed power lines. Air bags in the van have not deployed.

1. Where should you park the ambulance?

   A. Uphill and upwind from the hazard
   B. Uphill and downwind from the hazard
   C. Downhill and upwind from the hazard
   D. Downhill and downwind from the hazard

2. As an EMT, what is your role at the scene of this crash?

   A. To provide safe entrance and access to the patients
   B. To extricate the patients
   C. To assess and provide immediate medical care
   D. To provide traffic control and direction

3. Once the scene is deemed safe to approach, you attempt to gain access to the patients inside the van. Which of the following is an example of simple access?

   A. Opening a rear door
   B. Removing the windshield
   C. Breaking a side window
   D. Prying open a door

4. You note three occupants. There are two adults in the front and a small child in a child safety seat in the rear. Patient care should be initiated:

   A. in the order you reach each patient.
   B. in the order of age beginning with the youngest.

C. based on the mechanism of injury.
D. only after all patients have been triaged.

5. There are downed power lines at this scene. How should you handle this situation?

   A. Approach the scene carefully and avoid stepping on power lines.
   B. Use a public address system to instruct all patients with the ability to walk to come to the ambulance.
   C. Wait for the power company to tell you the scene is safe before approaching either vehicle.
   D. Ask the fire department to bring the patients to the ambulance, since the firefighters are wearing turnout gear.

6. While providing care for an entrapped occupant of the van, you note the unstable power pole start to sway. What should you do?

   A. Advise the safety officer or incident commander immediately.
   B. Immediately cease care and leave the scene.
   C. Request that the extrication be halted to address the problem while you continue to provide care.
   D. Nothing; the rescue team is handling the extrication and controlling the scene.

7. What additional resources would you request in this situation?
8. Define hazardous material.
9. Reasons for rescue failure can be summarized by the mnemonic FAILURE. What does FAILURE stand for?
10. Once the scene is safe to approach, what steps should you take to perform a primary assessment and provide care prior to the initiation of extrication?

CHAPTER 39

Incident Management

National EMS Education Standard Competencies

EMS Operations

Knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

Incident Management

› Establish and work within the incident management system. (pp 1411–1419)

Multiple-Casualty Incidents*

› Triage principles (pp 1420–1422)
› Resource management (pp 1411–1412, 1415–1418)
› Triage (pp 1420–1425)
- Performing (pp 1420–1424)
- Retriage (p 1421)
- Destination decisions (pp 1424–1425)
- Posttraumatic and cumulative stress (pp 1418, 1425)[1]

Hazardous Materials Awareness

› Risks and responsibilities of operating in a cold zone at a hazardous material or other special incident. (pp 1437–1439)

Knowledge Objectives

1. Describe the purpose of the National Incident Management System (NIMS) and its major components. (pp 1411–1412)
2. Describe the purpose of the incident command system (ICS) and its organizational structure. (pp 1412–1415)
3. Explain the role of EMS response within the ICS. (pp 1415–1417)
4. Describe how the ICS assists EMS in ensuring both personal safety and the safety of bystanders, health care professionals, and patients during an emergency. (pp 1416–1417)

5. Describe the role of the EMT in establishing command under the ICS. (p 1416)
6. Describe the purpose of the medical branch of the ICS and its organizational structure. (pp 1417–1419)
7. Describe the specific conditions that would define a situation as a mass-casualty incident (MCI); include examples. (pp 1419–1420)
8. Describe what occurs during primary and secondary triage, how the four triage categories are assigned to patients on the scene, and how destination decisions regarding triaged patients are made. (pp 1420–1422)
9. Explain how to perform the START and JumpSTART triage methods. (pp 1422–1424)
10. Contrast a disaster with a mass-casualty incident. (p 1425)
11. Describe the role of EMTs during a disaster operation. (p 1425)
12. Recognize the entry-level training or experience requirements identified by the HAZWOPER regulation for EMTs to respond to a HazMat incident. (p 1426)
13. Define hazardous material; include the classification system used by the NFPA. (pp 1426, 1439)
14. Discuss the specific reference materials that EMTs use to recognize a HazMat incident. (pp 1432–1436)
15. Explain the role of EMTs during a HazMat incident both before and after the HazMat team arrives; include the precautions required to ensure the safety of civilians and responders. (pp 1437–1439)
16. Describe how the three control zones are established at a HazMat incident, the characteristics of each zone, and the responders who work within each one. (pp 1437–1439)
17. Describe the four levels of personal protective equipment (PPE) required at a HazMat incident to protect responders from injury by or contamination from a particular substance. (pp 1439–1440)
18. Explain patient care at a HazMat incident; include the special requirements that are necessary for those patients who require immediate treatment and transport prior to full decontamination. (pp 1440–1441)

Skills Objectives

1. Demonstrate how to perform triage based on a fictional scenario that involves a mass-casualty incident. (pp 1420–1422)
2. Using a reference, correctly identify DOT labels, placards, and markings that are used to designate hazardous materials. (pp 1430–1432)
3. Demonstrate the ability to use a variety of reference materials to identify a hazardous material. (pp 1432–1436)

Introduction

Some of the most challenging situations you will encounter are disasters and mass-casualty incidents. In this text, a disaster refers to any situation that overwhelms your resources. A single incident with two critical patients can constitute a disaster if there is only one EMS unit available to respond. A **mass-casualty incident (MCI)** refers to any call that involves three or more patients, any situation that places such a great demand on available equipment or personnel that the system would require a **mutual aid response** (an agreement between neighboring EMS systems to respond when local resources are insufficient to handle the response), or any incident that has the potential to create one of the previously mentioned situations. Bus or train crashes and earthquakes are obvious examples of MCIs. These incidents can be overwhelming because you will find a large number of patients and not enough resources. When you respond to an event with a large number of patients, you must use a systematic approach to manage the incident efficiently. By learning to use the principles of the incident command system (ICS), you will be able to do the greatest good for the greatest number of people. As an EMT, you will typically be assigned to work within the EMS/ medical branch under an ICS, but you may be asked to function in other areas, which will be discussed later in this chapter. The National Incident Management System (NIMS) was developed to promote more efficient coordination between emergency responders at the regional, state, and national levels. To reduce on-scene problems and to increase your efficiency, you need a solid understanding of the basics of the NIMS. Training courses may also be accessed through the Federal Emergency Management System (FEMA) website.

National Incident Management System

The Department of Homeland Security implemented the **National Incident Management System (NIMS)** in 2004. Most incidents are handled at the local level, but major incidents require the involvement of multiple jurisdictions, agencies, and emergency response disciplines. The NIMS provides a framework to enable federal, state, and local governments, as well as private-sector and nongovernmental organizations, to work together effectively. The NIMS is used to prepare for, prevent, respond to, and recover from domestic incidents, regardless of cause, size, or complexity, including acts of catastrophic terrorism and hazardous materials (HazMat) incidents.

Two important underlying principles of the NIMS are flexibility and standardization. The organizational structure must be flexible enough to be rapidly adapted for use in any situation. The NIMS provides standardization in terminology, resource classification, personnel training, certification, and more. Another important feature of the NIMS is the concept of interoperability, which refers to the ability of agencies of different types or from different jurisdictions to communicate with each other.

The ICS is one component of the NIMS. The five major NIMS components are as follows:

1. **Preparedness.** The NIMS establishes measures for all responders to incorporate into their systems to prepare for their response to all incidents at any time, including procedures and protocols, licensure, and equipment certification.
2. **Communications and information management.** Effective communications, information management, and sharing are critical aspects of domestic incident management. The NIMS communications and information systems enable the essential functions needed to provide interoperability.

YOU are the Provider — PART 1

Your unit is dispatched to a crash just outside a local amusement park involving an open-air tram transporting guests from the parking lot to the front gate, and a passenger bus that swerved out of control while making a turn. Dispatch advises there have been multiple calls reporting the crash with varying reports of injuries.

1. How will you decide whether to declare this a mass-casualty incident?
2. How will the incident command system facilitate operations at this scene?

3. **Resource management.** The NIMS sets up mechanisms to describe, inventory, track, and dispatch resources before, during, and after an incident. The NIMS also defines standard procedures to recover equipment used during the incident.
4. **Command and management.** The NIMS standardizes incident management for all hazards and across all levels of government. The NIMS standard incident command structures are based on three key constructs: ICS, multiagency coordination systems, and public information systems.
5. **Ongoing management and maintenance.** The multijurisdictional, multidisciplinary NIMS Integration Center (NIC) provides strategic direction for and oversight of the NIMS. It supports routine maintenance and continuous improvement of the system in the long term, including research and development of supporting technologies.

Incident Command System

It is important for you to be familiar with the terminology and concepts of the **incident command system (ICS)**. (Some agencies refer to the incident command system as the incident management system.) The purpose of the ICS is to ensure responder and public safety, achieve incident management goals, and ensure the efficient use of resources.

As you know, communication is the building block of good patient care. Common terminology and the use of "clear text" communications (plain English as opposed to 10-codes) help responders from multiple agencies work efficiently together.

Using the ICS gives you a modular organizational structure that can be applied to all hazards. ICS can be activated for incidents ranging from a single vehicle crash with one patient to a natural gas pipeline explosion involving multiple communities and numerous injuries. The goal of the ICS is to make the best use of your resources to manage the environment around the incident and to treat patients during an emergency. The ICS is designed to avoid duplication of effort and **freelancing**, in which individual units or different organizations make independent and often inefficient decisions about the next appropriate action. Follow your local standard operating procedures for establishing the ICS.

One of the organizing principles of the ICS is to limit the **span of control** of any one individual. This principle refers to keeping the supervisor/worker ratio at one supervisor for three to seven workers. A supervisor who has more than seven people reporting to him or her is exceeding an effective span of control and needs to divide tasks and delegate the supervision of some tasks to another person.

The organizational levels may include sections, branches, divisions, and groups **Figure 39-1**:

- **Sections** are responsible for a major functional area such as finance, logistics, planning, or operations.
- **Branches** are managed by the branch director, and may be functional or geographic in nature. These tend to be established when span of control is a problem; for example, at larger incidents, where more oversight may be needed. Branches are in charge of activity directly related to the section (ie, fire, law enforcement, EMS, operations, etc).
- **Divisions** and **groups** serve to align resources and/or crews under one supervisor. Divisions usually refer to crews

working in the same geographic area. Groups usually refer to crews working in the same functional area, but possibly in different locations.

Generally speaking, the larger the incident, the more divisions there will be. A small incident may require only an IC and support from fire, EMS, and law enforcement. An incident on a much larger scale, such as the Boston Marathon bombing in 2013, will require massive efforts and many agencies working together.

In some regions, emergency operations centers may exist. The centers are usually operated by the city, state, or federal government. These centers will usually be activated only in a catastrophic event that may go on for days. Such events can involve hundreds of patients and tax the entire system.

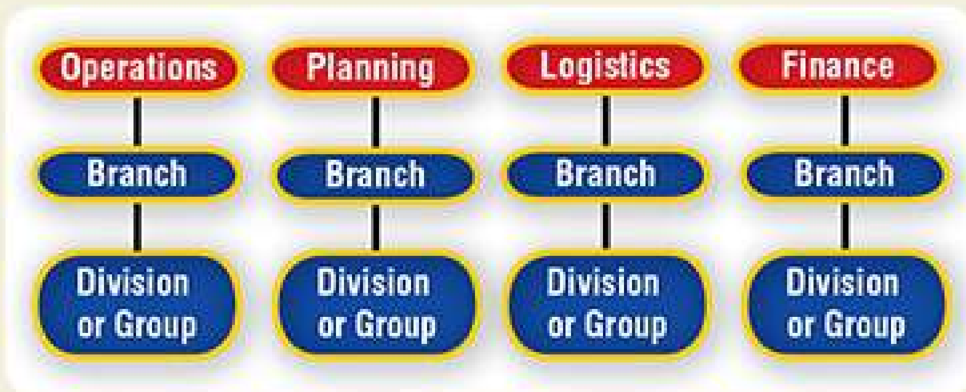

Figure 39-1 The ICS organizational structure may include sections, branches, divisions, and groups.

The responders who will participate in an MCI or a disaster should use the ICS. When an incident occurs, find out from your service who is in charge, how it is activated, and what your expected role will be.

Incident Command System Roles and Responsibilities

There are many roles defined in the ICS. The general staff includes command, finance, logistics, operations, and planning. It is important for you to understand the specific duties of each and how they work to coordinate the response. **Command** staff include the public information officer (PIO), safety officer, and liaison officer.

Command

The **incident commander (IC)** is the person in charge of the overall incident. The IC will assess the incident, establish the strategic objectives and priorities, and develop a plan to manage the incident **Figure 39-2**. The number of command duties the IC takes on often varies by the size of the incident. Small incidents often mean the IC will do it all. In an incident of medium size or complexity, the IC may delegate some functions but retain others. For example, at a motor vehicle crash site with multiple patients, the IC may designate a safety officer or assign a PIO but maintain responsibility for the other command functions. In a complex situation, the IC may appoint team members to all of the command roles.

Figure 39-2 The person in command at a mass-casualty incident oversees the incident and develops a plan for the response.

Courtesy of Captain David Jackson, Saginaw Township Fire Department.

Large MCIs, such as a HazMat incident, require a multiagency or multijurisdiction response and need to use a **unified command system**. In this case, plans are drawn up in advance by all agencies that assume a shared responsibility for decision making. The response plan should designate the lead and support agencies in several kinds of MCIs. (For example, the HazMat team will take the lead in a chemical leak, while the medical team will take the lead in a multivehicle crash.) Agencies that share a border should train often with each other to ensure that a unified command system will function well and that communication among the responders is well established before a real incident occurs.

A **single command system** is one in which one person is in charge, even if multiple agencies respond. It is generally used with incidents in which one agency has the majority of responsibility for incident management. Ideally, it is used for short-duration, limited incidents that require the services of a single agency.

Your IC should be on or near the scene, where he or she can easily communicate with all emergency responders. It is important that you know who the IC is, how to communicate with him or her, and where the **command post** is located. If the incident is very large, you will report to a supervisor working under the IC. (Remember the principle of span of control.) To make the IC easily identifiable, some type of garment is worn, such as a brightly colored vest labeled with the word COMMAND. If the command post is set up in a vehicle, it should be well marked, and you should know its location. Make sure that your supervisor or the IC knows of any plans or operations before they are initiated.

Communication is particularly important if a transfer of command takes place. Because an incident can rapidly change in size and complexity, an IC may turn over command to someone with more experience in a critical area. This change, or transfer of command, must take place in an orderly manner and, if possible, face-to-face. In extreme situations, it could be done by phone, radio, or email, although these methods are not recommended. Your agency should have standard operating procedures that govern the transfer of command. Make certain to follow the standard operating procedures. When an incident draws to a close, there should be a **termination of command**. Your agency should implement **demobilization** procedures as the situation deescalates or comes to an end.

Finance

The **finance** section chief is responsible for documenting all expenditures at an incident for reimbursement. Finance personnel are not usually needed at smaller incidents, but at larger incidents it is necessary to keep track of personnel hours and expenditures for materials and supplies. Ultimately, that information is reported at meetings of the general staff. Responding agencies and organizations may be eligible for reimbursement after the incident, and an efficient finance section chief will help your agency to succeed in the reimbursement process. Finance personnel should be trained in the process of assessing expenditures with an eye to reimbursement long before an actual incident.

The various functions within the finance section include: (1) the time unit, (2) the procurement unit, (3) the compensation and claims unit, and (4) the cost unit. The time unit is responsible for ensuring the daily recording of personnel time and equipment use. The procurement unit deals with all matters concerning vendor contracts. The compensation and claims unit has two major purposes: dealing with claims as a result of the incident, and injury compensation. Finally, the cost unit is responsible for collecting, analyzing, and reporting the costs related to an incident.

Logistics

The **logistics** section is responsible for communications equipment, facilities, food and water, fuel, lighting, and medical equipment and supplies for patients and emergency responders. Local standard operating procedures will list the medical equipment needed for the incident, depending on the type of incident. Logistics personnel are trained to find food, shelter, and health care for you and the other responders at the scene of an MCI. In a large incident, it is often necessary for many people to handle logistics, but only the section chief will report to the IC.

Operations

At a large or complex incident, the IC should appoint an **operations** section chief, who is responsible for managing the tactical operations usually handled by the IC on routine EMS calls. This frees the IC to coordinate with other agencies and the media, engage in strategic planning, and ensure that logistics are functioning effectively. The operations section chief will supervise the people working at the scene of the incident, who will be assigned to branches, divisions, and groups. Operations personnel often have experience in management within EMS.

Planning

The **planning** section solves problems as they arise during the incident. Planners obtain data about the problem, analyze the previous incident plan, and predict what or who is needed to make the new plan work. They need to work closely with the operations, finance, and, especially, logistics sections. Planners can and should call on technical experts to help with the planning process. They should document their decisions and what they learned from the incident and also set out a course for demobilizing the response when necessary.

Another function of the planning section is the development of an **incident action plan**, which is the central tool for planning during a response to a disaster emergency. The incident action plan is prepared by the planning section chief with input from the appropriate sections and units of the incident command team. It should be written at the outset of the response and revised continually throughout the response. In an initial response for an incident that is readily controlled, a written plan may not be necessary. Larger, more complex incidents will require an incident action plan to coordinate activities. The level of detail required in an incident action plan will vary according to the size and complexity of the response.

Command Staff

Three important positions that help the general staff (described previously) and the IC are the safety officer, the public information officer, and the liaison officer. The **safety officer** monitors the scene for conditions or operations that may present a hazard to responders and patients. The safety officer may need to work with environmental health and HazMat specialists. The importance of the safety officer cannot be underestimated—he or she has the authority to stop an emergency operation whenever a rescuer is in danger. A safety officer should remove hazards to EMS personnel and patients before the hazards cause injury.

The **public information officer (PIO)** provides the public and media with clear and understandable information. A wise PIO positions his or her headquarters well away from the incident command post and, most important, away from the incident, to minimize distractions. Also, the PIO must keep the media safe and from becoming part of the incident. The designated PIO may cooperate with PIOs from other agencies in a **joint information center (JIC)**. In some circumstances, the PIO/JIC may be responsible for distributing a message designed to help a situation, prevent panic, and provide evacuation directions.

The **liaison officer** relays information and concerns among command, the general staff, and other agencies. If an agency is not represented in the command structure, questions and input should be given through the liaison officer.

Communications and Information Management

Communications has historically been the weak point at most major incidents. To minimize the effects of communications problems, it is recommended that communications be integrated. This means that all agencies involved should be able to communicate quickly and effortlessly via radios. Communications allow for accountability throughout the incident, as well as instant communication between recipients. As always, and more so during a large incident, you must maintain professionalism on all radio communications, and remember to communicate clearly and concisely using clear text (no 10-codes).

Mobilization and Deployment

When an incident has been declared and the need for additional resources has been identified, a request is made for additional resources. Once a request is made, these resources are mobilized and deployed to the scene. It is important to wait until the request is made before you depart for the scene, to minimize the potential for freelancing.

Check-in at the Incident

On arrival at an incident, first check in with the incident commander at the base, staging area, or other location designated by the IC. If the incident is large in size or complexity, you will be assigned to a supervisor working under the IC. Check-in also allows for personnel tracking throughout the incident, and ensures that costs, wages, and reimbursement can be calculated accurately.

Initial Incident Briefing

After the check-in process is complete, report to your supervisor for an initial briefing that will allow you to get information regarding the incident, as well as your specific job functions and responsibilities.

Incident Record Keeping

Record keeping is important for financial reasons and for documentation purposes. If a large piece of equipment becomes inoperable, it may be possible for the agency to be reimbursed for replacement costs. Record keeping also allows for tracking of time spent on the incident for reimbursement purposes.

Accountability

Because of the large number of responders at a large incident, accountability is important. Accountability means keeping your supervisor advised of your location, actions, and completed tasks. It also includes advising your supervisor of the tasks that you have been unable to complete and what tools you need to complete them.

Incident Demobilization

Once the incident has been stabilized and all of the hazards mitigated, the IC will determine which resources are needed or not needed and when to begin demobilization. This process allows for a prompt return of resources to their parent organizations to be placed back in service.

EMS Response Within the Incident Command System

Preparedness

Preparedness involves the decisions made and basic planning done before an incident occurs. Every state is at risk for natural disasters, such as hurricanes, tornadoes, earthquakes, and wildfires. Therefore, preparedness in a given area involves anticipating the most likely natural disasters for the area, among other disasters.

Your EMS agency should have written disaster plans that you are regularly trained to carry out. A copy of the disaster plan should be kept in each EMS vehicle. EMS facilities should have disaster supplies for at least a 72-hour period of self-sufficiency. Your EMS service should have mutual aid agreements with surrounding organizations; these will facilitate requests for help in an emergency. All groups with mutual aid agreements should practice using the plans frequently. Organizations should share a list of resources with each other so they will know early on what they can access. Also, your local EMS organizations should develop an assistance program for the families of EMS responders. If EMS responders have concerns about their families during a disaster, their effectiveness on the job could be diminished.

Scene Size-up

Remember that scene size-up starts with dispatch. If dispatch information indicates a possible unsafe scene, stay away from the scene or get only close enough to make an assessment without putting yourself in harm's way. When you arrive first on the scene of an incident, you will make an initial assessment and some preliminary decisions. The size-up will be driven by three basic questions that you must ask yourself:

- *What do I have?*
- *What resources do I need?*
- *What do I need to do?*

These questions have a symbiotic relationship. The answer from one helps answer the others, and each answer represents a piece to the puzzle. Work as a team when you answer these questions because overlooking just one safety issue early on can start a chain reaction of problems.

What Do I Have?

Start with scene safety. First, assess the scene for hazards. Warn all other responders about hazardous materials, fuel spills, electrical hazards, or other safety concerns as soon as possible. Confirm the incident location.

Establish whether the incident is open or closed. An **open incident** is one that is not yet contained; there may be patients who have yet to be located and the situation may be ongoing, producing yet more patients. A **closed incident** is one that is contained and in which all casualties are accounted for. However, as with any situation, a closed incident may quickly become an open incident as situations change.

Estimate the number of casualties. Immediately provide a brief incident report to dispatch. An example of such a report would be: "EMT unit number one arriving on scene, multiple vehicles involved, full road blockage, no apparent hazards at this time, EMT unit number one is assuming command."

What Do I Need?

Decide what resources are needed. You may need more EMS responders, ambulances, or other forms of transportation. If extrication is required, a rescue unit and fire department response may be needed. If there are hazardous materials, request a HazMat team immediately (discussed later in the chapter). Many large EMS systems deploy specialized MCI units or mobile emergency room vehicles that are able to treat dozens of patients on the scene **Figure 39-3**.

What Do I Need to Do?

Keep the following priorities in mind:

- Safety
- Incident stabilization
- Preservation of property and the environment

You need to consider these priorities in the order they are given. Safety is paramount. Safety includes your life, your partner's life, and other responders' lives. Then, consider the safety of the patient and any bystanders. This will be difficult for anyone dedicated to saving lives, but it is important to put yourself and your partner first—you have the skills, and bystanders usually do not; the situation can worsen if you become a victim yourself. Often, if a responder is injured, other responders will focus on "their own," removing critical resources from the incident.

Figure 39-3 This mobile emergency room is staffed by EMTs, paramedics, and physicians who are able to provide advanced life support to multiple patients simultaneously on the scene of a mass-casualty incident.

YOU are the Provider — **PART 2**

Upon reaching the scene, you see utter chaos. Your unit is the first to arrive, and the large crowd makes it virtually impossible to determine the number of patients or the extent of injuries. The dispatcher advises that law enforcement, fire department, and additional EMS units are en route.

3. How should you and your partner proceed?

4. Once command has been established, what are your duties?

You may have to initially work to isolate or stabilize the incident before providing care to injured people—this is another difficult concept for all emergency workers. Remember, you cannot help the injured if the scene is unstable. An unstable scene can lead to an injured EMT.

Establishing Command

Once you have performed a good scene size-up and answered the three basic questions, command should be established by the most senior official, notification to other responders should go out, and necessary resources should be requested. Recall that a command system ensures that resources are effectively and efficiently coordinated. Command must be established early, preferably by the first-arriving, most experienced public safety official. These officials may include police, fire, or EMS personnel.

Communications

As discussed earlier, communications is often the key problem at an MCI or a disaster. The infrastructure may be damaged, or communications capabilities may be overwhelmed. If possible, use face-to-face communications to limit radio traffic.

Some organizations responding to a disaster might not know how to use a radio. If you communicate via radio, do not use 10-codes or signals. Most communications problems should be worked out before a disaster happens by designating channels strictly for command during a disaster. Whatever form of communications equipment is used, it must be reliable, durable, and field-tested. Be sure there are backups in place if the primary communications system does not work. Some regions have mobile self-contained communications centers, whereas others use local radio groups such as ham radio operators to assist with communications. Most important, your plan should include a "plan B" in case of communications failure.

The Medical Branch of Incident Command

What has traditionally been referred to as medical incident command is more commonly known as the medical (or EMS) branch of the ICS **Figure 39-4**. At incidents that have a significant medical factor, the IC should appoint someone as the medical branch director. This person will supervise the primary roles of the medical branch—triage, treatment, and transport of injured people. The medical branch director helps to ensure that EMS units responding to the scene are working within the ICS, each medical division or group receives a clear assignment before beginning work at the scene, and personnel remain with their vehicle in the staging area until they are assigned their duties. Depending on the scale of the incident, medical may be a branch or may fall under the logistics section as a unit.

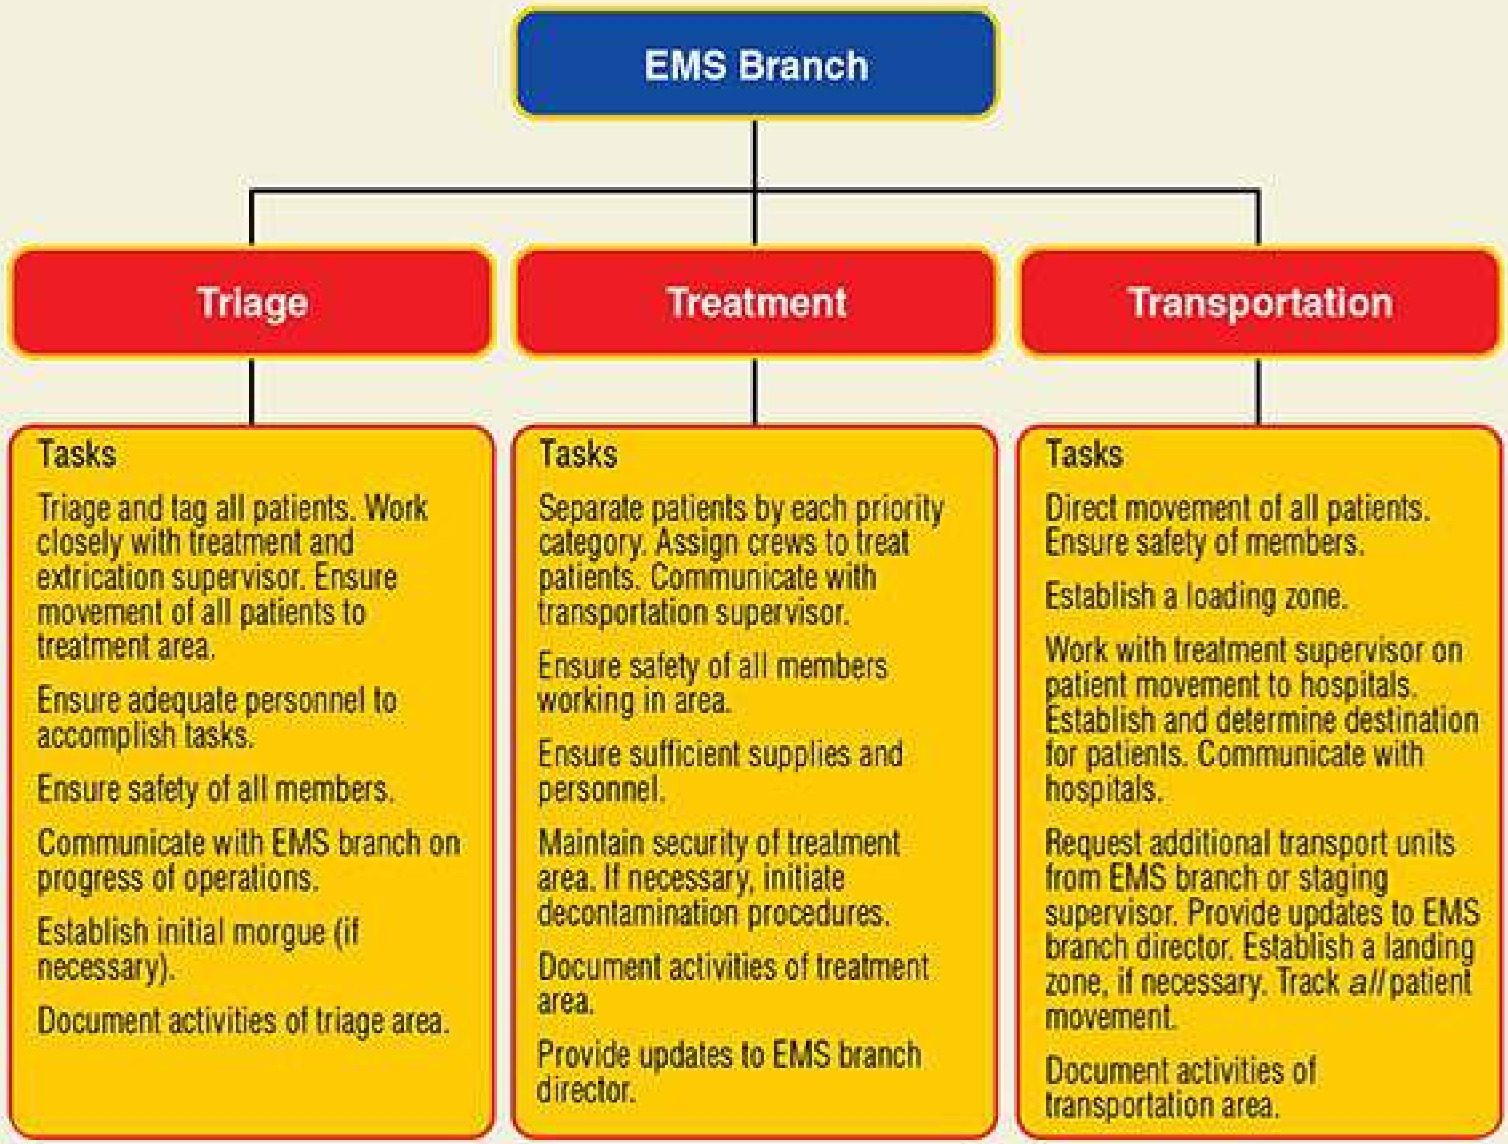

Figure 39-4 Components of the medical branch within the incident command system.

▶ Triage Supervisor

The **triage supervisor** is ultimately in charge of counting and prioritizing patients. During large incidents, a number of triage personnel may be needed. The primary duty of the triage division or group is to ensure that every patient receives initial assessment of his or her condition. One of the most difficult parts of being a triage supervisor is that you must not begin treatment until all patients are triaged, or you will compromise your triage efforts.

▶ Treatment Supervisor

The **treatment supervisor** will locate and set up the **treatment area** with a tier for each priority of patient. The treatment supervisor ensures that secondary triage of patients is performed and that adequate patient care is given as resources allow. The treatment supervisor also assists with moving patients to the **transportation area**. As the treatment supervisor supervises the responders, he or she must communicate with the medical branch director to request sufficient quantities of supplies, including bandages, burn supplies, airway and respiratory supplies, and patient packaging equipment.

Transportation Supervisor

The **transportation supervisor** coordinates the transportation and distribution of patients to appropriate receiving hospitals and helps to ensure that hospitals do not become overwhelmed by a patient surge. The transportation supervisor coordinates with the incident commander to ensure that enough personnel and ambulances are in the staging area or have been requested. Some regions may plan for a designated hospital to coordinate with area hospitals on destination decisions. An MCI typically disrupts the everyday functioning of the region's trauma system, so good coordination is needed. The transportation supervisor documents and tracks the number of transport vehicles, patients transported, and the facility destination of each vehicle and patient.

Staging Supervisor

A **staging supervisor** is assigned when an MCI or disaster requires a multivehicle or multiagency response. Emergency vehicles must have permission from the staging supervisor to enter an MCI scene and should drive only in the directed area. The staging area should be established away from the scene so that the parked vehicles are not in the way. The staging supervisor locates an area to stage equipment and responders, tracks unit arrivals, and releases vehicles and supplies when ordered by command. This position plans for efficient access to and exit from the scene and prevents traffic congestion among responding vehicles.

Physicians on Scene

In an MCI or disaster, some areas have plans in place for physicians to be sent to the scene. Sometimes, even without a plan, the enormity of the situation may require physicians on scene. Emergency physicians, especially, will have the ability to make difficult triage decisions. They also provide secondary triage decisions in the treatment area, deciding which priority patients are to be transported first. Physicians can provide on-scene medical direction for EMTs, and they can provide care as appropriate.

Rehabilitation Supervisor

In disasters or MCIs that will last for extended periods, a rehabilitation section for the responders should be established. The **rehabilitation supervisor** establishes an area that provides protection for responders from the elements and the situation. The **rehabilitation area** should be located away from exhaust fumes and crowds (especially members of the media) and out of view of the scene itself. Rehabilitation is where a responder's needs for rest, fluids, food, and protection from the elements are met. The rehabilitation supervisor must also monitor responders for signs of stress. These signs may include fatigue, altered thinking patterns, and complete collapse. Remember that all EMS personnel must be aware of signs of stress. Your service might consider having a defusing or debriefing team in this area. Responders should be encouraged to take advantage of these services but should never be forced to participate.

Extrication and Special Rescue

Some MCIs or disasters require search and rescue or extrication of patients **Figure 39-5**. An **extrication supervisor** or **rescue supervisor** may need to be appointed. These officers determine the type of equipment and resources needed for the situation. In some incidents, victims may need to be extricated or rescued by specially trained personnel before they can be triaged and treated. Because extrication and rescue are medically complex, the supervisors will usually function under the EMS branch of the ICS. Extrication and rescue can be dangerous, so team member safety is of utmost importance.

Morgue Supervisor

In some MCIs or disasters, there will be many dead patients. The **morgue supervisor** will work with area medical examiners, coroners, disaster mortuary assistance teams, and law enforcement agencies to coordinate removal of the bodies and even, possibly, body parts. The morgue supervisor should attempt to leave the dead victims in the location found, if possible, until a removal and storage plan can be determined. The location of victims may help in the identification of the dead victims in mass-fatality situations, or there may be crime scene considerations. If it is determined that a morgue area is needed, the morgue supervisor should ensure that the morgue is out of view of the living patients and other responders because the psychologic impact could worsen the situation. In addition, the morgue should be secured from the public to prevent theft of any personal effects of the dead victims.

Figure 39-5 Some disasters will involve search and rescue or extrication.

Mass-Casualty Incidents

As discussed earlier, an MCI is an emergency situation that involves three or more patients, places great demand on the EMS system, and/or has the potential to produce multiple casualties **Figure 39-6**. However, other causes of MCIs are far more common than disasters and are usually much smaller in scope. **Figure 39-7** is a diagrammed example of a residential building fire confined to one apartment that may only produce one patient but that has the potential to generate dozens of patients from among the responders and residents. Loss of power to a hospital or nursing home with ventilator-dependent and nonambulatory victims is considered an MCI, although no one is injured. By using the ICS and the NIMS and understanding the various roles and responsibilities of each position, the responders and/or IC can manage the incident in a smooth, organized manner.

Figure 39-6 Mass-casualty incidents can be large, such as the attack on September 11, 2001, or they can be much smaller in scope.

Courtesy of Michael Rieger/FEMA.

All systems have different protocols for when to declare an MCI and initiate the ICS; however, as an EMT, ask yourself the following questions when considering whether the call is an MCI:

- *How many seriously injured or ill patients can I care for effectively and transport in the ambulance? One? Two?*
- *What happens when I have three patients to manage?*
- *How long will it take for additional help to arrive?*
- *What happens if the number of patients exceeds the number of available ambulances?*

Obviously, you and your team cannot treat and transport all injured patients at the same time. At an MCI, you will often experience an increased demand for equipment and personnel. For example, you may realize that you are the only ambulance crew currently at the scene and there is a wait of 15 or more minutes before the next ambulance arrives. Never leave the scene with patients if there are still other patients present who are sick or wounded. This would leave patients at the scene without medical care and can be considered abandonment. If there are multiple patients and not enough resources to handle them without abandoning victims, you should declare an MCI (at least for the present time), request additional resources, and initiate the ICS and triage procedures (discussed next) **Figure 39-8**. Although this may cause some delay in initiating treatment to all patients, it will not adversely affect the patient care. Always follow your local protocol. Many large EMS systems deploy specialized MCI units or mobile emergency room vehicles that are able to treat dozens of patients on the scene.

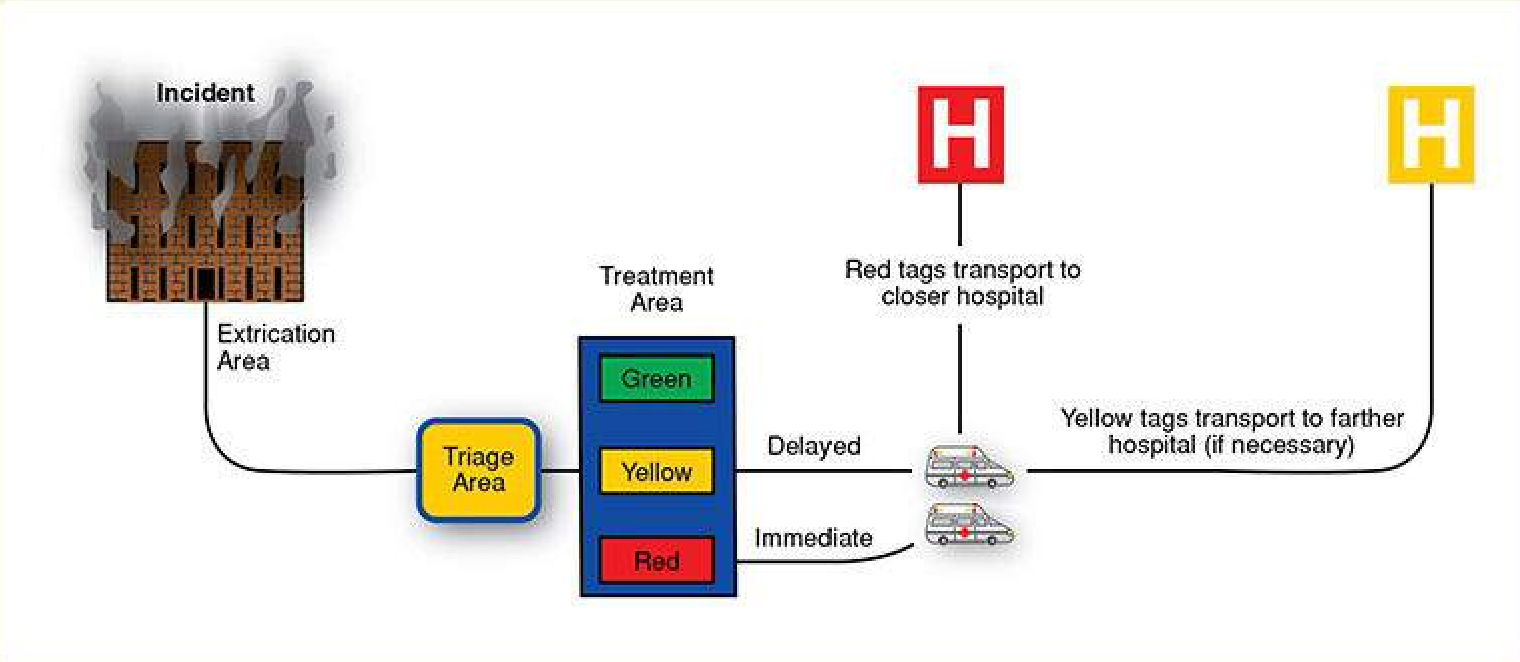

Figure 39-7 Diagram of a mass-casualty incident. The incident command system established at the scene of a building fire may look similar to this diagram.

Words of Wisdom

The terminology used to describe an incident with multiple patients varies in different communities. Many communities use *mass-casualty situation* to describe an emergency that involves more than one patient but use the term *mass-casualty incident* to describe larger scale events, such as those with more than 20 patients. In this text, the term *mass-casualty incident* is used to describe any call that involves three or more patients.

Figure 39-8 Mass-casualty incidents require additional ambulances and EMS providers from the immediate region.

Triage

Triage simply means *to sort* your patients based on the severity of their injuries **Figure 39-9**. The goal of doing the greatest good for the greatest number means that the triage assessment is brief and the patient condition categories are basic. **Primary triage** is the initial triage done in the field, allowing you to quickly and accurately categorize the patient's condition and transport needs, whereas **secondary triage** is done as patients are brought to the treatment area. During primary triage, patients are briefly assessed and then identified in some way, such as by attaching a triage tag or triage tape. The main information needed on the tag is a unique number and a triage category. Rapid and accurate triage will help bring order to the chaos of the MCI scene and allow the most critical patients to be transported first. After the primary triage, the triage supervisor should communicate the following information to the medical branch director:

Figure 39-9 Triage is the process of sorting and prioritizing patients based on severity of conditions.

Courtesy of Journalist 1st Class Mark D. Faram/U.S. Navy.

Words of Wisdom

Recall from Chapter 32, *Environmental Emergencies*, that you should use the reverse triage method with multiple victims of a lightning strike. With traditional triage, an apneic and pulseless patient would typically be triaged as "black" or "expectant." In the case of a lightning strike, however, treat cardiac or respiratory arrest victims first.

- The total number of patients
- The number of patients in each of the triage categories
- Recommendations for extrication and movement of patients to the treatment area
- Resources needed to complete triage and begin movement of patients

When the initial triage has been completed, secondary triage, or retriage, can occur, allowing you to reassess all remaining patients and to upgrade the triage category, if necessary. In smaller MCI events, this step may not be necessary, if enough resources have arrived on the scene.

Triage Categories

There are four common triage categories. You can remember them using the mnemonic IDME, which stands for Immediate (red), Delayed (yellow), Minor or Minimal (green; hold), and Expectant (black; likely to die or dead) Table 39-1. This is the order of priority for treatment and transport of the patients at an MCI.

Table 39-1 Triage Priorities

Triage Category	Typical Injuries
Red tag: first priority (immediate) Patients who need immediate care and transport Treat these patients first, and transport as soon as possible	▪ Airway and breathing compromise ▪ Uncontrolled or severe bleeding ▪ Severe medical problems ▪ Signs of shock (hypoperfusion) ▪ Severe burns ▪ Open chest or abdominal injuries
Yellow tag: second priority (delayed) Patients whose treatment and transport can be temporarily delayed	▪ Burns without airway compromise ▪ Major or multiple bone or joint injuries ▪ Back injuries with or without spinal cord damage
Green tag: third priority, minimal (walking wounded) Patients who require minimal or no treatment and transport can be delayed until last	▪ Minor fractures ▪ Minor soft-tissue injuries
Black tag: fourth priority (expectant) Patients who are already dead or have little chance for survival; treat salvageable patients before treating these patients	▪ Obvious death ▪ Obviously nonsurvivable injury, such as major open brain trauma ▪ Respiratory arrest (if limited resources) ▪ Cardiac arrest

Immediate (red-tag) patients are your first priority. They need immediate care and transport. They usually have problems with the ABCs, head trauma, or signs and symptoms of shock.

Delayed (yellow-tag) patients are the second priority and need treatment and transport, but it can be delayed. Patients usually have multiple injuries to bones or joints, including back injuries with or without spinal cord injury.

Minimal (green-tag) patients are the third priority. Patients may require no field or only minimal treatment. In some parts of the world, this is the hold category. These patients are the "walking wounded" at the scene. If they have any apparent injuries, they are usually soft-tissue injuries such as contusions, abrasions, and lacerations.

The last priority is the expectant (black-tag) patients who are dead or whose injuries are so severe that they have, at best, a minimal chance of survival. This category may include patients who are in cardiac arrest or who have an open head injury, for example. If you have limited resources, this category may also include patients in respiratory arrest. Patients in this category receive treatment and transport only after patients in the other three categories have received care.

Triage Tags

Whatever triage system is used, it is vital that a patient has a tag or some type of label. Tagging patients early assists in tracking them and keeping an accurate record of their condition. Triage tags should be water proof and easily read Figure 39-10. The patient tags or tape should be color-coded and should clearly show the category of the patients. The use of symbols and colors to indicate the triage categories is important in case some responders are color-blind.

The tags will become part of the patient's medical record. Most have a tear-off receipt with a number correlating with the number on the tag. When torn off by the transportation officer, it will assist him or her in tracking the patient. If the patient is unconscious and cannot be identified at the scene, the tag will be an identifier for tracking purposes. Some areas use digital photography to assist in identifying patients later. The photograph is catalogued with the patient's tag number, and the patient's location is tracked with this information. When family members are brought to crisis centers to help locate loved ones, the pictures may be of assistance. This technique has been used effectively in Europe and Israel with Polaroid or digital photos. Another way of tracking and accounting for patients is to issue only 20 to 25 cards or tags at a time with a scorecard to mark how patients are triaged and their priority. When the responder returns for more tags, the scorecard will provide a patient count to help command and the staff to develop a plan to respond and ensure that appropriate resources are either available or summoned. Whatever labeling system is used, it is imperative for the transportation officer to be able to identify which patient was transported by which unit and to which destination, and the priority of the patient's condition.

▶ START Triage

START triage is one of the easiest methods of triage. START stands for Simple Triage And Rapid Treatment. The staff members at Hoag Memorial Hospital, Newport Beach, CA, developed this method of triage. It is easily mastered with practice and will give you the ability to rapidly categorize patients at an MCI. START triage uses a limited assessment of the patient's ability to walk, respiratory status, hemodynamic status (pulse), and neurologic status.

The first step of the START triage system is performed on arrival at the scene by calling out to patients at the disaster site, "If you can hear my voice and are able to walk..." and then directing patients to an easily identifiable landmark. The injured people in this group are the walking wounded and are considered minimal (green) priority, or third-priority, patients.

The second step in the START process is directed toward nonwalking patients. Move to the first nonambulatory patient and assess the respiratory status. If the patient is not breathing, open the airway by using a simple manual maneuver. A patient who still does not begin to breathe is triaged as expectant (black). If the patient begins to breathe, tag him or her as immediate (red), place in the recovery position, and move on to the next patient **Figure 39-11**.

If the patient is breathing, make a quick estimation of the respiratory rate. A patient who is breathing faster than 30 breaths/min or slower than 10 breaths/ min is triaged as an immediate priority (red). If the patient is breathing from 10 to 29 breaths/min, move to the next step of the assessment.

The next step is to assess the hemodynamic status of the patient by checking for bilateral radial pulses. An absent radial pulse implies the patient is hypotensive; tag him or her as an immediate priority. If the radial pulse is present, go to the next assessment.

The final assessment in START triage is to assess the patient's neurologic status, which simply means to assess the patient's ability to follow simple commands, such as "Show me three fingers." This assessment establishes that the patient can understand and follow commands. A patient who is unconscious or cannot follow simple commands is an immediate priority patient. A patient who complies with a simple command should be triaged in the delayed category (yellow).

Figure 39-11 **A.** A START triage tag is ripped to the level of severity. **B.** A SMART triage tag folds to the level of severity.

Words of Wisdom

Another triage method is the Sort, Assess, Lifesaving interventions, and Treatment and/or Transport (SALT) triage system. This triage system begins with a global sorting of patients. This step identifies the patients who are able to understand verbal instructions and are therefore likely to have good systemic perfusion. Patients who can walk are asked to move to a designated area and are assigned last priority. This is an attempt to decrease the number of patients leaving the scene and overwhelming local hospital resources before EMS can begin to move highest priority patients. Once those patients have been identified and moved, each remaining patient is assessed individually. The SALT method differs from others in its lifesaving intervention steps, which include bleeding control, opening the airway, two rescue breaths for children, needle decompression for tension pneumothorax, and auto-injector antidotes. These interventions may be all that is needed to upgrade the patient's condition on the SALT triage scale. The final step is treatment and/ or transport.

JumpSTART Triage for Pediatric Patients

Lou Romig, MD, recognized that the START triage system does not take into account the physiologic and developmental differences of pediatric patients. She developed the **JumpSTART triage** system for pediatric patients. JumpSTART is intended for use in children younger than 8 years or who appear to weigh less than 100 pounds (45 kg). As in START, the JumpSTART system begins by identifying the walking wounded. Infants or children not developed enough to walk or follow commands (including children with special needs) should be taken as soon as possible to the treatment area for immediate secondary triage. This action assists in getting children who cannot take care of their own basic needs into a health care provider's hands. There are several differences within the respiratory status assessment compared with that in START. First, if you find that a pediatric patient is not breathing, immediately check the pulse. If there is no pulse, label the patient as expectant (black). If the patient is not breathing but has a pulse, open the airway with a manual maneuver. If the patient does not begin to breathe, give five rescue breaths and check respirations again. A child who does not begin to breathe should be labeled expectant. The primary reason for this difference is that the most common cause of cardiac arrest in children is respiratory arrest.

The next step of the JumpSTART process is to assess the approximate rate of respirations. A child who is breathing fewer than 15 breaths/min or more than 45 breaths/min is tagged as an immediate priority (red), and you move on to the next patient. If the respirations are within the range of 15 to 45 breaths/min, the patient is assessed further.

The next assessment in JumpSTART triage is also the hemodynamic status of the patient. Just like in START, you are simply checking for a distal pulse. This does not need to be the brachial pulse; assess the pulse that you feel the most competent and comfortable checking. If there is an absence of a distal pulse, label the child as an immediate priority and move to the next patient. If the child has a distal pulse, move on to the next assessment.

The final assessment is for neurologic status. Because of the developmental differences in children, their responses will vary. For JumpSTART, a modified AVPU score is used. A child who is unresponsive or responds to pain by posturing or with incomprehensible sounds or is unable to localize pain is tagged as an immediate priority. A child who responds to pain by localizing it or withdrawing from it or is alert is considered a delayed-priority patient (yellow).

Triage Special Considerations

There are a few special situations in triage. Patients who are hysterical and disruptive to rescue efforts may need to be handled as an immediate priority and transported off the site, even if they are not seriously injured. Panic breeds panic, and this type of behavior could have a negative impact on other patients and on the responders.

A responder who becomes sick or injured during the rescue effort should be handled as an immediate priority and be transported off the site as soon as possible to avoid negative impact to the morale of remaining responders.

HazMat and weapons of mass destruction incidents force the HazMat team to identify patients as contaminated or decontaminated before the regular triage process. Contamination by chemicals or biologic weapons in a treatment area, a hospital, or trauma center could obstruct all systems and organizations coping with the MCI or disaster. Bear in mind that some incidents may require multiple triage areas or teams because the victims are located far apart.

Destination Decisions

All patients triaged as immediate (red) or delayed (yellow) should preferably be transported by ground ambulance or air ambulance, if available, to the most appropriate facility (trauma, burn, or pediatric center, etc). In extremely large situations, a bus may transport the walking wounded. If a bus is used for minimal-priority patients, it is strongly suggested that they be transported to a hospital or clinic distant from the MCI or disaster site to avoid overwhelming the local area hospital resources. Refer to the Centers for Disease Control and Prevention 2011 decision scheme for field triage of injured patients presented in Chapter 24, *Trauma Overview*. If a bus is used, plan for at least one EMT or paramedic to ride on board and to have an ambulance follow the bus. If a minimal-priority patient's condition worsens, the patient could be moved to the ambulance and transported to a closer facility. The EMT or paramedic can stay with the minimal-priority patients until their arrival at the designated hospital. Any worsening of a patient's condition must be relayed to the receiving hospital as soon as possible in whatever manner the incident dictates.

YOU are the Provider PART 3

Using the ambulance's public address (PA) system, you ask for anyone who can walk to come to the front gate, where a bus will be positioned to transport them. Next, you approach a supine middle-aged woman who is unresponsive with slow respirations. She has weak radial pulses. The next patient you encounter is a teenage boy who is apneic with a weak carotid pulse and no radial pulses. You note exposed brain matter. The third patient is an older woman with a severe laceration through the neck and chest; the neck injury has caused near decapitation. She is apneic and pulseless.

5. What are your considerations in determining whether you should stop and provide treatment for the first patient?
6. What triage categories should you assign to the second and third patients?

Immediate-priority patients should be transported two at a time until all are transported from the site. Then patients in the delayed category can be transported two or three at a time until all are at a hospital. Finally, the walking wounded are transported. Expectant patients who are still alive would receive treatment and transport at this time. Dead victims are handled or transported according to the standing operating procedure for the area.

It is important to remember that during an MCI, local hospitals may have their resources overwhelmed. Early notification to receiving facilities will allow for the hospitals to increase staffing and move patients within their facility as required. Typically, EMS agencies will know a hospital's surge capacity, which will tell the agency how many patients of each category the hospital is able to safely handle and care for.

Disaster Management

A **disaster** is a widespread event that disrupts functions and resources of a community and threatens lives and property. Many disasters do not necessarily result in personal injuries; for example, droughts causing widespread crop damage. On the other hand, many disasters such as floods, fires, and hurricanes will result in widespread injuries. Unlike an MCI, which generally lasts no longer than a few hours, emergency responders will generally be on the scene of a disaster for days to weeks and sometimes months (as in the events following Hurricane Katrina in 2005). Although you can "declare" an MCI as an EMT, only an elected official can declare a disaster.

Your role in a disaster is to respond when requested and to report to the IC for assigned tasks. In a disaster with an overwhelming number of casualties, area hospitals may decide that they cannot treat all patients at their facility. In this case, they may mobilize medical and nursing teams with equipment and set up a **casualty collection area** at a facility near the disaster scene, such as a warehouse. Once at the casualty collection area, the teams can perform triage, provide medical care, and transport patients to the hospital on a priority basis.

If a casualty collection area is established, it will be coordinated through the ICS in the same way as all other branches and areas of the operation. This is usually done only in a major disaster such as an earthquake when transportation to a hospital facility is impossible or involves prolonged delays. It may take several hours to establish a casualty collection area.

Words of Wisdom

Mass-casualty incidents and disasters take a physical and emotional toll on emergency responders. Make certain that you are medically evaluated if you have been injured, come into contact with any hazardous substance, or inhale any dust, fumes, or smoke. Often the health effects of such exposures do not manifest for years and are difficult to link back to a particular event. Also be aware of the signs of stress in yourself and in your coworkers. Consider taking advantage of critical incident stress debriefing (CISD)/critical incident stress management (CISM) opportunities after an incident if you feel they may be valuable. Chapter 2, *Workplace Safety and Wellness*, covers stress and CISD/CISM in detail.

Words of Wisdom

Urban Search and Rescue teams (USARs) and Disaster Medical Assistance Teams (DMATs) may be mobilized in the event of a natural disaster or mass-casualty incident. USARs typically provide rescue and initial medical stabilization to patients entrapped in confined spaces, such as from a structural collapse. DMATs provide medical care during an incident; they include providers such as physicians, paramedics, nurses, and EMTs who work at a federal level. DMATs arrive with sufficient supplies and equipment to provide care for at least 72 hours or until further aid arrives or the situation is resolved.

Introduction to Hazardous Materials

Your training has taught you that rapid response to the scene of a crash can save lives. However, when you arrive at the scene of a possible HazMat incident, you must first step back and assess the situation. This can be very stressful for you, particularly if you can see a patient. However, rushing into an unsafe scene can have catastrophic results. If you are overcome by a hazardous substance, not only will patients suffer because you will be unable to assist them, but you will also place a strain on the system because you will require emergency care.

Words of Wisdom

Methamphetamine (meth) is an illegal substance that has gained in popularity due to its increased accessibility and relatively low cost. Meth is manufactured in illegal labs with highly volatile chemicals in a process known as "cooking." The toxic fumes from meth labs not only create respiratory hazards, but may also ignite, causing fires or explosions. Exposure to the toxic fumes may cause irritation to the nose and throat, headaches, confusion, altered mental status, dizziness, nausea and/or vomiting, and respiratory problems.

You may find meth labs anywhere in the country, including homes, garages, abandoned trailers, or the trunk of a vehicle. People who cook meth are often exposed to the toxins or have burn injuries because the risk of explosion is high. Therefore, your potential for contact with a meth lab is high.

When responding to a general medical call, you may not realize that you are responding to a hazardous area. A house with all of the windows covered, glass cookware with a powdery residue, or a strong smell of an unusual odor like ammonia, cat urine, or nail polish remover is a sign of a potential meth lab. When responding to a motor vehicle crash, be aware of any vehicle with paint peeling off the back, especially around the seams where the trunk closes. If you have any suspicions that you may be in the presence of a meth lab, leave the area immediately and notify law enforcement to secure the scene and arrange for decontamination and cleanup.

Because of the unique aspects of responding to and working at a **hazardous materials (HazMat) incident**, the Occupational Safety and Health Administration, or OSHA, has published a set of guidelines known as the Hazardous Waste Operations and Emergency Response (HAZWOPER). All providers, including EMTs, must meet specific additional training requirements before becoming involved in HazMat incidents. As an EMT, you need training at the First Responder Awareness Level. This text does not include the skills and information necessary to meet those requirements. You need to check with your agency for information about specific awareness level training.

On the basis of the HAZWOPER regulation, first responders at the awareness level should have sufficient training or experience to demonstrate competency in the following areas:

- An understanding of what hazardous substances are and the risks associated with them
- An understanding of the potential outcomes of an incident
- The ability to recognize the presence of hazardous substances
- The ability to identify the hazardous substances, if possible
- An understanding of the role of the first responder awareness individual in the emergency response plan
- The ability to determine the need for additional resources and to notify the communication center

Recognizing a Hazardous Material

A **hazardous material** is any material that poses an unreasonable risk of damage or injury to people, property, or the environment if it is not properly controlled during handling, storage, manufacture, processing, packaging, use and disposal, and transportation. Recognizing a HazMat incident, determining the identity of the material(s), and understanding the hazards involved often require some detective work. You must train yourself to take the time to look at the whole scene so that you can identify the critical visual indicators and fit them into what you know about the problem.

Hazardous materials may be involved in any of the following situations **Figure 39-12**:

- A truck or train crash in which a substance is leaking from a tank truck or railroad tank car
- A leak, fire, or other emergency at an industrial plant, refinery, or other complex where chemicals or explosives are produced, used, or stored
- A leak or rupture of an underground natural gas pipe
- Deterioration of underground fuel tanks and seepage of oil or gasoline into the surrounding ground
- Buildup of methane or other by-products of waste decomposition in sewers or sewage-processing plants
- A motor vehicle crash in which a gas tank has ruptured

Initially, it is important to approach the scene from a safe location and direction. The traditional rules of staying uphill and upwind are a good place to start. In addition, it may be wise to use binoculars and view the scene from a safe distance. Be sure to question anyone involved in the incident—a wealth of information may be available to you if you simply ask the right person. Take enough time to assess the scene and interpret other clues such as dead animals near the point of release, discolored pavement, dead grass, visible vapors or puddles, or labels that may help identify the presence of a hazardous material. Once you have a basic idea of what happened or determine that danger may be present, you can begin to formulate a plan for addressing the incident.

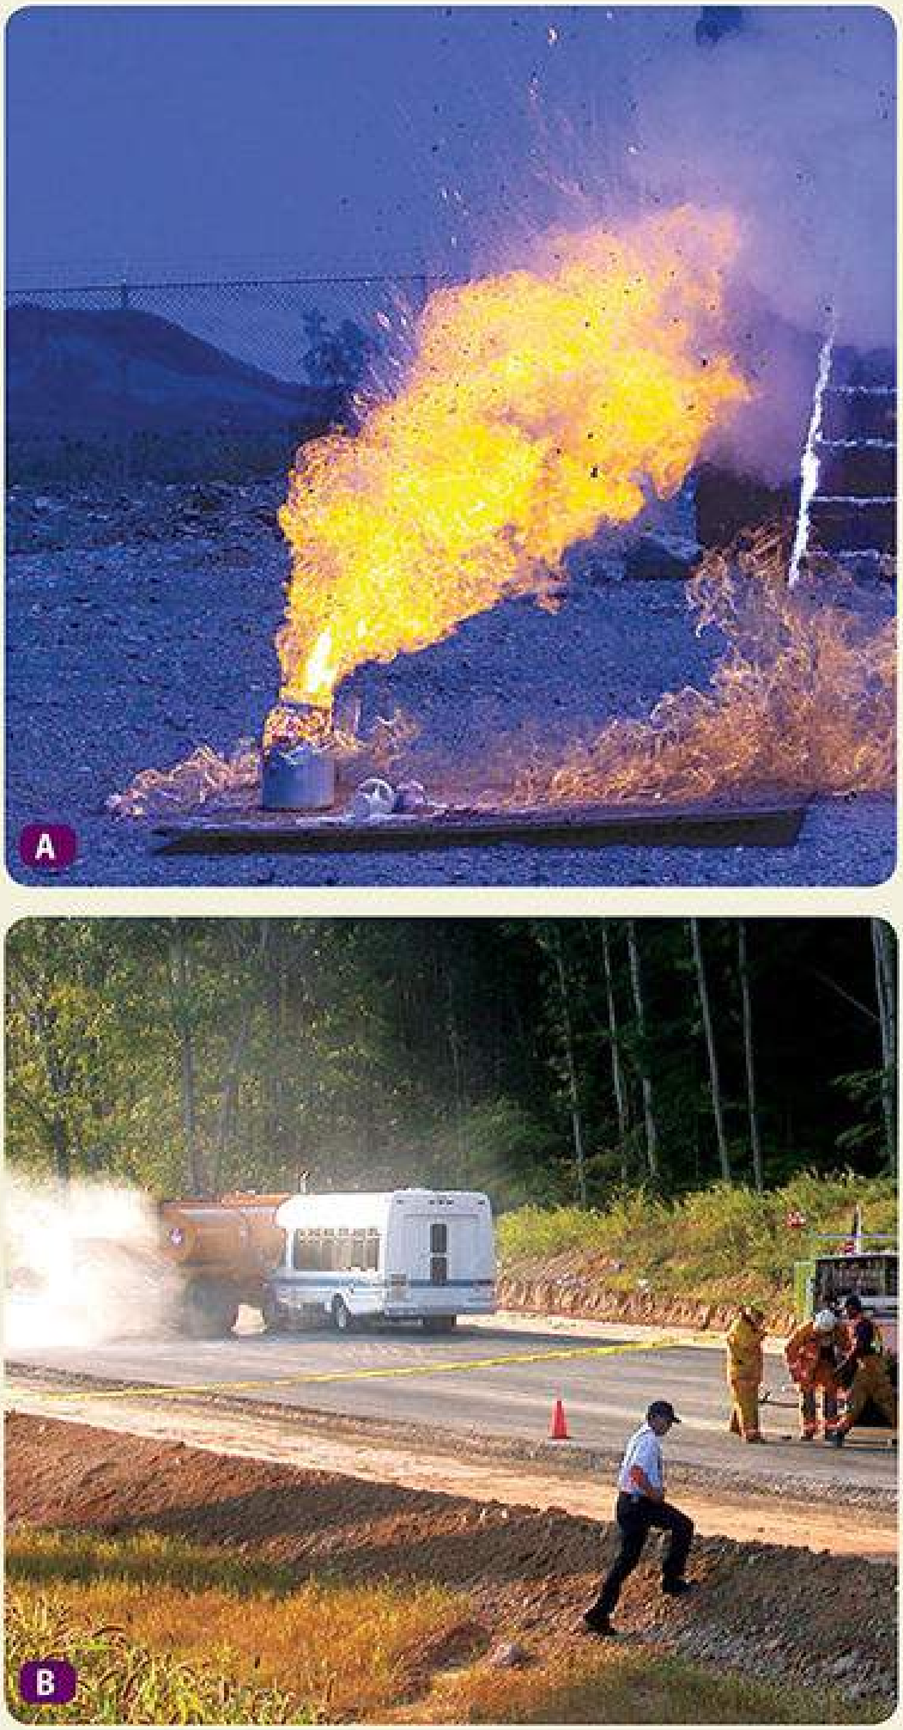

Figure 39-12 Two examples of hazardous materials incidents.

A: Courtesy of Rob L. Jackson/U.S. Marines; B: Courtesy of George Roarty/Virginia Department of Emergency Management.

Occupancy and Location

A wide variety of chemicals are stored in warehouses, hospitals, laboratories, industrial complexes, residential garages, bowling alleys, home improvement centers, garden supply stores, restaurants, and scores of other facilities or businesses in your response area. So many different chemicals exist in so many different locations that you could encounter almost anything during any type of emergency situation. The location and type of building are two good indicators of the possible presence of a hazardous material. For example, a biomedical laboratory is more likely than a preschool to have chemicals that could be hazardous on site.

Senses

Another way to detect the presence of hazardous materials is to use your senses, although this technique must be used carefully to avoid exposure. The senses you can safely use are sight and sound. Initially, the farther you are from the incident, the safer you will be. When it comes to HazMat incidents, "leading with your nose" is not a good tactic—but using binoculars from a distance is.

Clues that are seen or heard from a distance may enable you to take precautionary steps. Vapor clouds at the scene, for example, are a signal to move yourself and others away to a place of safety; the sound of an alarm from a toxic gas sensor in a chemical storage room or laboratory may also serve as a warning to retreat. Some highly vaporous and odorous chemicals—chlorine and ammonia, for example—may be detected by smell a long way from the actual point of release.

Containers

In basic terms, a **container** is any vessel or receptacle that holds a material. Often the container's type, size, and material of construction provide important clues about the nature of the substance inside. Nevertheless, do not rely solely on the type of container when making a determination about hazardous materials.

Red phosphorus from a drug laboratory, for example, might be found in an unmarked plastic container. In this case, there may not be legitimate markings to alert you to the possible contents. Gasoline or waste solvents may be stored in 55-gallon (208-L) steel drums. Sulfuric acid, at 97% concentration, could be found in a polyethylene drum that might be colored black, red, white, or blue. In most cases, there is no correlation between the color of the drum and the possible contents. The same sulfuric acid might also be found in a 1-gallon (3.8-L) amber glass container. Steel or polyethylene drums, bags, high-pressure gas cylinders, railroad tank cars, plastic buckets, aboveground and underground storage tanks, cargo tanks, and pipelines are all examples of how hazardous materials are packaged, stored, and shipped **Figure 39-13**.

Figure 39-13

Drums may be constructed of many different types of materials, including cardboard, polyethylene, and stainless steel. The drum shown here is made of polyethylene.

Courtesy of EMD Chemicals, Inc.

Some recognizable chemical containers, such as 55-gallon (208-L) drums and compressed gas cylinders, can be found in almost every type of manufacturing facility. Materials stored in a cardboard drum are usually in solid form. Stainless steel containers hold particularly dangerous chemicals, and cold liquids are kept in containers designed to maintain the appropriate temperature **Figure 39-14**.

Figure 39-14 A series of chemical storage containers.

One way to distinguish containers is to divide them into two categories based on their capacity: bulk and non-bulk storage containers.

Safety Tips

When you consider locations for possible hazardous materials incidents, do not limit your thinking. You may be surprised at how many different kinds of containers you may find in your area.

Container Volume

Bulk storage containers include fixed tanks, highway cargo tanks, rail tank cars, totes, and intermodal tanks. In general, bulk storage containers are found in buildings that rely on and need to store large quantities of a particular chemical. Most manufacturing facilities have at least one type of bulk storage container. Often these bulk storage containers are surrounded by a secondary containment system to help control an accidental release. **Secondary containment** is an engineered method to control spilled or released product if the main containment vessel fails. A 5,000-gallon (18,927-L) vertical storage tank, for example, may be surrounded by a series of short walls that form a catch basin around the tank.

Large-volume horizontal tanks are also common. When stored above ground, these tanks are referred to as aboveground storage tanks; if they are placed underground, they are known as underground storage tanks. These tanks can hold a few hundred gallons to several million gallons of product and are usually made of aluminum, steel, or plastic.

Another commonly encountered bulk storage vessel is the tote, also referred to as an intermediate bulk container. Totes have capacities ranging from 119 gallons to 703 gallons (450 to 2,661 L); the most common sizes are 350 and 550 gallons (1,325 and 2,082 L). These portable plastic tanks are surrounded by a stainless steel web that adds both structural stability and protection to the container. They can contain any type of chemical, including flammable liquids, corrosives, food-grade liquids, or oxidizers **Figure 39-15**.

Shipping and storing totes can be hazardous. These containers often are stacked atop one another and moved with a forklift, and a mishap with the loading or moving process can damage the tote. Because totes have no secondary containment system, any leak has the potential to create a large puddle. In addition, the steel webbing around the tote makes it difficult to access and patch leaks.

Intermodal tanks are both shipping and storage vessels. They hold between 5,000 and 6,000 gallons (18,927 and 22,712 L) of product and can be pressurized or nonpressurized. Intermodal tanks can also be used to ship and store gaseous substances that have been chilled until they liquefy, such as liquid nitrogen. In most cases, an intermodal tank is shipped to a facility, where it is stored and used and then returned to the shipper for refilling. Intermodal tanks can be shipped by all methods of transportation—air, sea, and land **Figure 39-16**.

Figure 39-15 A tote is a commonly encountered bulk storage vessel.

Nonbulk Storage Vessels

Essentially, **nonbulk storage vessels** are all types of containers other than bulk containers. Nonbulk storage vessels can hold a few ounces to 119 gallons (450 L) of product and include vessels such as drums, bags, compressed gas cylinders, cryogenic containers, and more. Nonbulk storage vessels hold commonly used commercial and industrial chemicals such as solvents, industrial cleaners, and compounds. This section describes the most commonly encountered types of nonbulk storage vessels.

Drums. **Drums** are easily recognizable, barrel-like containers. They are used to store a wide variety of substances, including food-grade materials, corrosives, flammable liquids, and grease. Drums may be constructed of low-carbon steel, polyethylene, cardboard, stainless steel, nickel, or other materials. Generally, the nature of the chemical dictates the construction of the storage drum. Steel utility drums, for example, hold flammable liquids, cleaning fluids, oil, and other noncorrosive chemicals. Polyethylene drums are used for corrosives such as acids, bases, oxidizers, and other materials that cannot be stored in steel containers. Cardboard drums hold solid materials such as soap flakes, sodium hydroxide pellets, and food-grade materials. Stainless steel or other heavy-duty drums generally hold materials too aggressive (ie, too reactive) for either plain steel or polyethylene.

Bags. Bags are commonly used to store solids and powders such as cement powder, sand, pesticides, soda ash, and slaked lime. Storage bags may be constructed of plastic, paper, or plastic-lined paper. Bags come in different sizes and weights, depending on their contents.

Pesticide bags must be labeled with specific information **Figure 39-17**. You can learn a great deal from the label, including the following details:

- Name of the product
- Active ingredients
- Hazard statement
- The total amount of product in the container
- The manufacturer's name and address
- The Environmental Protection Agency (EPA) registration number, which provides proof that the product was registered with the EPA

- The EPA establishment number, which shows where the product was manufactured
- Signal words to indicate the relative toxicity of the material:
  – Danger—Poison: Highly toxic by all routes of entry
  – Danger: Severe eye damage or skin irritation
  – Warning: Moderately toxic
  – Caution: Minor toxicity and minor eye damage or skin irritation
- Practical first-aid treatment description
- Directions for use
- Agricultural use requirements
- Precautionary statements such as mixing directions or potential environmental hazards
- Storage and disposal information
- Classification statement on who may use the product

In addition, every pesticide label must carry the statement, "Keep out of reach of children."

Carboys. Some corrosives and other types of chemicals are transported and stored in carboys **Figure 39-18**. A carboy is a glass, plastic, or steel container that holds 5 to 15 gallons (19 to 57 L) of product. Glass carboys are often placed in a protective wood, foam, fiberglass, or steel box to help prevent breakage. For example, nitric acid, sulfuric acid, and other strong acids are often transported and stored in thick glass carboys protected by a wooden or polystyrene (Styrofoam) crate to shield the glass container from damage during normal shipping.

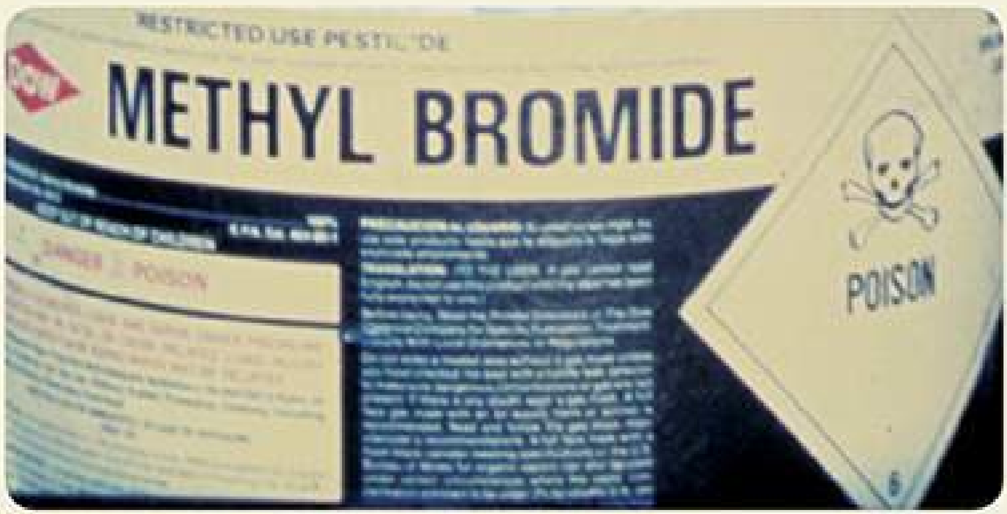

Figure 39-17 A pesticide bag must be labeled with the appropriate information.

Courtesy of the USDA.

Figure 39-18 A carboy is used to transport and store corrosive chemicals.

Courtesy of EMD Chemicals, Inc.

Cylinders. Several types of cylinders are used to hold liquids and gases. Uninsulated compressed gas cylinders are used to store substances such as nitrogen, argon, helium, and oxygen. They come in a range of sizes. As an EMT, you are very familiar with the shape of a cylinder; it holds the oxygen for your patients.

The Department of Transportation Marking System

The presence of labels, placards, and other markings on buildings, packages, boxes, and containers can often enable you to identify a released chemical. When used correctly, marking systems indicate the presence of a hazardous material from a safe distance and provide clues about the substance.

The US Department of Transportation (DOT) marking system is an identification system characterized by labels, placards, and markings Figure 39-19.

This marking system is used in the United States when materials are being transported from one location to another. The same marking system is also used in Canada by Transport Canada.

Placards are diamond-shaped indicators (10.75 inches [27 cm] per side) that are placed on all four sides of highway transport vehicles, railroad tank cars, and other forms of transportation carrying hazardous materials Figure 39-20. Labels are smaller versions (4 inches [10 cm] per side) of placards; they are placed on the four sides of individual boxes and smaller packages being transported.

Placards, labels, and markings are intended to give a general idea of the hazard inside a particular container or cargo tank. A placard identifies the broad hazard class (flammable, poison, corrosive) to which the material inside belongs. A label on a box inside a delivery truck, for example, relates only to the potential hazard inside that particular package Figure 39-21.

Other Considerations

The DOT system does not require that all chemical shipments be marked with placards or labels. In most cases, the package or cargo tank must contain a certain amount of hazardous material before a placard is required. For example, the “1,000-pound rule” applies to blasting agents, flammable and nonflammable gases, flammable/combustible liquids, flammable solids, air-reactive solids, oxidizers and organic peroxides, poison solids, corrosives, and miscellaneous (class 9) materials. Placards are required for these materials only when the shipment weighs more than 1,000 pounds (454 kg). Commercial package delivery services often carry small amounts of hazardous materials that fall below that weight limit. The vehicle exterior will not display placards to warn you of the danger.

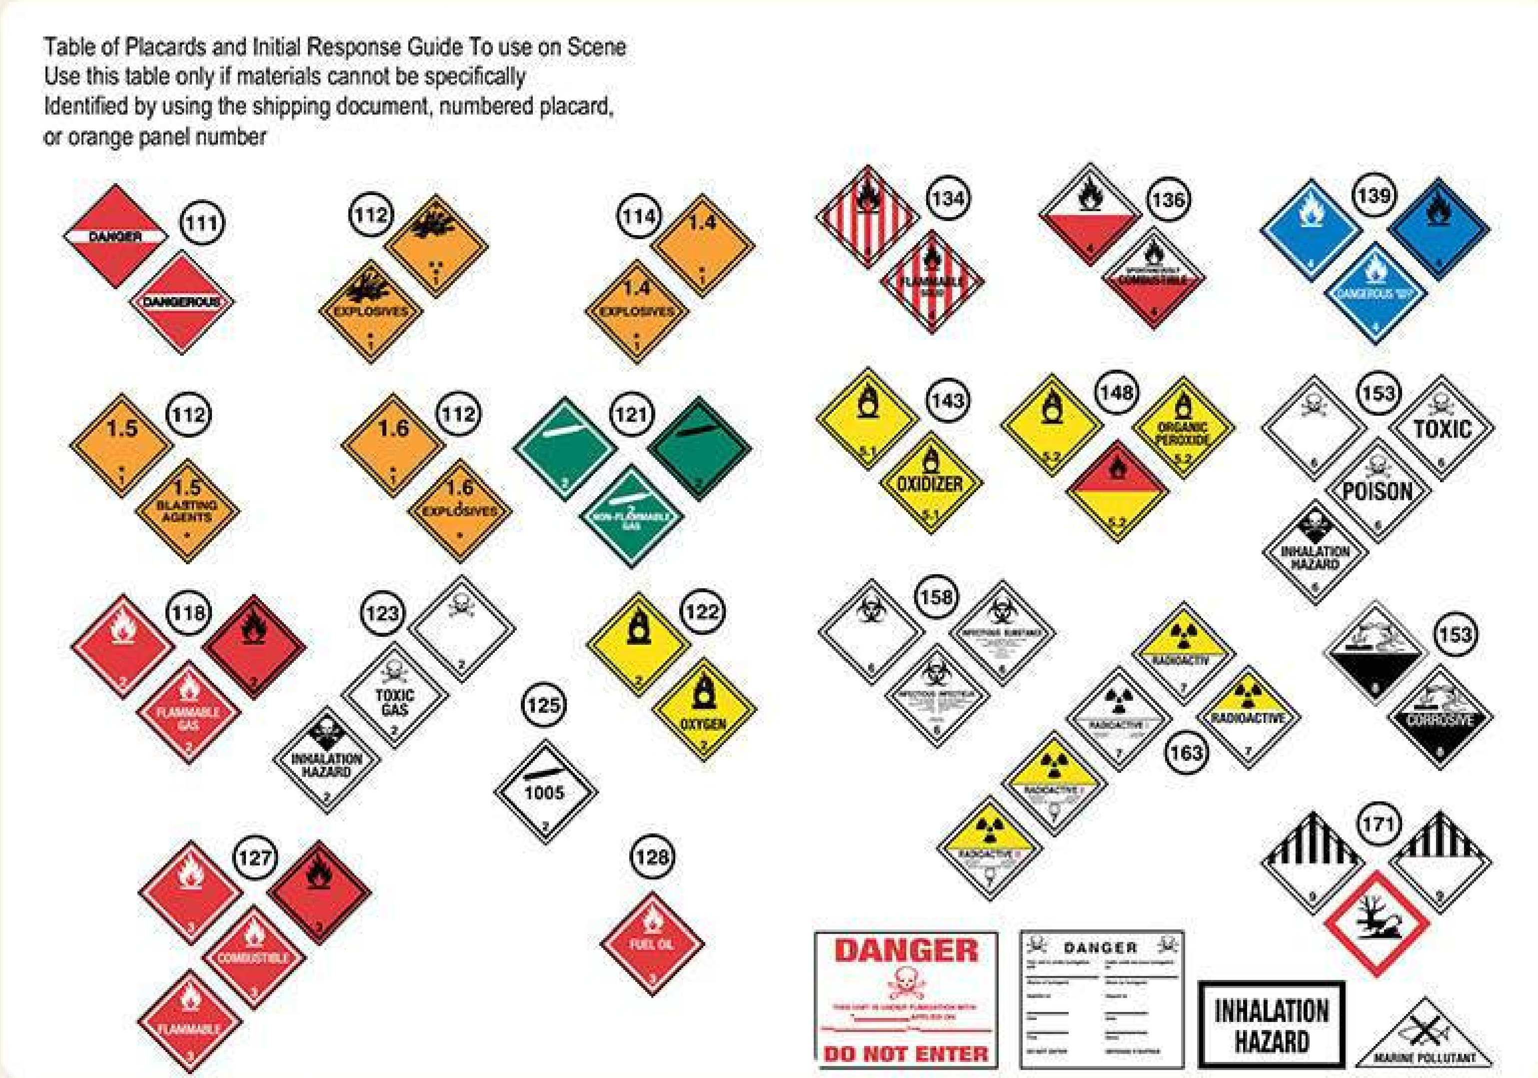

Figure 39-19 The Department of Transportation uses labels, placards, and markings (such as these found in the *Emergency Response Guidebook*) to give a general idea of the hazard inside a particular container or cargo tank.

Courtesy of the U.S. Department of Transportation.

Figure 39-20 A placard is a large diamond-shaped indicator that is placed on all sides of transport vehicles that carry hazardous materials.

© Mark Winfrey/ShutterStock.

Conversely, some chemicals are so hazardous that shipping any amount of them requires the use of labels or placards. These materials include explosives, poisonous gases, water-reactive solids, and high-level radioactive substances. A four-digit United Nations number may be required on some placards. This number identifies the specific material being shipped; a list of United Nations numbers is included in the *Emergency Response Guidebook*.

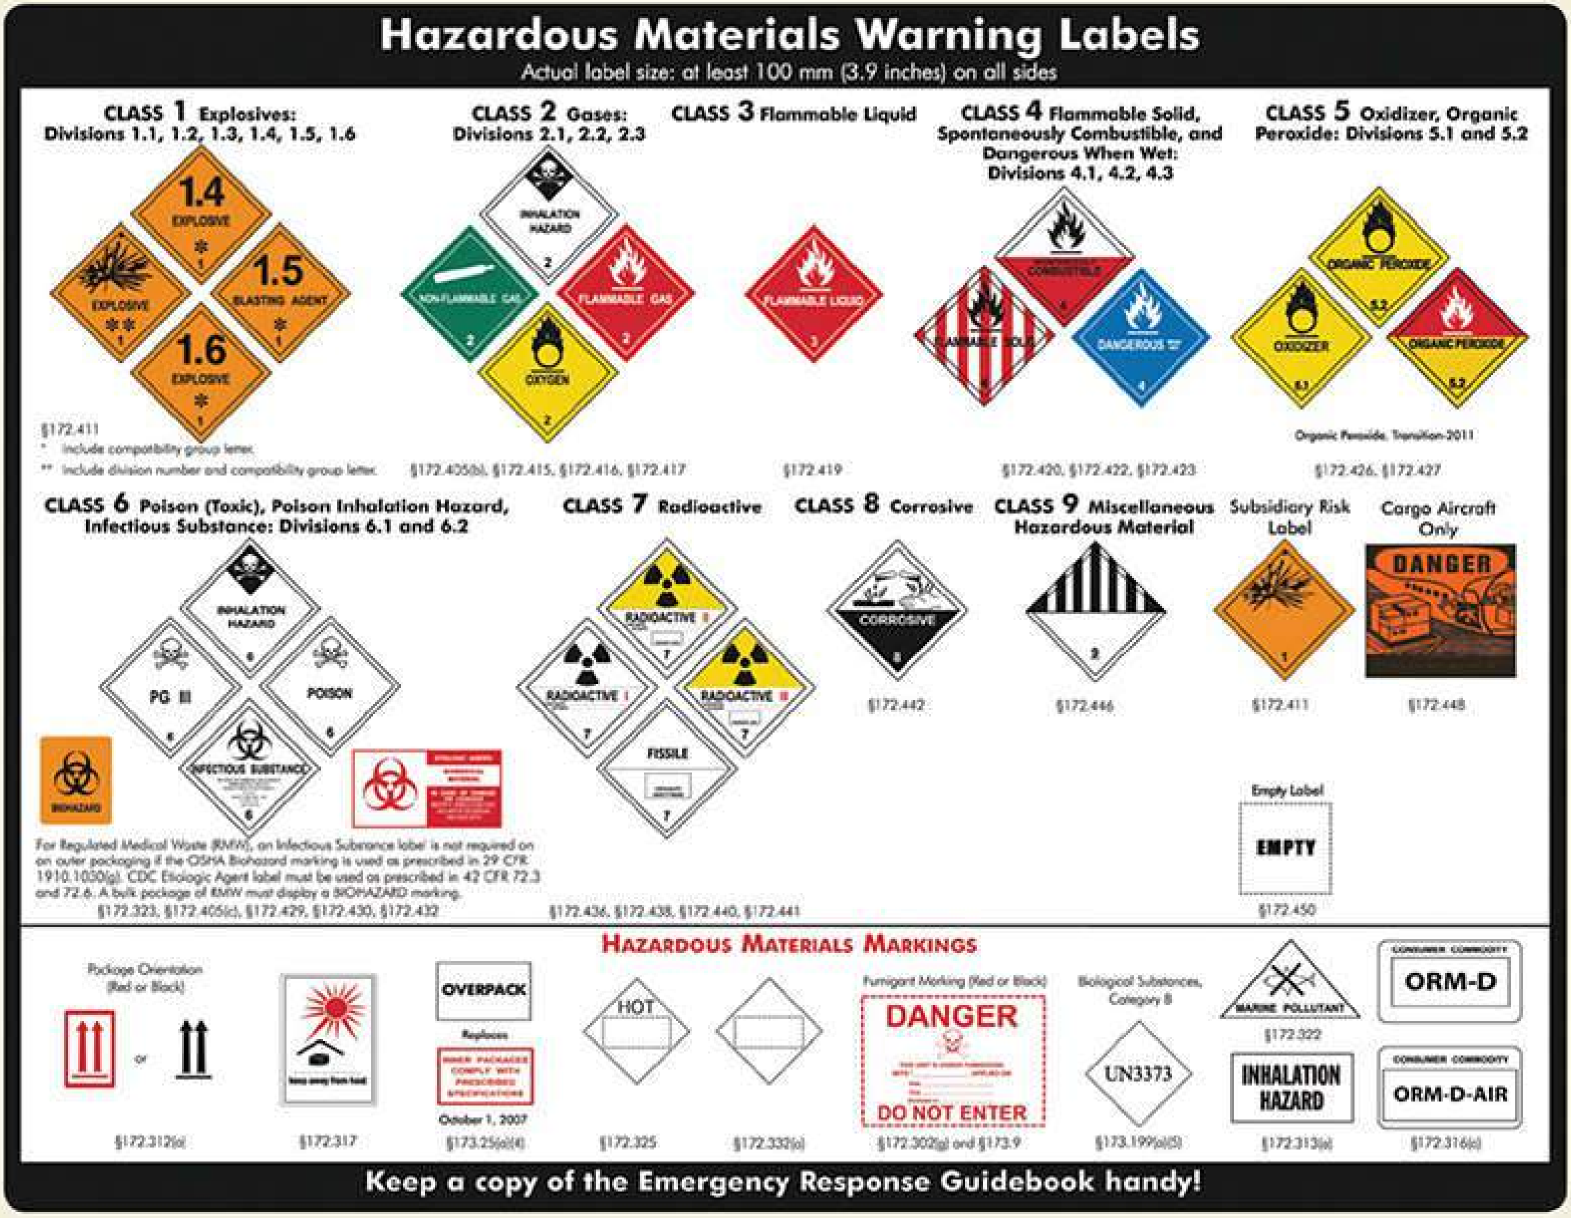

Figure 39-21 A label is a smaller version of the placard and is placed on boxes or smaller packages that contain hazardous materials.

References

Numerous reference materials are available to you, including the DOT's *Emergency Response Guidebook* and Jones & Bartlett Learning's *Fire Fighter's Handbook of Hazardous Materials*. The following sections describe these resources.

The *Emergency Response Guidebook*

The DOT's ***Emergency Response Guidebook (ERG)*** offers a certain amount of guidance for responders operating at a HazMat incident **Figure 39-22**. This guide is updated every 3 to 4 years and provides information on approximately 4,000 chemicals. The US DOT and the Secretariat of Communications and Transportation of Mexico, along with Transport Canada, jointly developed the *Emergency Response Guidebook*. You can download a free copy of the ERG via the Pipeline and Hazardous Materials Safety Administration (PHMSA) website.

Material Safety Data Sheets

A common source of information about a particular chemical is the **material safety data sheet (MSDS)** (or safety data sheet [SDS]) specific to that substance **Figure 39-23**. Essentially, the MSDS provides basic information about the chemical makeup of a substance, the potential hazards it presents, appropriate first aid in the event of an exposure, and other pertinent data for safe handling of the material. The MSDS will typically include the following details:

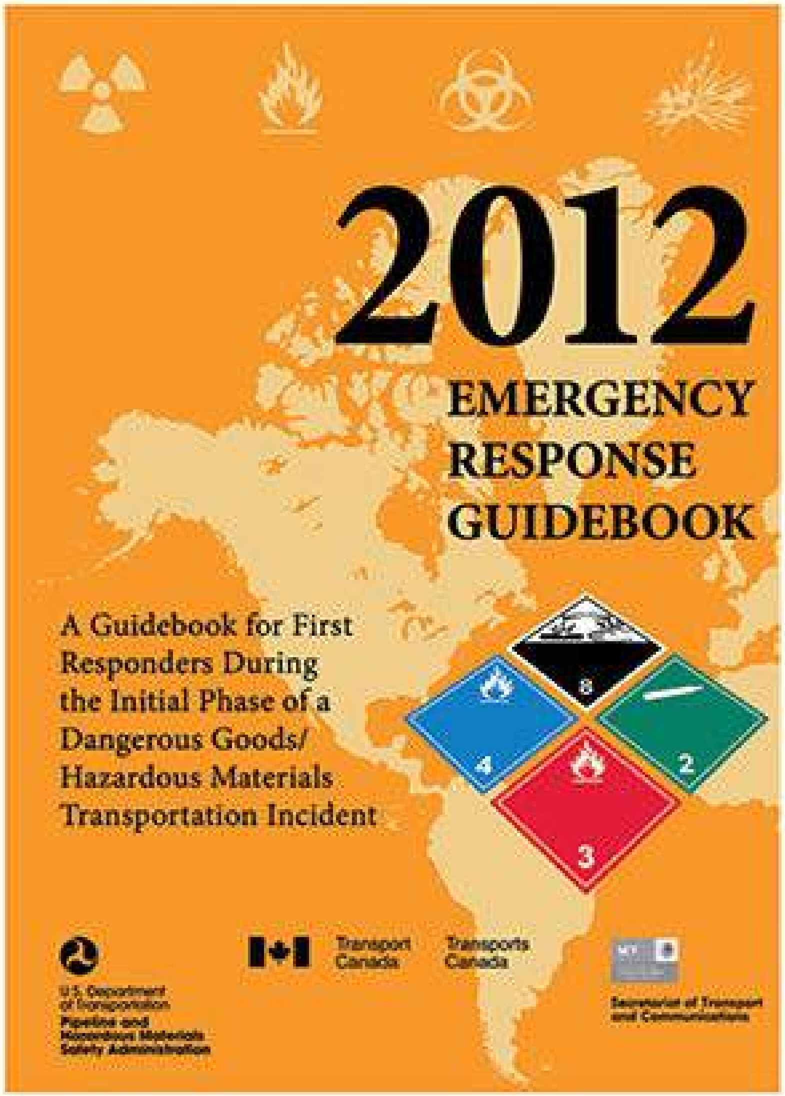

Figure 39-22 *The Emergency Response Guidebook* is a reference used as a base for your initial actions at a hazardous materials incident.

Courtesy of the U.S. Department of Transportation.

- The name of the chemical, including any synonyms for it
- Physical and chemical characteristics of the material
- Physical hazards of the material
- Health hazards of the material
- Signs and symptoms of exposure
- Routes of entry
- Permissible exposure limits
- Responsible-party contact
- Precautions for safe handling (including hygiene practices, protective measures, and procedures for cleaning up spills or leaks)

- Applicable control measures, including personal protective equipment
- Emergency and first-aid procedures
- Appropriate waste disposal

All facilities that use or store chemicals are required by law to have an MSDS on file for each chemical used or stored in the facility. Many sites, especially those that stock many different chemicals, may keep this information archived on a computer database. Although the MSDS is not a definitive response tool, it is a key piece of the puzzle. The MSDS can also be obtained from the transporting vehicle.

Shipping Papers

Shipping papers are required whenever materials are transported from one place to another. They include the names and addresses of the shipper and the receiver, identify the material being shipped, and specify the quantity and weight of each part of the shipment. Shipping papers for road and highway transportation are called **bills of lading** or **freight bills** and are located in the cab of the vehicle **Figure 39-24**. Drivers transporting chemicals are required by law to have a set of shipping papers on their person or within easy reach inside the cab at all times.

YOU are the Provider PART 4

While triaging the patients, several other ambulances and other pieces of fire department equipment arrive on the scene, as well as a battalion chief who assumes command. You update him on your findings and the status of your EMS personnel and ambulances. There are 37 walking wounded (green) who will need to be loaded onto a bus for transport. Of the 3 remaining patients, 2 have been tagged expectant (black) and one is immediate (red).

7. What changes, if any, should you make in your initial triage assignments with the arrival of additional responders?
8. What should you consider in deciding whether to set up a treatment area at this incident?

MATERIAL SAFETY DATA SHEET
ANHYDROUS AMMONIA

NATIONAL AMMONIA	NORTHEASTERN AMMONIA
HAMLER INDUSTRIES	BOWER AMMONIA & CHEMICAL

735 Davisville Road, Third Floor, Southampton, PA 18966; 215-322-1238

CORPORATE EMERGENCY TELEPHONE NUMBER: 800-643-6226 CHEMTREC: 800-424-9300

DESCRIPTION

CHEMICAL NAME: Ammonia, Anhydrous — **CAS REGISTRY NO**: 7664-41-7

SYNONYMS: Ammonia — **CHEMICAL FAMILY**: Inorganic Nitrogen Compound

FORMULA: NH_3 — **MOL. WT**: 17.03 (NH_3) — **COMPOSITION**: 99+% Ammonia

STATEMENT OF HEALTH HAZARD

HAZARD DESCRIPTION:

Ammonia is an irritant and corrosive to the skin, eyes, respiratory tract and mucous membranes. Exposure to liquid or rapidly expanding gases may cause severe chemical burns and frostbite to the eyes, lungs and skin. Skin and respiratory related diseases could be aggravated by exposure.

Not recognized by OSHA as a carcinogen.
Not listed in the National Toxicology Program.
Not listed as a carcinogen by the International Agency for Research on Cancer.

EXPOSURE LIMITS FOR AMMONIA: Vapor

OSHA	50 ppm,	35 mg / m^3 PEL	8 hour TWA
NIOSH	35 ppm,	27 mg / m^3 STEL 15 minutes	
	25 ppm,	18 mg / m^3 REL	10 hour TWA
	300 ppm,	IDLH	
ACGIH	25 ppm,	18 mg / m^3 TLV	8 hour TWA
	35 ppm,	27 mg / m^3 STEL 15 minutes	

TOXICITY: LD 50 (Oral / Rat) 350 mg / kg

PHYSICAL DATA

BOILING POINT: -28°F at 1 Atm.
PH: N/A
SPECIFIC GRAVITY OF GAS (air = 1): 0.596 at 32°F
SPECIFIC GRAVITY OF LIQUID (water = 1): 0.682 at 28°F (Compared to water at 39°F).
PERCENT VOLATILE: 100% at 212°F
APPEARANCE AND ODOR: Colorless liquid or gas with pungent odor.
CRITICAL TEMPERATURE: 271.4°F
GAS SPECIFIC VOLUME: 20.78 Ft^3/Lb at 32°F and 1 Atm.

VAPOR DENSITY: 0.0481 Lb/Ft^3 at 32°F
LIQUID DENSITY: 38.00 Lb/Ft^3 at 70°F
APPROXIMATE FREEZING POINT: -108°F
WEIGHT (per gallon): 5.15 pounds at 60°F
VAPOR PRESSURE: 114 psig at 70°F
SOLUBILITY IN WATER (per 100 pounds of water): 86.9 pounds at 32°F, 51 pounds at 68°F
SURFACE TENSION: 23.4 Dynes / cm at 52°F
CRITICAL PRESSURE: 111.5 atm

STRAIGHT BILL OF LADING
ORIGINAL - NOT NEGOTIABLE

BOL/Reference No.
RSI82715

CARRIER: NORFOLK SOUTHERN

Date: 12/23/2008

Shipper: RSI LOGISTICS, INC (OKEMOS, MI US)

The property described below, in apparent good order, except as noted (contents and condition of packages unknown), marked, consigned, and destined as indicated below, which said carrier (the word carrier being understood throughout this contract as meaning any person or corporation in possession of the property under the contract) agrees to carry to its usual place of delivery at said destination, if on itsroute, otherwise to deliver to another carrier on the route to said destination. It is mutually agreed, as to each carrier of all or any said property, that every service to be performed hereunder shall be subject to all the terms and conditions of the Uniform Domestic Straight Bill of Lading set forth (1) in Official, Southern, Western and Illinois Freight Classificatio n in effect on the date hereof, if this isa rail or a rail-water shipment, or (2) in the applicable motor carrier classification or tariff if this is a motor carrier shipment

Shipper hereby certifies that he is familiar with all the terms and conditions or the said bill of lading, including those on the back thereof, set forth in the classification or tariff which governs the transportation of this shipment, and the said terms and conditions are hereby agreed to by the shipper and accepted for himself and his assigns.

Consignee Information: CONSIGNEE DEER PARK, TX Address: City: DEER PARK, TX US	
Route: NS-ESTL-BNSF	
Origin Switch Route:	
Destination Switch Route: HUSTN-PTRA	Rail Car No: GATX290861

CHEMTREC

Located in Falls Church, VA, the Chemical Transportation Emergency Center (CHEMTREC), now operated by the American Chemistry Council, is an agency that provides invaluable technical information for first responders of all disciplines who are called upon to respond to chemical incidents. The toll-free number for CHEMTREC is 1-800-262-8200. CHEMTREC can provide you with technical chemical information via telephone, fax, or other electronic media. It also offers a phone conferencing service to connect you with thousands of shippers, subject matter experts, and chemical manufacturers.

When you call CHEMTREC, be sure to have the following basic information ready:

- The name of the chemical(s) involved in the incident (if known)
- Name of the caller and callback telephone number
- Location of the incident or problem
- Shipper or manufacturer of the chemical (if known)
- Container type
- Railcar or vehicle markings or numbers
- The shipping carrier's name
- Recipient of material
- Local conditions and exact description of the situation

When you are speaking with CHEMTREC personnel, spell out all chemical names; if using a third party, such as a dispatcher, it is vital that you confirm all spellings to avoid misunderstandings. One number or letter out of place could throw off all subsequent research. When in doubt, be sure to obtain clarification.

Identification

Unfortunately, even with all of these resources, identifying materials can still be difficult. Little consistency is used on labels and placards, and sometimes dishonest transporters will not label containers or vessels appropriately. The laws and regulations that cover labeling of packages and transport vehicles can also be misleading. As discussed previously, in most cases, the package or tank must contain a certain amount of a hazardous material before a placard is required. For example, because of the small quantities of hazardous materials that are involved, a truck carrying 99 pounds (45 kg) of HazMat No. 1 and 99 pounds (45 kg) of both HazMat No. 2 and HazMat No. 3 may not be required by law to display any labels or placards. The truck may show only a "Please drive carefully" placard, implying that it does not carry hazardous materials. Therefore, a crash involving this truck is a serious situation, but you would not necessarily know this if you relied on labels and placards. Always maintain a high index of suspicion when approaching the scene of a truck or train tanker crash.

Some substances are not hazardous; however, when mixed with another substance, they may become highly toxic. There may not be regulations against carrying such substances together on one truck or railroad car (or adjacent tank cars). The driver of a commercial truck and the conductor of a train, however, must carry shipping papers that identify what is being transported in their care. These shipping papers may be your first clue that there is a possible HazMat problem, although, depending on the nature of the incident, the papers may not be available to you.

In the event of a leak or spill, a HazMat incident is often indicated by the presence of the following:

- A visible cloud or strange-looking smoke resulting from the escaping substance
- A leak or spill from a tank, container, truck, or railroad car with or without HazMat placards or labels
- An unusual, strong, noxious (harmful), harsh odor in the area

To indicate the presence of normally odorless toxic gases or fluids during a leak or spill, manufacturers may add a substance that produces a strong noxious odor. However, a large number of hazardous gases and fluids are essentially odorless (or do not have a distinctive unpleasant smell) even when a substantial leak or spill has occurred. In some incidents, a large number of people are exposed and may be injured or killed before the presence of a HazMat incident is identified. If you approach a scene where more than one person has collapsed or is unconscious or in respiratory distress, you should assume that there has been a HazMat leak or spill and that it is unsafe to enter the area.

It is important for you to understand the potential danger of hazardous materials and know how to operate safely at a HazMat incident. If you do not follow the proper safety measures, you and many others could end up needlessly injured or dead. The safety of you and your team, the other responders, and the public must be your most important concern.

Words of Wisdom

Safety considerations at HazMat scenes differ considerably from those involved in emergency response in general. A HazMat scene requires you to have an even higher degree of alertness than usual to avoid entering a dangerous environment and to help others avoid it. There is also a need to prevent the spread of contamination to yourself and your ambulance. Understanding these two concepts is a good start toward safe operations in the presence of hazardous materials.

There will be times when the ambulance is the first to arrive at the scene. If, as you approach, any signs suggest that a HazMat incident has occurred, stop at a safe distance and park upwind or uphill from the incident. After rapidly sizing up the scene, call for a HazMat team. If you do not recognize the danger until you are too close, immediately leave the area. Once you have reached a safe place, try to rapidly assess the situation and provide as much information as possible when calling for the HazMat team, including your specific location, the size and shape of the containers of the hazardous material, and what you have observed and have been told has occurred. Do not reenter the scene, and do not leave the area until you have been cleared by the HazMat team, or you may contribute to the situation by spreading hazardous materials. Finally, do not allow civilians to enter the scene, if possible. No one should enter the area without the proper protective equipment, respiratory protection, or training.

Above all, avoid all contact with the material!

HazMat Scene Operations

Once you have recognized the incident as one involving hazardous materials and have called for the HazMat team, focus your efforts on activities that will ensure the safety and survival of the greatest number of people. Use the ambulance's public address system to alert people who are near the scene and direct them to move to a location where they will be sufficiently far from danger. With the aid of others on your team, try to set up a perimeter to stop traffic and people from entering the area.

Establishing Control Zones

Setting control zones and limiting access to the incident site helps reduce the number of civilians and responders who may be exposed to the released substance. **Control zones** are established at a HazMat incident based on the chemical and physical properties of the released material, the environmental factors at the time of the release, and the general layout of the scene. Of course, isolating a city block in the busy downtown area of a large city presents far different challenges than isolating the area around a rolled-over cargo tank on an interstate highway. Each situation is different, requiring flexibility and thoughtfulness. Securing access to the incident helps ensure that no one will accidentally enter a contaminated area.

If the incident takes place inside a structure, the best place to control access is at the normal points of ingress and egress (entry and exit)—doors. Once the doors are secured so that no unauthorized personnel can enter, appropriately trained emergency response crews can begin to isolate other areas as appropriate.

The same concept applies to outdoor incidents. The goal is to secure logical access points around the hazard. Begin by controlling intersections, on and off ramps, service roads, and other access routes to the scene. Law enforcement officers should assist by diverting traffic at a safe distance outside the hazard area. They should block off streets, close intersections, and redirect traffic as needed.

During a long-term incident, highway department or public works department employees may be called upon to set up traffic barriers. Whatever methods or devices are used to restrict access, they should not limit or prevent a rapid withdrawal of responders from the area.

It is not uncommon to set large control zones at the onset of an incident, only to discover that the zones may have been established too liberally. At the same time, control zones should not be defined too narrowly **Figure 39-25**. As the IC gets more information about the specifics of the chemical or material involved, the control zones may be expanded or reduced. Ideally, the control zones will be established in the right place the first time. Wind shifts are a common reason why control zones are modified during the incident. If there is a prevailing wind pattern in your area, factor that consideration into your decision making when it comes to control zones.

Typically, control zones at HazMat incidents are labeled as *hot, warm,* or *cold.* You may also discover that other terms are used, such as *exclusionary zone* (hot zone), *contamination reduction zone* (warm zone), and *outer perimeter* (cold zone). In any case, make sure you understand the terminology used in your jurisdiction. Be aware that different jurisdictions may use terminology and setup procedures unlike the ones used in your agency. As long as you understand the concepts behind the actions and remember that safety is the main focus, the act of setting up and naming zones can remain flexible.

The **hot zone** is the area immediately surrounding the release, which is also the most contaminated area. Its boundaries should be set large enough that adverse effects from the released substance will not affect people outside of the hot zone. An incident involving a gaseous substance or a vapor, for example, may require a larger hot zone than one involving a solid or nonvolatile liquid leak. In some cases, atmospheric monitoring, plume modeling, or reference sources such as the *Emergency Response Guidebook* may prove useful in helping to establish the perimeters of a hot zone. Specially trained responders, in accordance with their level of training, should be tasked with using these tools. Keep in mind that the physical characteristics of the released substance will significantly affect the size and layout of the hot zone. In addition, all specially trained responders entering the hot zone should avoid contact with the product to the greatest extent possible. Adhering to this important policy makes the job of decontamination easier and reduces the risk of cross-contamination.

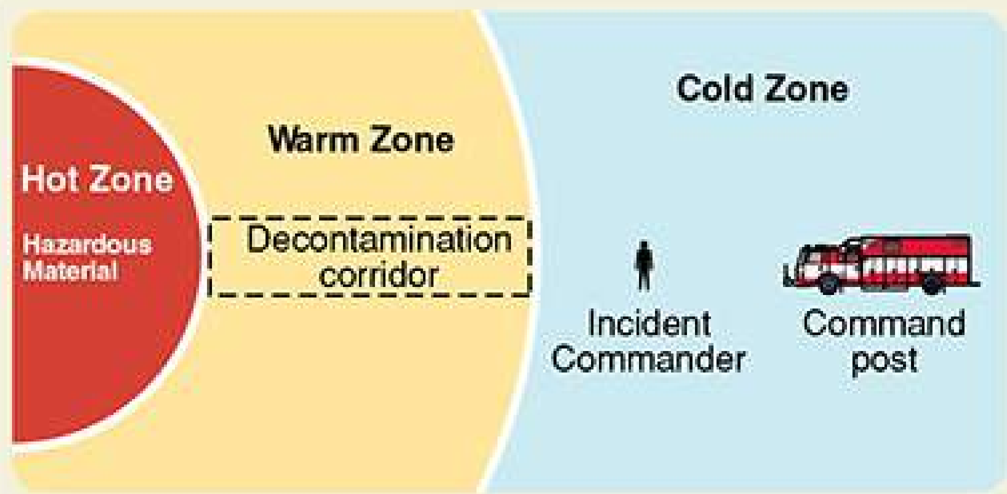

Figure 39-25 Control zones spread outward from the center of a hazardous materials incident.

Personnel accountability is important, so access into the hot zone must be limited to only the responders necessary to control the incident. All personnel and equipment must be decontaminated when they leave the hot zone. This practice ensures that contamination is not inadvertently spread to “clean” areas of the scene.

The **warm zone** is where personnel and equipment transition into and out of the hot zone. It contains control points for access to the hot zone as well as the decontamination area. Only the minimal number of personnel and the equipment necessary to perform decontamination, or support those operating in the hot zone, should be permitted in the warm zone.

A patient’s skin and clothing may contain hazardous material, so the **decontamination area** is set up in the warm zone. The decontamination area is the designated area where contaminants are removed before an individual can go to another area. **Decontamination** is the process of removing or neutralizing and properly disposing of hazardous materials from equipment, patients, and rescue personnel. The decontamination area must include special containers for contaminated clothing and special bags to isolate each patient’s personal effects safely until they can be decontaminated **Figure 39-26**. The area will also contain a number of special facilities to thoroughly wash and rinse patients and backboards. The water that is used must be captured and delivered into special sealable containers.

Anyone who leaves the hot zone must pass through the decontamination area. Firefighters’ and HazMat team members’ outer protective gear is rinsed and washed in the decontamination area before it is removed **Figure 39-27**. To prevent needless contact and transmission of splash or residues, different personnel are used in the decontamination and treatment areas. Do not move into the decontamination area unless you are properly trained and equipped. Wait for the patients to be brought to you.

Beyond the warm zone is the **cold zone**. The cold zone is a safe area where personnel do not need to wear any special protective clothing for safe operation. Personnel staging, the command post, EMS providers, and the area for medical monitoring, support, and/or treatment after decontamination are all located in the cold zone.

Figure 39-26 Patients should be decontaminated before they are taken to treatment areas.

Figure 39-27 The decontamination zone is where firefighters' and HazMat team members' outer protective gear is rinsed and washed before removal.

Courtesy of Airman 1st Class Scherrie Gates/U.S. Air Force.

Role of the EMT

As an EMT, your job is to report to a designated area outside of the hot and warm zones and provide triage, treatment, transport, or rehabilitation when HazMat team members bring patients to you.

Classification of Hazardous Materials

The National Fire Protection Association (NFPA) 704 Hazardous Materials Classification standard classifies hazardous materials according to health hazard or toxicity levels, fire hazard, chemical reactive hazard, and special hazards (such as radiation and acids) for fixed facilities that store hazardous materials. Toxicity protection levels are also classified according to the level of personal protection required. For your safety, you must know the type and degree of health, fire, and reactive hazard protection you need to operate safely near these substances before you enter the scene.

Toxicity Level

Toxicity levels are measures of the health risk that a substance poses to someone who comes into contact with it. There are five toxicity levels: 0, 1, 2, 3, and 4. The higher the number, the greater the toxicity, as follows:

- **Level 0** includes materials that would cause little, if any, health hazard if you came into contact with them.
- **Level 1** includes materials that would cause irritation on contact but only mild residual injury, even without treatment.
- **Level 2** includes materials that could cause temporary damage or residual injury unless prompt medical treatment is provided. Both levels 1 and 2 are considered slightly hazardous but require use of self-contained breathing apparatus (SCBA) if you are going to come into contact with them.
- **Level 3** includes materials that are extremely hazardous to health. Contact with these materials requires full protective gear so that none of your skin surface is exposed.
- **Level 4** includes materials that are so hazardous that minimal contact will cause death. For level 4 substances, you need specialized gear that is designed for protection against that particular hazard.

You must note that all health hazard levels, with the exception of 0, require respiratory and chemical protective gear that is not standard on most ambulances and specialized training. Table 39-2 further describes the four hazard classes.

Personal Protective Equipment Level

Personal protective equipment (PPE) levels indicate the amount and type of protective gear that you need to prevent injury from a particular substance. The four recognized protection levels, A, B, C, and D, are as follows Figure 39-28:

- **Level A**, the most hazardous, requires fully encapsulated, chemical-resistant protective clothing that provides full body protection, as well as SCBA and special, sealed equipment.
- **Level B** requires nonencapsulated protective clothing or clothing that is designed to protect against a particular hazard Figure 39-29. Usually, this clothing is made of material that will let only limited amounts of moisture and vapor pass through (nonpermeable). Level B also requires eye protection and breathing devices that contain their own air supply, such as SCBA.

Table 39-2 Toxicity Levels of Hazardous Materials

Level	Health Hazard	Protection Needed
0	Little or no hazard	None
1	Slightly hazardous	SCBA (level C suit) only
2	Slightly hazardous	SCBA (level C suit) only
3	Extremely hazardous	Full protection, with no exposed skin (level A or B suit)
4	Minimal exposure causes death	Special HazMat gear (level A suit)

Figure 39-28 Four levels of protection. **A.** Level A protection. **B.** Level B protection. **C.** Level C protection. **D.** Level D protection.

A, B: © Jones & Bartlett Learning. Photographed by Glen E. Ellman. C: Courtesy of The DuPont Company; D: © Jones & Bartlett Learning. Courtesy of MIEMSS.

- **Level C**, like Level B, requires the use of nonpermeable clothing and eye protection. In addition, face masks that filter all inhaled outside air must be used.
- **Level D** requires a work uniform, such as coveralls, that affords minimal protection.
- All levels of protection require the use of gloves. Two pairs of rubber gloves are needed for protection in case one pair must be removed because of heavy contamination.

Figure 39-29 Workers in Level B protection.

Caring for Patients at a HazMat Incident

Generally, HazMat team members who are trained in prehospital emergency care will initiate emergency care for patients who have been exposed to a hazardous material. However, because of the dangers, time constraints, and bulky protective gear that team members wear, it is practical only to provide the simplest assessment and essential care in the hazard zone and the decontamination area. In addition, to avoid entrapment and spread of contaminants, no bandages or splints are applied—except pressure dressings that are needed to control bleeding—until the “clean” (decontaminated) patient has been moved to the treatment area. Therefore, when you are providing care in the treatment area, assess and treat the patient in the same way as you would a patient who has not been previously assessed or treated.

Your care of patients at a HazMat incident must address the following two issues:

- Any trauma that has resulted from other related mechanisms, such as vehicle crash, fire, or explosion
- The injury and harm that have resulted from exposure to the hazardous substance

Most serious injuries and deaths from hazardous materials result from airway and breathing problems. Therefore, be sure to maintain the airway, and, if the patient appears to be in distress, give oxygen at 12 to 15 L/min with a nonrebreathing mask. Monitor the patient’s breathing at all times. If you see signs that indicate that respiratory distress is increasing, you may need to provide assisted ventilation with a bag-valve mask (BVM) and high-flow oxygen.

Treat the patient's injuries in the same way that you would treat any injury. There are few specific antidotes or treatments for exposure to most hazardous materials. Different people may respond differently to contact with the same hazardous material. Therefore, your treatment for the patient's exposure to the toxic substance should focus mainly on supportive care and initiating prompt transport to the hospital.

If antidotes or other special treatments need to be initiated in the field, they will be ordered by medical control and relayed to the officer in charge of EMS operations at the scene. If special treatment includes medications, intravenous fluids, or other advanced care, paramedics or other advanced personnel will be sent to work with you at the treatment area.

Special Care

In some cases, before the decontamination area has been completely set up, the HazMat team will find one or two patients who need immediate treatment and transport without delay if they are to survive. Even if the decontamination area is set up and functioning, some patients may have such respiratory distress or otherwise urgent critical condition that the time necessary for full decontamination may prove fatal. If additional delay for proper decontamination seems life threatening in nontoxic exposure situations, it may be necessary to simply cut away all of the patient's clothing and do a rapid rinse to remove the majority of the contaminating matter before transport.

If you must treat and transport a patient who has not been properly decontaminated, you will need to increase the amount of protective clothing you wear, including the use of SCBA. At the least, this should include two pairs of gloves, goggles or a face shield, a protective coat, respiratory protection, and a disposable fluid-impervious apron or similar outfit. Many HazMat teams carry lightweight, easy-to-use, disposable, fluid-impervious protective suits for such a purpose. Remember, however, that transporting a contaminated patient merely increases the scope of the event. The decision to transport even one patient with critical injuries rests with the IC, who bases his or her decision on recommendations made by the HazMat team.

Prior to your arrival on scene, there are steps you can take to make decontaminating the ambulance easier. First, tape the cabinet doors shut. Any equipment kits, monitors, and other items that will not be used en route should be removed from the patient compartment and placed in the front of the ambulance or in outside compartments. Before loading the patient, turn on the power vent ceiling fan and patient compartment air-conditioning unit fan. Unless the weather is too severe, the windows in the driver's area and sliding side windows in the patient compartment should also be partially opened to prevent creating a "closed box" inside the ambulance and to ensure that it is properly ventilated for the safety of the patient, you, and your team members.

When you leave the scene, inform the hospital that you are transporting a critically injured patient who has not been fully decontaminated at the scene. This will allow the hospital to prepare to receive the patient. Many emergency departments (EDs) have decontamination facilities and trained personnel for such an event. You may be diverted to a facility with these capabilities if the receiving hospital is not so equipped. On arrival, one EMT enters the ED and, after giving hospital staff the report and advising them again of the incomplete decontamination, obtains directions before the patient is unloaded and brought inside. If there are enough ambulances at a HazMat scene, one may be isolated and used only to transport such patients. Remember, the ambulance needs to be decontaminated before transporting another patient.

YOU are the Provider — PART 5

As the patients are being retriaged and treated, the IC contacts the local trauma center to advise staff of the situation and to determine how many of the walking wounded they can handle in addition to the one critically injured patient. Hospital staff advises him that they can handle 10 of the patients. You reassess a boy whom you originally triaged as expectant. He is now apneic and pulseless. Your partner begins cardiopulmonary resuscitation (CPR) as you contact medical control. Based on the patient's injuries, medical control determines that resuscitation is not indicated.

9. What factors should be considered when determining the appropriate transport destination?
10. Why did medical control advise termination of resuscitation?

YOU are the Provider — SUMMARY

1. How will you decide whether to declare this a mass-casualty incident?

In this case, you are responding to an incident involving *at least* three patients, and the severity of their injuries is unknown. One ambulance and two EMTs can effectively treat and transport only two stable patients *or* one critical patient at a time. In addition, there will likely be a crowd at the scene, which may hinder responder access and pose a possible danger to them.

On the basis of the information provided by dispatch, you should request additional EMS units. It is arguably better to call for help earlier, rather than wait until you arrive at the scene and find yourself overwhelmed by patients—some of whom may be critically injured. The longer it takes to call for help, the longer it will take for help to arrive.

2. How will the incident command system facilitate operations at this scene?

You have requested the assistance of other EMS units because you have determined that there are more patients than you can effectively care for. When the other units arrive, the ICS will facilitate the processes of triage, treatment, and transport; it will also help control the duplication of efforts and freelancing, in which individual units or different organizations make independent and often inefficient decisions that could compromise the effectiveness of the entire operation.

3. How should you and your partner proceed?

Once you have conducted a good scene size-up and answered the three basic questions—*What do I have? What resources do I need? What do I need to do?* —command should be established by the highest ranking public safety provider present, notification to other responders should go out, and necessary resources should be requested. In this instance, you and your partner will need to establish command until more senior personnel arrive.

4. Once command has been established, what are your duties?

Once an IC and safety officer have been identified, you and your partner should begin the process of locating the patients and triaging them.

Because you and your partner are the only EMTs at the scene, you will initially need to function as the triage and treatment officer, and the primary and secondary triage will likely occur in the same area. If you have triaged all patients and additional help has still not arrived, begin treating the most critically injured patients first. As additional EMTs and ambulances arrive, they should be assigned accordingly—again, with priority given to the most critically injured patients.

5. What are your considerations in determining whether you should stop and provide treatment for the first patient?

Major treatment is not allowed during the triage process; however, because this patient is breathing—although slowly—and has a pulse, it is acceptable to stop and roll her to the recovery position. This may facilitate her breathing and possibly improve her condition. Due to her altered mental status, respiratory status, and weak pulses, she should be categorized as immediate (red). You should return to treat her as soon as you have completed triage.

6. What triage categories should be assigned to the second and third patients?

Both patients should be categorized as expectant (black tag). The boy is unresponsive; is not breathing; has a slow, weak carotid pulse; and has no radial pulses. He also has exposed brain matter indicating injury that is highly likely to be incompatible with life. If adequate help was available at the scene, this patient would be categorized as immediate. The near decapitation injury in the older woman is also likely to be incompatible with life. Compared with others encountered during your triage, these two patients have the least likely chance of survival. If you and your partner were to focus on treating these two patients, the condition of the patient you categorized as red could deteriorate further, potentially resulting in the death of multiple patients.

7. What changes, if any, should you make in your initial triage assignments with the arrival of additional responders?

One patient was initially triaged as immediate (red tag); her triage category should stay the same. Remember, do not downgrade a patient's initial triage category; only upgrade it if the patient's condition deteriorates.

When you and your partner were the only EMTs at the scene, you had to decide which patients were the most critical, yet the most likely to survive with immediate treatment and prompt transport. The nonbreathing teenage boy and the older woman with near decapitation were initially triaged as expectant (black tag) because they were the least likely to survive and your available resources were limited. However, now that you have a sufficient number of EMTs and ambulances at the scene, reconsider their triage categories. Patients triaged as red and yellow should still receive the most immediate treatment and transport.

If you leave the teenager in the expectant category, he will die. However, if you provide immediate treatment and prompt transport, there is a chance that he will survive. Because he is pulseless and apneic, begin CPR and contact medical control; treatment and transport may still be indicated.

8. What should you consider in deciding whether to set up a treatment area at this incident?

Initially, there were only two EMTs at the scene and three critically injured patients. It would be more practical and time-saving to triage and treat the patients in the same area. Taking the time to set up a treatment area would delay patient care and would require more personnel. Once more EMS resources arrive at the scene, there may be a need for a designated treatment area if transport will be delayed for any of the patients.

9. What factors should be considered when determining the appropriate transport destination?

As soon as you declare an MCI, notify area hospitals as early as possible, inform them of the situation, and determine their surge capacity; this will tell you how many patients of each category they are able to safely and effectively care for. It will also allow the hospitals to increase their staffing and, if needed, move patients within the facility.

Do *not* begin transport until the intended destination facility has been notified and has accepted the patient(s). There must be a plan of action in place *before* any patients are transported from the scene.

The basic principles of transport that apply to any other patient also apply to MCIs; the most critically injured (red-tagged) patients should be transported to a designated trauma center, whereas yellow-tagged patients can be transported to hospitals that are located a farther away. In cases where the closest trauma center is located a great distance away, air medical transport should be considered.

10. Why did medical control advise termination of resuscitation?

He is a poor candidate because he is apneic with a weak carotid pulse and exposed brain matter. A patient who is critically injured will require more resources than are available and will pull valuable resources from others who may benefit from less time-consuming care. Multiple other patients may be saved in the amount of time required to treat this one individual. Even though it would be ideal to save everyone, the purpose of triage is to do the most good for the greatest number.

However, once all other patients are treated, or if there is enough manpower, even those patients who are considered poor candidates may receive treatment. This patient's age is a consideration for attempting resuscitation. While an older person is more likely to have concomitant issues and a more extensive medical history, a younger person may respond well to minimal treatment. If unsure, initiate treatment and contact medical control for further direction.

Ready for Review

- The National Incident Management System (NIMS) provides a framework to enable federal, state, and local governments, as well as private-sector and nongovernmental organizations, to work together effectively and efficiently. The NIMS is used to prepare for, prevent, respond to, and recover from domestic incidents, regardless of cause, size, or complexity, including acts of catastrophic terrorism and hazardous materials (HazMat) incidents.
- The five major NIMS components are preparedness, communications and information management, resource management, command management, and ongoing management and maintenance.
- The purpose of the incident command system is to ensure responder and public safety; achieve incident management goals; and ensure the efficient use of resources.
- Preparedness involves the decisions made and basic planning done before an incident occurs.
- Your agency should have written disaster plans that you are regularly trained to carry out.
- At incidents that have a significant medical factor, the incident commander should appoint someone as the medical group or branch leader. This person will supervise the primary roles of the medical group: triage, treatment, and transport of the injured.
- A mass-casualty incident (MCI) refers to any call that involves three or more patients, any situation that places such a great demand on available equipment or personnel that the system would require a mutual aid response, or any incident that has a potential to create one of the previously mentioned situations.
- The goal of triage is to do the greatest good for the greatest number of people. This means that the triage assessment is brief and the patient condition categories are basic.

- There are four basic triage categories that can be recalled using the mnemonic IDME:
  - Immediate (red)
  - Delayed (yellow)
  - Minimal (green; hold)
  - Expectant (black; likely to die or dead)
- A disaster is a widespread event that disrupts functions and resources of a community and threatens lives and property.
- Many disasters, such as a drought, may not involve personal injuries.
- When you arrive at the scene of a HazMat incident, you must first step back and assess the situation. This can be very stressful, particularly if you see a patient.
- A valuable resource for determining what the hazardous material is and what you should do is CHEMTREC.

Vital Vocabulary

bills of lading The shipping papers used for transport of chemicals over roads and highways; also referred to as freight bills.

bulk storage containers Any container other than nonbulky storage containers such as fixed tanks, highway cargo tanks, rail tank cars, totes, and intermodal tanks. These are typically found in manufacturing facilities and are often surrounded by a secondary containment system to help control an accidental release.

carboys Glass, plastic, or steel containers, ranging in volume from 5 to 15 gallons (19 to 57 L).

casualty collection area An area set up by physicians, nurses, and other hospital staff near a major disaster scene where patients can receive further triage and medical care.

Chemical Transportation Emergency Center (CHEMTREC) An agency that assists emergency responders in identifying and handling hazardous materials transport incidents.

closed incident An incident that is contained; all casualties are accounted for.

cold zone A safe area at a hazardous materials incident for the agencies involved in the operations. The incident commander, the command post, EMS providers, and other support functions necessary to control the incident should be located in this zone. Also referred to as the clean zone or the support zone.

command In incident command, the position that oversees the incident, establishes the objectives and priorities, and develops a response plan.

command post The designated field command center where the incident commander and support staff are located.

container Any vessel or receptacle that holds material, including storage vessels, pipelines, and packaging.

control zones Areas at a hazardous materials incident that are designated as hot, warm, or cold, based on safety issues and the degree of hazard found there.

cylinders Portable, compressed gas containers used to hold liquids and gases such as nitrogen, argon, helium, and oxygen. They have a range of sizes and internal pressures.

decontamination The process of removing or neutralizing and properly disposing of hazardous materials from equipment, patients, and responders.

decontamination area The designated area in a hazardous materials incident where all patients and responders must be decontaminated before going to another area.

demobilization The process of directing responders to return to their facilities when work at a disaster or mass-casualty incident has finished, at least for those particular responders.

disaster A widespread event that disrupts community resources and functions, in turn threatening public safety, citizens' lives, and property.

drums Barrel-like containers used to store a wide variety of substances, including food-grade materials, corrosives, flammable liquids, and grease. May be constructed of low-carbon steel, polyethylene, cardboard, stainless steel, nickel, or other materials.

Emergency Response Guidebook (ERG) A preliminary action guide for first responders operating at a hazardous materials incident in coordination with the US Department of Transportation's labels and placards marking system. Jointly developed by the DOT, the Secretariat of Communications and Transportation of Mexico, and Transport Canada.

extrication supervisor In incident command, the person appointed to determine the type of equipment and resources needed for a situation involving extrication or special rescue; also called the rescue officer.

finance In incident command, the position in an incident responsible for accounting of all expenditures.

freelancing When individual units or different organizations make independent and often inefficient decisions about the next appropriate action.

freight bills The shipping papers used for transport of chemicals along roads and highways; also referred to as bills of lading.

hazardous material Any substance that is toxic, poisonous, radioactive, flammable, or explosive and causes injury or death with exposure.

hazardous materials (HazMat) incident An incident in which a hazardous material is no longer properly contained and isolated.

hot zone The area immediately surrounding a hazardous materials spill or incident site that endangers life and health. All responders working in this zone must wear appropriate protective clothing and equipment. Entry requires approval by the incident commander or other designated officer.

incident action plan An oral or written plan stating general objectives reflecting the overall strategy for managing an incident.

incident command system (ICS) A system implemented to manage disasters and mass-casualty incidents in which section chiefs, including finance, logistics, operations, and planning, report to the incident commander.

incident commander (IC) The overall leader of the incident command system to whom commanders or leaders of incident command system divisions report.

intermodal tanks Shipping and storage vessels that can be either pressurized or nonpressurized.

joint information center (JIC) An area designated by the incident commander, or a designee, in which public information officers from multiple agencies distribute information about the incident.

JumpSTART triage A sorting system for pediatric patients younger than 8 years or weighing less than 100 pounds (45 kg). There is a minor adaptation for infants because they cannot ambulate on their own.

liaison officer In incident command, the person who relays information, concerns, and requests among responding agencies.

logistics In incident command, the position that helps procure and stockpile equipment and supplies during an incident.

material safety data sheet (MSDS) A form, provided by manufacturers and compounders (blenders) of chemicals, containing information about chemical composition, physical and chemical properties, health and safety hazards, emergency response, and waste disposal of a specific material; also known as safety data sheet (SDS).

mass-casualty incident (MCI) An emergency situation involving three or more patients or that can place great demand on the equipment or personnel of the EMS system or has the potential to produce multiple casualties.

morgue supervisor In incident command, the person who works with area medical examiners, coroners, and law enforcement agencies to coordinate the disposition of dead victims.

mutual aid response An agreement between neighboring EMS systems to respond to mass-casualty incidents or disasters in each other’s region when local resources are insufficient to handle the response.

National Incident Management System (NIMS) A Department of Homeland Security system designed to enable federal, state, and local governments and private-sector and nongovernmental organizations to effectively and efficiently prepare for, prevent, respond to, and recover from domestic incidents, regardless of cause, size, or complexity, including acts of catastrophic terrorism.

nonbulk storage vessels Any container other than bulk storage containers such as drums, bags, compressed gas cylinders, and cryogenic containers. These hold commonly used commercial and industrial chemicals such as solvents, industrial cleaners, and compounds.

open incident An incident that is not yet contained; there may be patients to be located and the situation may be ongoing, producing more patients.

operations In incident command, the position that carries out the orders of the commander to help resolve the incident.

personal protective equipment (PPE) levels Indicates the amount and type of protective equipment that an individual needs to avoid injury during contact with a hazardous material.

placards Signage required to be placed on all four sides of highway transport vehicles, railroad tank cars, and other forms of hazardous materials transportation; the sign identifies the hazardous contents of the vehicle, using a standardization system with 10¾-inch (27-cm) diamond-shaped indicators.

planning In incident command, the position that ultimately produces a plan to resolve any incident.

primary triage A type of patient sorting used to rapidly categorize patients; the focus is on speed in locating all patients and determining an initial priority as their conditions warrant.

public information officer (PIO) In incident command, the person who keeps the public informed and relates any information to the media.

rehabilitation area The area that provides protection and treatment to firefighters and other responders working at an emergency. Here, workers are medically monitored and receive any needed care as they enter and leave the scene.

rehabilitation supervisor In incident command, the person who establishes an area that provides protection for responders from the elements and the situation.

rescue supervisor In incident command, the person appointed to determine the type of equipment and resources needed for a situation involving extrication or special rescue; also called the extrication officer.

safety officer In incident command, the person who monitors the scene for conditions or operations that may present a hazard to responders and patients; he or she may stop an operation when responder safety is an issue.

secondary containment An engineered method to control spilled or released product if the main containment vessel fails.

secondary triage A type of patient sorting used in the treatment area that involves retriage of patients.

single command system A command system in which one person is in charge, generally used with small incidents that involve only one responding agency or one jurisdiction.

span of control In incident command, the subordinate positions under the commander's direction to which the workload is distributed; the ideal supervisor/worker ratio is one supervisor for three to seven workers.

staging supervisor In incident command, the person who locates an area to stage equipment and personnel and tracks unit arrival and deployment from the staging area.

START triage A patient sorting process that stands for Simple Triage And Rapid Treatment and uses a limited assessment of the patient's ability to walk, respiratory status, hemodynamic status, and neurologic status.

termination of command The end of the incident command structure when an incident draws to a close.

toxicity levels Indicates the risk that a hazardous material poses to the health of an individual who comes into contact with it.

transportation area The area in a mass-casualty incident where ambulances and crews are organized to transport patients from the treatment area to receiving hospitals.

transportation supervisor In incident command, the person in charge of the transportation sector in a mass-casualty incident who assigns patients from the treatment area to awaiting ambulances in the transportation area.

treatment area The location in a mass-casualty incident where patients are brought after being triaged and assigned a priority, where they are reassessed, treated, and monitored until transport to the hospital.

treatment supervisor In incident command, the person, usually a physician, who is in charge of and directs EMS providers at the treatment area in a mass-casualty incident.

triage The process of sorting patients based on the severity of injury and medical need to establish treatment and transportation priorities.

triage supervisor In incident command, the person in charge of the incident command triage sector who directs the sorting of patients into triage categories in a mass-casualty incident.

unified command system A command system used in larger incidents in which there is a multiagency response or multiple jurisdictions are involved.

warm zone The area located between the hot zone and the cold zone at a hazardous materials incident. The decontamination corridor is located in this zone.

Assessment *in Action*

© Jones & Bartlett Learning. Courtesy of MIEMSS.

You and your partner are dispatched to the scene of an industrial incident where an explosion has taken place. En route you receive a call on the radio from the local fire chief advising that oxygen and multiple other chemicals are stored at this facility, including pesticides and acids, and HazMat precautions should be followed. After arriving near the scene, you are directed to the staging area where patients will be brought to you once they have been decontaminated by the HazMat team. The HazMat team is made up of properly trained firefighters who are dressed appropriately to enter the scene and are responsible for initiating care of any ill or injured patients.

1. The HazMat team members enter the hot zone to approach the patients. They visually examine the containers to determine what chemicals may be in the hot zone. Which type of drum is used for the storage of corrosives such as acids, bases, or oxidizers?

   A. Steel
   B. Polyethylene
   C. Cardboard
   D. Nickel

2. The HazMat team members continue their visual examination of the containers. Oxygen is stored in which type of container?

   A. Cylinder
   B. Drum

C. Intermodal tank
D. Carboy

3. Once patients have been decontaminated and brought to the staging area, how should you continue care?

   A. Treat the airway only.
   B. Apply splints and bandages.
   C. Take vital signs and provide transport.
   D. Begin as if they have not received any treatment.

4. The HazMat team finds a small pesticide bag underneath a patient after lifting him. Which of the following is a requirement when labeling pesticide bags?

   A. Permissible exposure limits
   B. Routes of entry
   C. The EPA establishment number
   D. Contact information for the responsible party

5. The incident commander arrives with a notebook containing basic information about the chemical makeup of a substance, the potential hazard it presents, appropriate first aid in the event of an exposure, and other pertinent data for safe handling of the material. This information is contained in which of the following resources?

   A. Placards
   B. Labels
   C. Material Safety Data Sheet (MSDS)
   D. *Emergency Response Guidebook (ERG)*

6. Which control zone at a HazMat incident includes the area immediately surrounding the release, which is also the most contaminated area and the area that the HazMat team works in?

   A. Hot zone
   B. Contamination zone
   C. Warm zone
   D. Outer perimeter

7. In which control zone would you find the staging area for EMS?

   A. Hot zone
   B. Contamination zone
   C. Outer perimeter
   D. Cold zone

8. Which toxicity level includes materials that are extremely hazardous to health? Contact with these materials requires full protective gear so that none of your skin surface is exposed.

   A. Level 1
   B. Level 2
   C. Level 3
   D. Level 4

9. You may be required to call CHEMTREC to gain further information on potential exposures. List the basic information needed when calling CHEMTREC.

10. As an EMT, what is your role at a HazMat incident?

*This text uses the term mass-casualty incident.

CHAPTER 40

Terrorism Response and Disaster Management

Courtesy of Journalist 1st Class Mark D. Faram/U.S. Navy.

National EMS Education Standard Competencies

EMS Operations

Knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

Mass-Casualty Incidents Due to Terrorism and Disaster

› Risks and responsibilities of operating on the scene of a natural or man-made disaster. (pp 1451–1474)

Knowledge Objectives

1. Define international terrorism and domestic terrorism; include examples of incidents that have been caused by each one. (p 1451)
2. Name four different types of goals that commonly motivate terrorist groups to carry out terrorist attacks. (p 1452)
3. Define weapon of mass destruction (WMD) and weapon of mass casualty (WMC); include examples of weapons considered WMDs. (p 1453)
4. Explain how the Department of Homeland Security (DHS) National Terrorism Advisory System (NTAS) relates to the actions and precautions EMTs must take while performing their daily activities. (p 1454)
5. Name the key observations EMTs must make on every call to determine the potential of a terrorist attack. (p 1454)
6. Explain the critical response actions related to establishing and reassessing scene safety, personnel protection, notification procedures, and establishing command EMTs must perform at a suspected terrorist event. (pp 1454–1457)
7. Discuss the history of chemical agents, their four main classifications, routes of exposure, and the effects on patient care. (pp 1457–1463)
8. List three categories of biologic agents, their routes of exposure, effects on the patient, and patient care. (pp 1463–1471)
9. Explain the role of EMS in relation to syndromic surveillance and points of distribution (PODS) during a biologic event. (pp 1470–1471)
10. Discuss the history of nuclear/radiologic devices, sources of radiologic materials and dispersal devices, medical management of patients, and protective measures EMTs must take during a nuclear/radiologic incident. (pp 1471–1473)

11. Describe the mechanisms of injury caused by incendiary and explosive devices; include the types and severity of wounds. (pp 1473–1474)

Skills Objectives

1. Demonstrate the steps EMTs can take to establish and reassess scene safety based on a scenario of a terrorist event. (pp 1454–1457)
2. Demonstrate the steps EMTs can take for the management of a patient exposed to a chemical agent. (pp 1457–1463)
3. Demonstrate the use of the DuoDote Auto-Injector and/or the Antidote Treatment Nerve Agent Auto-Injector. (pp 1461–1462)

Introduction

The increase in terrorist activity makes it possible that you may be called on to respond to a terrorist event during your career. International terrorists and domestic groups have increased their targeting of civilian populations with acts of terror. The question is not will terrorists strike again, but rather when and where they will strike. You must be mentally and physically prepared for the possibility of a terrorist event.

The use of weapons of mass destruction (WMDs), or weapons of mass casualty (WMCs), further complicates the management of the terrorist incident and places you in greater danger. Although it is difficult to plan and anticipate a response to many terrorist events, there are several key principles that apply to every response. This chapter discusses the types of terrorist events, personnel safety, and patient management and gives you tools to prepare to respond to these events. You will learn the signs, symptoms, and treatment of patients who have been exposed to nuclear, chemical, or biologic agents or an explosive attack. At the end of this chapter, you will be able to answer the following key questions:

- What are my initial actions?
- Whom should I notify, and what should I tell them?
- What type of additional resources do I require?
- How should I proceed to address the needs of the victims?
- How do I ensure my and my partner's safety, as well as the safety of the victims?
- What is the clinical presentation of a victim exposed to a WMD?
- How do I assess and treat patients of WMD?
- How should I avoid becoming contaminated or cross-contaminated with a WMD agent?

What Is Terrorism?

No one is quite sure who was the first terrorist, but terrorist forces have been at work since early civilizations. Today, terrorists pose a threat to nations and cultures everywhere. International terrorism has brought a new fear into the lives of many American citizens.

The US Department of Justice defines both **international terrorism** and **domestic terrorism** with these points:

- Involves violent acts or acts dangerous to human life that violate federal or state law
- Appears to be intended (i) to intimidate or coerce a civilian population; (ii) to influence the policy of a government by intimidation or coercion; or (iii) to affect the conduct of a government by mass destruction, assassination, or kidnapping

One difference between the two is location. International terrorism occurs primarily outside the territorial jurisdiction of the United States, and domestic terrorism occurs primarily within the territorial jurisdiction of the United States.

Modern-day terrorism is common in the Middle East, where terrorist groups frequently attack civilian populations. In Central and South America, political terrorist groups target oil resources as a means to instill fear.

In the United States, domestic terrorists have carried out multiple attacks in previous years. The Centennial Park bombing during the 1996 Summer Olympics, the destruction of the Alfred P. Murrah Federal Building in Oklahoma City in 1995, and, most recently, the Boston Marathon bombing in 2013 are examples **Figure 40-1**.

Figure 40-1 The bombing at the Boston Marathon in 2013 is a recent example of domestic terrorism.

Terrorist organizations are often categorized based on their beliefs and goals. Only a small percentage of groups actually turn toward terrorism as a means to achieve their goals, such as the following:

1. **Religious extremist groups/doomsday cults.** These include groups such as Aum Shinrikyo, who carried out chemical attacks in Tokyo in 1994 and 1995. Some of these groups may participate in apocalyptic violence.
2. **Extremist political groups.** They may include violent separatist groups and those who seek political, religious, economic, and social freedom Figure 40-2.
3. **Cyber terrorists.** They attack a population's technological infrastructure as a means to draw attention to their cause.
4. **Single-issue groups.** These include antiabortion groups, animal rights groups, anarchists, racists, and even ecoterrorists who threaten or use violence as a means to protect the environment Figure 40-3.

Most terrorist attacks require the coordination of multiple terrorists or "actors" working together. Nineteen hijackers worked together to commit the worst act of terrorism in US history on September 11, 2001 Figure 40-4. At least four terrorists worked together to commit the London Subway bombings on July 7, 2005. However, in a few instances there has been a single terrorist responsible for causing devastating results. Terrorists who acted alone carried out each of the Atlanta abortion clinic attacks in 1996 and the 1996 Summer Olympics attack.

Figure 40-2 Militant groups in Afghanistan, Iraq, Syria, and Nigeria have been associated with terrorism.

Figure 40-3 Demonstrators being held back by police near the World Bank in Washington, DC.

YOU are the Provider — PART 1

At 1005 hours, you are dispatched to an abortion clinic where a car crashed into the building and then exploded. According to dispatch, the frantic caller could not tell her how many victims were involved; he could tell her only that the building was on fire. Law enforcement and the fire department's hazardous materials (HazMat) team are en route to the scene as well. The weather is clear, and a light breeze is blowing from the northwest.

1. On the basis of the dispatch information, how should you approach this incident?
2. What indicators suggest that an incident is the result of terrorism?

Figure 40-4 The September 11, 2001, attack on the World Trade Center in New York City accounted for the majority of the deaths caused by terrorists in 2001.

Weapons of Mass Destruction

A **weapon of mass destruction (WMD)**, or **weapon of mass casualty (WMC)**, is any agent designed to bring about mass death, casualties, and/or massive damage to property and infrastructure (bridges, tunnels, airports, and seaports). To help remember the different kinds of weapons of mass destruction, use the mnemonic **B-NICE**: **b**iologic, **n**uclear, **i**ncendiary, **c**hemical, and **e**xplosive weapons; or CBRNE for chemical, biologic, radiologic, nuclear, and explosive weapons.

To date, the preferred WMD for terrorists has been explosive devices. Terrorist groups have favored tactics that use truck bombs or car or pedestrian suicide bombers. Many previous terrorist attempts to use either chemical or biologic weapons to their full capacity have been unsuccessful. Nonetheless, as an EMT, ensure you understand the destructive potential of these weapons.

The motives and tactics of the new-age terrorist groups have begun to change. As with the doomsday cults, many terrorist groups participate in indiscriminate killing. This doctrine of total carnage would make the use of WMDs highly desirable. WMDs are relatively easy to obtain or create and are specifically geared toward killing a large number of people. Had the proper techniques been used during the 1995 Aum Shinrikyo attack on the Tokyo subway, there may have been tens of thousands of casualties. Since the fall of the former Soviet Union, the technology and expertise to produce WMDs may be available to terrorist groups with sufficient funding. Moreover, the technical recipes for making B-NICE weapons can be readily found on the Internet; in fact, they have even been published on terrorist group websites.

Words of Wisdom

Chemical warfare may consist of agents in the form of a liquid, powder, or vapor.

Chemical Terrorism/Warfare

Chemical agents are manufactured substances that can have devastating effects on living organisms. They can be produced in liquid, powder, or vapor form depending on the desired route of exposure and dissemination technique. Developed during World War I (WWI), these agents have been implicated in thousands of deaths since being introduced on the battlefield and since then have been used to terrorize civilian populations. These agents consist of the following types:

- Vesicants (blister agents)
- Respiratory agents (choking agents)
- Nerve agents
- Metabolic agents (cyanides)

Biologic Terrorism/Warfare

Biologic agents are organisms that cause disease. They are generally found in nature; however, for terrorist use, they are cultivated, synthesized, and mutated in a laboratory. The **weaponization** of biologic agents is performed to artificially maximize the target population's exposure to the germ, thereby exposing the greatest number of people and achieving the desired result.

The primary types of biologic agents that you may come into contact with during a biologic event include the following:

- Viruses
- Bacteria
- Toxins

Nuclear/Radiologic Terrorism

There have been only two publicly known incidents involving the use of a nuclear device. During World War II (WWII), Hiroshima and Nagasaki were devastated when they were targeted with nuclear bombs. The awesome destructive power demonstrated by the attack ended WWII and has served as a deterrent to nuclear war.

There are nations that hold close ties with terrorist groups (known as **state-sponsored terrorism**) and have obtained some degree of nuclear capability.

It is also possible for a terrorist to secure radioactive materials or waste to perpetrate an act of terror. These materials are far easier for a terrorist to acquire than are nuclear weapons, and require less expertise to use. The difficulties in developing a nuclear weapon are well documented. Radioactive materials, however, such as those in radiologic dispersal devices (RDDs), also known as "dirty bombs," can cause widespread panic and civil disturbances. These devices are covered later in this chapter.

EMT Response to Terrorism

When you respond to a terrorist event, the basic foundations of patient care remain the same; however, the treatment can and will vary. Terrorist events can produce a single casualty, hundreds of casualties, or even thousands of casualties. In all cases, you must remember situational awareness. Your response in one situation may not be appropriate for another situation. In large-scale terrorist events, it is important to use triage and base patient care on available resources.

Recognizing a Terrorist Event (Indicators)

The planning of most acts of terror is **covert**, which means that the public safety community generally has no prior knowledge of the time, location, or nature of the attack. This element of surprise makes responding to an event more complex. You must constantly be aware of your surroundings and understand the possible risks for terrorism associated with certain locations, at certain times. Therefore, it is important that you know the current threat level issued by the federal government through the Department of Homeland Security (DHS).

In April 2011, the color-coded Homeland Security Advisory System was replaced by the National Terrorism Advisory System (NTAS). Alerts from the NTAS contain a summary of the threat and the actions that first responders, government agencies, and the public can take to maintain safety. On the basis of threat information, make sure you take the appropriate actions and precautions while you continue to perform your daily duties and response to calls.

The DHS has not issued specific recommendations for EMS personnel to follow in response to specific threats. Follow your local protocols, policies, and procedures.

It is your responsibility to make sure you are aware of information sent out by the advisory system at the start of your workday. Daily newspapers, television news programs, and multiple websites (including the DHS website) all give up-to-date information. Many EMS organizations are starting to display the advisory system on boards where it can be seen by staff when they arrive for a shift.

Understanding and being aware of the current threat is only the beginning of responding safely to calls. To determine the potential for a terrorist attack, make the following observations on every call:

- **Type of location.** Is the location a monument, infrastructure, government building, or a specific type of location such as a temple? Is there a large gathering? Is there a special event taking place?
- **Type of call.** Is there a report of an explosion or suspicious device nearby? Are there reports of people fleeing the scene?
- **Number of patients.** Are there multiple victims with similar signs and symptoms? This is probably the single most important clue that a terrorist attack or an incident involving a WMD has occurred.
- **Victims' statements.** This is probably the second best indication of a terrorist or WMD event. Are the victims fleeing the scene giving statements such as, "Everyone is passing out," "There was a loud explosion," or "There are a lot of people shaking on the ground." If so, something is occurring that you do not want to rush in to, even if it is questionable as to whether or not it is a terrorist event.
- **Preincident indicators.** Has there been a recent increase in violent political activism? Are you aware of any credible threats made against the location, gathering, or occasion?

Response Actions

Once you suspect that a terrorist event has occurred or a WMD has been used, there are certain actions you must take to ensure you will be safe and properly prepared to help the community.

Scene Safety

Remember to stage your vehicle a safe distance (usually 1 to 2 blocks) from the incident, and wait for law enforcement personnel to advise you that the scene has been made secure. If you have any doubt that it may not be safe, do not enter. When dealing with a WMD scene, assume you will not be able to enter the scene where the event has occurred—nor do you want to. The best location for staging is upwind and uphill from the incident. Wait for assistance from those who are trained in assessing and managing WMD scenes **Figure 40-5**. Expect that a perimeter will be created, usually by law enforcement personnel, in an effort to isolate the scene, prevent further contamination of evidence, and protect rescuers and the public from further danger. Also remember the following rules:

- Failure to park your vehicle at a safe location can place you and your partner in danger **Figure 40-6**. Always have an escape plan determined beforehand, in case the scene becomes unsafe.
- If your vehicle is blocked in by other emergency vehicles or damaged by a secondary device (or event), you will be unable to provide transportation for victims **Figure 40-7** or escape yourself.

Terrorists have been known to plant additional explosives that are set to explode after the initial bomb. This type of **secondary device** is intended primarily to injure responders and to secure media coverage because the media generally arrive on scene just after the initial response. Secondary devices may include various types of electronic equipment such as cell phones or pagers that are designed to detonate when they are activated.

Responder Safety (Personnel Protection)

The best form of protection from a WMD agent is preventing yourself from coming into contact with the agent. The greatest threats facing you in a WMD attack are contamination and **cross-contamination**. Contamination with an agent occurs when you have direct contact with the WMD or are exposed to it. Cross-contamination occurs when you come into contact with a contaminated person who has not yet been decontaminated.

Notification Procedures

When you suspect a terrorist or WMD event has taken place, notify the dispatcher. Vital information needs to be communicated effectively if you are to receive the appropriate assistance (see Chapter 4, *Communications and Documentation*, for information on effective communication). Inform dispatch of the nature of the event, any additional resources that may be required, the estimated number of patients, and the upwind route of approach or optimal route of approach.

Figure 40-5 Improper staging of a mass-casualty scene can lead to injury or even death of EMS personnel. Wait for trained personnel to assist in assessing and managing such scenes.

Figure 40-6 Park your vehicle at a safe location.

Figure 40-7 Make sure your vehicle is not blocked in by other emergency vehicles.

Words of Wisdom

One way to distinguish between an antiterrorist and a terrorist mass-casualty event is whether the intentional use of a WMD affects multiple people. These patients will generally exhibit the same signs and symptoms. It is highly unlikely for more than one person to experience a seizure at any given time. It is not uncommon to find multiple patients complaining of difficulty breathing at the scene of a fire. However, the same report in the subway at rush hour, when no smell of smoke has been reported, is certainly cause for suspicion. In these situations, use your good judgment and resist the urge to "rush in and help."

It is extremely important to establish a staging area, where other units will converge. Be mindful of access and exit routes when you direct units to respond to a location. It is unwise to have units respond to the front entrance of a hotel or apartment building that has had an explosion (see Chapter 37, *Transport Operations*, on vehicle positioning). Last, trained responders in the proper protective equipment are the only people equipped to handle the WMD incident. These specialized units, traditionally HazMat teams, must be requested as early as possible because of the time required to assemble and dispatch the team and their equipment. Many jurisdictions share HazMat teams, so the team may have to travel a long distance to reach the location of the event. It is always better to be safe than sorry; call the team early, and the outcome of the call will be more favorable.

Keep in mind that there may be more than one type of device or agent present.

Words of Wisdom

Weapons of Mass Destruction

On September 11, 2001, communications were severely affected by the collapse of the World Trade Center. The primary communications repeater was located on top of one of the towers. In addition, excess radio traffic made transmitting and receiving messages extremely difficult. Not only were radio communications affected, but most cell phones and the majority of radio and television stations were disabled. The lesson learned from this event is to have multiple backups to your ability to communicate with your dispatcher. In the event of a terrorist or WMD event, refrain from using the radio unless you have something important to transmit. If you do transmit, gather your thoughts and speak in as calm a tone as possible, avoiding unnecessary chatter. Remember, while you are transmitting, others may be unable to call for help.

Establishing Command

The first provider on the scene must begin to sort out the chaos and define his or her responsibilities under the incident command system (ICS). As the first person on scene, you may need to establish command until additional personnel arrive. Depending on the circumstances and stage of the operation, you and other EMTs may function as medical branch directors, triage supervisors, treatment supervisors, transportation supervisors, logistic officers, or command and general staff. If the initial ICS is already in place, then immediately find the medical staging officer to receive your assignment. Chapter 39, *Incident Management*, discusses in detail how to work within the ICS and the National Incident Management System (NIMS).

Reassessing Scene Safety

Do not rely on others to secure your safety. It is your responsibility to constantly assess and reassess the scene for safety. This is an important component of situational awareness. It is easy to overlook a suspicious package while you are treating casualties. Stay alert. Something as subtle as a change in the wind direction during a gas attack or an increase in the number of contaminated patients can place you in danger. Never become so involved with the tasks you are performing that you do not look around and make sure the scene remains safe.

YOU are the Provider — PART 2

The HazMat team has assessed the scene. On the basis of its assessment and observations, the team has determined that radiation is present in the area of the incident. The driver of the vehicle is obviously deceased, and there are four patients who require emergency care. The severity of their injuries, however, is unknown.

3. On the basis of the HazMat team's findings, what has most likely occurred?
4. What should be done first to ensure the scene is safe for you and other EMS personnel to enter?

Words of Wisdom

While it may be difficult for you because of ethical or moral reasons to treat a suspected criminal or suspected terrorist, it is important that this patient receive the same care as any other patient. You are not the judge or jury. It is up to the legal system to prove in a court of law that someone is guilty.

Chemical Agents

Chemical agents are liquids or gases that are dispersed to kill or injure. Modern-day chemicals were first developed during WWI and WWII. During the Cold War, many of these agents were perfected and stockpiled. Whereas the United States has long renounced the use of chemical weapons, many nations still develop and stockpile them. These agents are deadly and pose a threat if they are acquired by terrorists.

Chemical weapons have several classifications. The properties or characteristics of an agent can be described as liquid, gas, or solid material. **Persistency** and **volatility** describe how long the agent will stay on a surface before it evaporates. Persistent or nonvolatile agents can remain on a surface for long periods, usually longer than 24 hours. Nonpersistent or volatile agents evaporate relatively fast when left on a surface in the optimal temperature range. An agent that is described as highly persistent (such as VX, a nerve agent) can remain in the environment for weeks to months, whereas an agent that is highly volatile (such as sarin, also a nerve agent) will turn from liquid to gas (evaporate) within minutes to seconds.

Route of exposure is how the agent most effectively enters the body. Chemical agents can have either a vapor or contact hazard. Agents with a **vapor hazard** enter the body through the respiratory tract in the form of vapors. Agents with a **contact hazard** (or skin hazard) give off very little vapor or no vapors and enter the body through the skin.

Vesicants (Blister Agents)

The primary route of exposure of blister agents, or **vesicants**, is the skin (contact); however, if vesicants are left on the skin or clothing long enough, they produce vapors that can enter the respiratory tract. Vesicants cause burn-like blisters to form on the victim's skin and in the respiratory tract. The vesicant agents consist of sulfur mustard (H), lewisite (L), and phosgene oxime (CX) (the symbols H, L, and CX are military designations for these chemicals). The vesicants usually cause the most damage to damp or moist areas of the body, such as the armpits, groin, and respiratory tract. Signs of vesicant exposure on the skin include the following:

- Skin irritation, burning, and reddening
- Immediate, intense skin pain (with L and CX)
- Formation of large blisters
- Gray discoloration of skin (a sign of permanent damage seen with L and CX)
- Swollen and closed or irritated eyes
- Permanent eye injury (including blindness)

If vapors were inhaled, the patient may experience the following signs and symptoms:

- Hoarseness and stridor
- Severe cough
- Hemoptysis (coughing up blood)
- Severe dyspnea

Sulfur mustard (H), commonly known as mustard gas, is a brownish, yellowish oily substance that is generally considered very persistent. When released, mustard gas has the distinct smell of garlic or mustard and is quickly absorbed into the skin and/or mucous membranes. As the agent is absorbed into the skin, it begins an irreversible process of damage to the cells. Absorption through the skin or mucous membranes usually occurs within seconds, and damage to the underlying cells takes place within 1 to 2 minutes.

Mustard gas is considered a **mutagen**, which means that it mutates, damages, and changes the structures of cells. Eventually, cellular death will occur. On the surface, the patient will generally not produce any signs or symptoms until 4 to 6 hours after exposure (depending on concentration and amount of exposure) **Figure 40-8**.

The patient will experience a progressive reddening of the affected area, which will gradually develop into large blisters. These blisters are very similar in shape and appearance to those associated with thermal second-degree burns. The fluid within the blisters does not contain any of the agent; however, the skin covering the area is considered contaminated until trained personnel have decontaminated the patient.

Figure 40-8 Skin damage resulting from exposure to sulfur mustard (H).

Courtesy of Dr. Saeed Keshavarz/RCCI, Research Center of Chemical Injuries/IRAN.

Mustard gas also attacks vulnerable cells within the bone marrow and depletes the body's ability to reproduce white blood cells. Like other burns, the primary complication associated with vesicant blisters is secondary infection. If the patient survives the initial direct injury from the agent, the depletion of the white blood cells leaves the patient with a decreased resistance to infections. Although sulfur mustard is regarded as persistent, the vapors it releases when dispersed can be inhaled. This creates upper and lower airway compromise. The result is damage and swelling of the airways. The airway compromise makes the patient's condition far more serious.

Lewisite (L) and **phosgene oxime (CX)** produce blister wounds very similar to those caused by mustard gas. They are highly volatile and have a rapid onset of symptoms, compared with the delayed onset seen with mustard gas. These agents produce immediate intense pain and discomfort when contact is made. The patient's skin may have a grayish discoloration at the contaminated site. While tissue damage also occurs with exposure to these agents, they do not cause the secondary cellular injury that is associated with mustard gas.

Vesicant Agent Treatment

There are no antidotes for mustard gas or CX exposure. British anti-lewisite is the antidote for agent L; however, it is not carried by civilian EMS. Ensure the patient has been decontaminated before you initiate any treatment. If any agent has been inhaled, the patient may require prompt airway support as soon as decontamination is completed. Initiate transport as soon as possible. Generally, burn centers are best equipped to handle the wounds and subsequent infections produced by vesicants. Follow your local protocols when deciding the transport destination.

Pulmonary Agents (Choking Agents)

The pulmonary agents are gases that cause immediate harm to people exposed to them and include chlorine (Cl) and phosgene. These agents produce respiratory-related symptoms such as dyspnea and tachypnea. The primary route of exposure for these agents is through the respiratory tract, which makes them an inhalation or vapor hazard. Once inside the lungs, they damage the lung tissue and fluid leaks into the lungs. Pulmonary edema develops in the patient, resulting in difficulty breathing because of severely impaired gas exchange.

Chlorine (Cl) was the first chemical agent ever used in warfare. It has a distinct odor of bleach and creates a green haze when released as a gas. Initially, it produces upper airway irritation and a choking sensation. The patient may later experience the following signs and symptoms:

- Shortness of breath
- Tightness in chest
- Hoarseness and stridor as the result of upper airway constriction
- Gasping and coughing

With serious exposures, patients may experience pulmonary edema, complete airway constriction, and death. The fumes from a mixture of household bleach and ammonia create an acid gas that produces similar effects. According to the American Association of Poison Control Centers' 2013 data report, human exposure involving household cleaning substances was the third most frequently reported exposure.

Do not confuse **phosgene** with phosgene oxime, a blistering agent, or vesicant. Not only has phosgene been produced for chemical warfare, but it is a product of combustion that might be produced as a result of a fire involving other chemicals, such as at a textile factory or house or from metalwork or burning Freon (a liquid chemical used in refrigeration). Therefore, you may encounter a victim of exposure to this gas during the course of a normal call or at a fire scene. Phosgene is a very potent agent that has a delayed onset of symptoms, usually hours. Unlike Cl, when phosgene enters the body, it generally does not produce severe irritation that would possibly cause the victim to leave the area or hold his or her breath. In fact, the odor produced by the chemical is similar to that of freshly mowed grass or hay. The result is that much more of the gas may enter the body unnoticed. Initially, a mild exposure may include the following signs and symptoms:

- Nausea
- Tightness in chest
- Severe cough
- Dyspnea on exertion

The victim of a severe exposure may present with dyspnea at rest and excessive pulmonary edema. The pulmonary edema may be so severe that the patient continually coughs up white or pink-tinged fluid. A severe exposure produces such large amounts of fluid in the lungs that the patient may actually become hypovolemic and subsequently hypotensive.

Pulmonary Agent Treatment

The best initial treatment of any patient who has been exposed to a pulmonary agent is to remove the patient from the contaminated atmosphere. This should be done by trained personnel in the proper personal protective equipment (PPE).

Aggressively manage the ABCs, paying particular attention to oxygenation, ventilation, and suctioning if required. Do not allow the patient to be active because this will worsen the condition. There are not any antidotes to counteract the pulmonary agents. The primary goals for basic life support prehospital emergency care are to perform the ABCs, allow the patient to rest in a position of comfort with his or her head elevated, and initiate rapid transport. If the patient's condition does not improve with basic airway support, consider requesting an advance life support (ALS) intercept. Continuous positive airway pressure (CPAP) may benefit some of these patients, but others will require more advanced airway management.

Nerve Agents

The **nerve agents** are among the most deadly chemicals developed. They are classified as WMDs. Nerve agents are not readily available to the general public and are extremely toxic and rapidly fatal with any route of exposure. Designed to kill a large number of people with small quantities, nerve agents can cause cardiac arrest within seconds to minutes of exposure. Nerve agents, discovered while in search of a superior pesticide, are a class of chemical called organophosphates, which are found in household bug sprays, agricultural pesticides, and some industrial chemicals at much lower strengths then in the weaponized form. Organophosphates block an essential enzyme in the nervous system, causing the body's organs to become overstimulated and burn out.

G agents came from the early nerve agents, the G-series, which were developed by German scientists (hence the G) in the period after WWI and during WWII. There are three G-series agents, which are all designed with the same basic chemical structure with slight variations to produce different properties. The two variations of these agents are lethality and volatility. The following G agents are listed from high volatility to low volatility:

- **Sarin (GB)**. Highly volatile colorless and odorless liquid. Turns from liquid to gas within seconds to minutes at room temperature. Highly lethal, with an **LD_{50}** of about 1 drop, depending on the purity. The LD_{50} is the standard measurement that represents the amount that will kill 50% of a population exposed to this level. Sarin is primarily a vapor hazard, with the respiratory tract as the main route of entry. This agent is especially dangerous in enclosed environments such as office buildings, shopping malls, and subway cars. When this agent comes into contact with the skin, it is quickly absorbed and evaporates. When sarin is on clothing, it has the effect of **off-gassing**, which means that the vapors are continuously released over a period of time (like perfume). This renders the victim and the victim's clothing contaminated.
- **Soman (GD)**. Twice as persistent as sarin and five times as lethal. It has a fruity odor as a result of the type of alcohol used in the agent and generally has no color. This agent is a contact and inhalation hazard that can enter the body through skin absorption and through the respiratory tract. A unique additive in GD causes it to bind to the cells that it attacks faster than any other agent. This irreversible binding is called **aging**, which makes it more difficult to treat patients who have been exposed.
- **Tabun (GA)**. Approximately half as lethal as sarin and 36 times more persistent. Under the proper conditions it will remain present for several days. It has a fruity smell and an appearance similar to sarin. The components used to manufacture GA are easy to acquire, and the agent is easy to manufacture, which makes it unique. GA is a contact and inhalation hazard that can enter the body through skin absorption and through the respiratory tract.
- **V agent (VX)**. Clear oily agent that has no odor and looks like baby oil. V agent was developed by the British after WWII and has chemical properties similar to the G-series agents. The difference is that VX is more than 100 times more lethal than sarin and is extremely persistent **Figure 40-9**. In fact, VX is so persistent that given the proper conditions, it will remain relatively unchanged for weeks to months. These properties make VX primarily a contact hazard because it lets off very little vapor. It is easily absorbed into the skin, and the oily residue that remains on the skin's surface is extremely difficult to decontaminate.

Nerve agents all produce similar symptoms but have varying routes of entry. Nerve agents differ slightly in lethal concentration or dose and also differ in their volatility. Some agents are designed to quickly become a gas (nonpersistent or highly volatile), whereas others remain a liquid for a period of time (persistent or nonvolatile). These agents have been used successfully in warfare and, until recently, were the only type of chemical agent that had been used successfully in a terrorist act. Once the agent has entered the body through skin contact or through the respiratory system, the patient will begin to exhibit a pattern of predictable symptoms. Like all chemical agents, the severity of the patient's symptoms will depend on the route of exposure of the agent and the amount of exposure.

The symptoms are described in **Table 40-1** using the military mnemonic SLUDGEM and the medical mnemonic DUMBELS. The medical mnemonic is more useful to you because it lists the more dangerous symptoms associated with exposure to nerve agents.

Figure 40-9 VX is the most toxic chemical ever created. The dot on the penny demonstrates the amount needed to achieve the lethal dose.

Table 40-1 Symptoms of Exposure to Nerve Agents

Military Mnemonic: SLUDGEM	Medical Mnemonic: DUMBELS (all age groups)
Salivation, **S**weating	**D**iarrhea
Lacrimation (excessive tearing) (also Rhinorrhea)	**U**rination
Urination	**M**iosis (pinpoint pupils) **M**uscle weakness
Defecation, **D**rooling, **D**iarrhea	**B**radycardia, **B**ronchospasm, **B**ronchorrhea
Gastric upset and cramps	**E**mesis (vomiting)
Emesis (vomiting)	**L**acrimation (excessive tearing) (also Rhinorrhea)
Muscle twitching/**M**iosis (pinpoint pupils)	**S**eizures, **S**alivation, **S**weating

YOU are the Provider — PART 3

You have been informed that the patients have been properly decontaminated and have been moved to an area that has been designated as being safe for you to enter. After donning the appropriate personal protective equipment, you and the other responders report to the incident scene.

5. Given the situation, what are some unique concerns about this incident?
6. What types of injuries should you expect to encounter?

Safety Tips

Industrial Chemicals/Insecticides

The basic chemical ingredient in nerve agents is organophosphate. This is a common chemical that is used in lesser concentrations for insecticides. Whereas industrial chemicals do not possess sufficient lethality to be effective WMDs, they are easy to acquire and inexpensive and have similar effects to the nerve agents. Crop-duster planes could be used to disseminate these chemicals. Be cautious when responding to calls where insecticide equipment is stored and used, such as a farm or supply stores that sells these products. The symptoms and medical management of victims of organophosphate insecticide poisoning are identical to those of the nerve agents.

There are only a handful of medical conditions that are associated with the bilateral pinpoint constricted pupils (**miosis**) seen with nerve agent exposure. Conditions such as a cerebrovascular accident, direct light to both eyes, and a drug overdose all can cause bilaterally constricted pupils. Therefore, assess the patient for all of the SLUDGEM/DUMBELS signs and symptoms to determine whether the patient has been exposed to a nerve agent.

Miosis is the most common symptom of nerve agent exposure and can remain for days to weeks. This symptom, along with the others listed in Table 40-1, will help you recognize exposure to a nerve agent early. Miosis will be seen quickly in a vapor exposure but may occur later after an isolated skin exposure. In some cases the patient may have been exposed to both.

The seizures that are associated with nerve agent exposure are unlike those found in patients with a history of seizure. The seizure will continue until the patient dies or until treatment is given with a nerve agent antidote kit (DuoDote Auto-Injector or Antidote Treatment Nerve Agent Auto-Injector [ATNAA]).

Nerve Agent Treatment

Fatalities from severe exposure to a nerve agent occur as a result of respiratory complications, which lead to respiratory arrest. Once the patient has been decontaminated, be prepared to treat aggressively, if the patient is to be saved. You can greatly increase the patient's chances of survival simply by providing airway and ventilatory support. As with all emergencies, securing the ABCs is the best and most important treatment that you can provide. Often in patients exposed to these agents, seizures will begin and will not stop. These patients will require administration of nerve agent antidote kits in addition to support of the ABCs.

Words of Wisdom

On March 20, 1995, members of Aum Shinrikyo, a Japanese cult, released sarin (GB) in the Tokyo subway. The first arriving medical responders were met with chaos as hundreds and then thousands of people fled the subway system **Figure 40-10**. Many were contaminated and showed signs and symptoms of nerve agent exposure. In the end, more than 5,000 people sought medical care for exposure to sarin, and 12 people died. None of the EMS personnel wore protective clothing, so most became cross-contaminated. Remember, you can avoid becoming exposed. Do not become a victim. Medical professionals responding to an attack in 1995, where cult members released sarin in the Tokyo subway.

Figure 40-10 Medical professionals responding to an attack in 1995, where cult members released sarin in the Tokyo subway.

Medical treatment for nerve agent exposure may include the **DuoDote Auto-Injector**. The DuoDote Auto-Injector contains 2.1 mg of atropine and 600 mg of pralidoxime chloride (2-PAM) and is delivered as a single dose through one needle. Atropine is used to block the nerve agent. However, because the nerve agent may remain in the body for long periods, 2-PAM is used to eliminate the agent from the body. Many of the symptoms described in the DUMBELS mnemonic will be reversed with the use of atropine; however, you may need to administer many doses to see these results. The military form of this combination injector is the **Antidote Treatment Nerve Agent Auto-Injector (ATNAA)**.

In some regions, EMTs may carry DuoDote kits on the unit and will be called on to administer the antidotes to themselves or their patients. If your service carries a nerve agent antidote, refer to your local protocols for dosage and usage information. These medications are delivered using the same technique as the EpiPen auto-injector; however, multiple doses may need to be administered. Activated antidote kits need to be properly disposed into a sharps container.

Table 40-2 has been provided for quick reference and comparison of the nerve agents.

Metabolic Agents (Cyanides)

Hydrogen cyanide (AC) and cyanogen chloride (CK) are both agents that affect the body's ability to use oxygen. **Cyanide** is a colorless gas that has an odor similar to almonds. The effects of the cyanides begin on the cellular level and are very rapidly seen at the organ and system levels. Unlike nerve agents, however, these deadly gases are commonly found in many industrial settings. Cyanides are produced every year in massive quantities throughout the United States for industrial uses such as gold and silver mining, photography, and plastics processing. They are often present in fires associated with textile and plastic factories. In fact, cyanide is naturally found in the pits of many fruits in very low doses.

There is very little difference in the symptoms found between AC and CK. In low doses, these chemicals are associated with dizziness, light-headedness, headache, and vomiting. Higher doses will produce symptoms that include the following:

- Shortness of breath and gasping respirations
- Respiratory distress or arrest
- Tachypnea
- Flushed skin
- Tachycardia
- Altered mental status
- Seizures
- Coma
- Apnea
- Cardiac arrest

The symptoms associated with the inhalation of a large amount of cyanide will all appear within several minutes. Death is likely unless the patient is treated promptly.

Table 40-2 The Nerve Agents

Name	Military Designation	Odor	Special Features	Onset of Symptoms	Volatility	Route of Exposure
Tabun	GA	Fruity	Easy to manufacture	Immediate	Low	Skin contact and vapor hazard
Sarin	GB	None (if pure) or strong	Will off-gas while on victim's clothing	Immediate	High	Primarily respiratory vapor hazard; skin exposure is extremely lethal
Soman	GD	Fruity	Ages rapidly; difficult to treat	Immediate	Moderate	Skin contact; minimal vapor hazard
V agent	VX	None	Most lethal chemical agent; difficult to decontaminate	Immediate	Very low	Skin contact; no vapor hazard (unless aerosolized)

Words of Wisdom

Patients exposed to cyanide and who have shortness of breath will have a normal pulse oximetry reading.

Cyanide Agent Treatment

Cyanide binds with the body's cells, preventing oxygen from being used. Several medications act as antidotes, but most services do not carry them. Once trained personnel wearing the proper PPE have removed the patient from the source of exposure, even if there is no liquid contamination, all of the patient's clothes must be removed to prevent off-gassing in the ambulance. Trained and protected personnel must decontaminate any patients who may have been exposed to liquid contamination before you can initiate treatment. Then support the patient's ABCs. Mild effects of cyanide exposure will generally resolve by simply removing the victim from the source of contamination and administering supplemental oxygen. Severe exposure, however, will require aggressive oxygenation and perhaps ventilation with supplemental oxygen. Always use a bag-valve mask (BVM) or oxygen-powered ventilator device to ventilate a victim of a metabolic agent. The agent can easily be passed on from the patient to you through mouth-to-mouth or mouth-to-mask ventilations. Initiate transport immediately if antidote by ALS is not available.

Words of Wisdom

Always make sure your patients have been thoroughly decontaminated by trained personnel before you come into contact with them. Chemical agents are primarily a vapor hazard, and all of the patient's clothing must be removed prior to treatment to prevent off-gassing to you. Finally, never perform mouth-to-mouth or mouth-to-mask ventilation on a victim of a chemical agent exposure. Many of the vapors may linger in the patient's airway, and cross-contamination may occur.

Table 40-3 summarizes the chemical agents. The odors of the particular chemicals are provided for informational purposes only. The sense of smell is a poor tool to use to determine whether there is a chemical agent present. Many people are unable to smell the agents, and the odor could be derived from another source. This information is useful to you if you receive reports from victims who claimed to smell bleach or garlic, for example. Never enter a potentially hazardous area and "smell" to determine whether a chemical agent is present.

Biologic Agents

Biologic agents pose many difficult issues when used as a WMD. Biologic agents can be almost completely undetectable. Also, most of the diseases caused by these agents will be similar to other minor illnesses commonly seen by EMS providers.

Biologic agents are grouped as viruses, bacteria, and neurotoxins and may be spread in various ways. **Dissemination** is the means by which a terrorist will spread the agent—for example, poisoning the water supply or aerosolizing the agent into the air or ventilation system of a building. A **disease vector** is an animal that spreads disease, once infected, to another animal. For example, bubonic plague can be spread by infected rats; smallpox by infected humans; and West Nile virus by infected mosquitoes. How easily the disease is able to spread from one human to another human is called *communicability*. Some diseases, such as those caused by the human immunodeficiency virus (HIV), are difficult to spread by routine contact. Therefore, communicability is considered low. In other instances when communicability is high, such as with smallpox, the person is considered **contagious**. Typically, routine standard precautions are enough to prevent contamination from contagious biologic organisms.

Incubation is the period of time between the person becoming exposed to the agent and the appearance of the first symptoms. The incubation period is especially important for you to understand. Although your patient may not exhibit signs or symptoms, he or she may be contagious.

Be aware of when you should suspect the use of biologic agents. If the agent is in the form of a powder, such as in the October 2001 Amerithrax attacks involving letters laced with anthrax powder appearing in the US mail, the incident must be handled by HazMat specialists. Patients who come into direct contact with the agent need to be decontaminated before you make any contact with them or initiate treatment.

Viruses

Viruses are germs that require a living host to multiply and survive. A virus is a simple organism and cannot thrive outside of a host (living body). Once in the body, the virus invades healthy cells and replicates itself to spread through the host. As the virus spreads, so does the disease that it carries. Viruses spread from host to host by direct methods, such as through respiratory droplets, or through vectors. A *vector* is any agent that acts as a carrier or transporter.

Table 40-3 Chemical Agents						
Name	**Military Designations**	**Odor**	**Lethality**	**Onset of Symptoms**	**Volatility**	**Primary Route of Exposure**
Nerve agents	Tabun (GA) Sarin (GB) Soman (GD) VX	Fruity or none	Highly lethal chemical agents; kill within minutes; effects are reversible with antidotes	Immediate	Moderate (GA, GD) Very high (GB) Low (VX)	GA—both GB—vapor hazard GD—both VX—contact hazard
Vesicants	Mustard (H) Lewisite (L) Phosgene oxime (CX)	Garlic (H) Geranium (L)	Cause large blisters to form; inhalation severely damages upper airway; severe, intense pain and grayish skin discoloration (L and CX)	Delayed (H) Immediate (L, CX)	Very low (H, L) Moderate (CX)	Primarily contact, with some vapor hazard
Pulmonary agents	Chlorine (Cl) Phosgene (CG)	Bleach Cut grass (CG)	Cause irritation choking (Cl); severe pulmonary edema (CG)	Immediate (Cl) Delayed (CG)	Very high	Vapor hazard
Cyanide agents	Hydrogen cyanide (AC) Cyanogen chloride (CK)	Almonds (AC) Irritating (CK)	Highly lethal chemical gases; kill within minutes; effects are reversible with antidotes	Immediate	Very high	Vapor hazard

Viral agents that may be used during a biologic terrorist release pose an extraordinary problem for health care providers, especially those in EMS. Although some viral agents do have vaccines, there is no treatment of a viral infection other than antiviral medications for some agents. Because of this characteristic, the following viruses have the potential to be used as terrorism agents.

Smallpox

Smallpox is a highly contagious disease. Use all forms of standard precautions to prevent cross-contamination. Simply by wearing examination gloves, a HEPA-filtered respirator, and eye protection, you will greatly reduce your risk of contamination. The last natural case of smallpox in the world was seen in 1977. Before the rash and blisters show, the illness will start with a high fever and body aches and headaches. The patient's temperature is usually in the range of 101°F to 104°F (38.3°C to 40°C).

An easy, quick way to differentiate the smallpox rash from other skin disorders is to observe the size, shape, and location of the lesions. In smallpox, all the lesions are identical in their development. In other skin disorders, the lesions will be in various stages of healing and development. Smallpox blisters begin on the face and extremities and eventually move toward the chest and abdomen. The disease is in its most contagious phase when the blisters begin to form Figure 40-11. Unprotected contact with these blisters will promote transmission of the disease Table 40-4. There is a vaccine to prevent smallpox; however, it has been linked to medical complications and, in rare cases, death. Should an outbreak occur, the US government has enough vaccine to vaccinate every person in the United States.

Figure 40-11 In smallpox, all the lesions are identical in their development. In other skin disorders, the lesions will be in various stages of healing and development.

Courtesy of CDC.

Viral Hemorrhagic Fevers

Viral hemorrhagic fevers (VHF) consist of a group of diseases caused by viruses that include the Ebola, Rift Valley, Marburg, and yellow fever viruses, among others. This group of viruses causes the blood in the body to seep out from the tissues and blood vessels **Figure 40-12**. Initially, the patient will have flulike symptoms, progressing to more serious symptoms such as internal and external hemorrhaging. Outbreaks are not uncommon in Africa and South America; however, outbreaks in the United States are extremely rare. Use all standard precautions when treating these illnesses. Mortality rates can range from 5% to 90%, depending on the strain of virus, the victim's age and health condition, and the availability of a modern health care system **Table 40-5**.

Figure 40-12 Viral hemorrhagic fevers cause the blood vessels and tissues to seep blood. The end result is ecchymosis, bloody sputum, and blood In the patient's stool. Notice the severe discoloration in this patient with Crimean Congo hemorrhagic fever, indicating internal bleeding.

Courtesy of Professor Robert Swanepoel/National Institute for Communicable Disease, South Africa.

Table 40-4 Characteristics of Smallpox

Dissemination	Aerosolized for warfare or terrorist uses
Communicability	High from infected patients or contaminated items (such as blankets); person-to-person transmission possible
Route of entry	Inhalation of coughed droplets or direct skin contact with blisters
Signs and symptoms	Severe fever, malaise, body aches, headaches, small blisters on the skin, bleeding of the skin and mucous membranes; incubation period 10 to 12 days; duration of the illness, approximately 4 weeks
Medical management	Standard precautions; no specific treatment; provide supportive care (ABCs)

Bacteria

Unlike viruses, bacteria do not require a host to multiply and live. These single-celled microorganisms reproduce rapidly and are much more complex and larger than viruses. They can grow up to 100 times larger than the largest virus. Bacteria contain all the cellular structures of a normal cell and are completely self-sufficient. Most bacterial infections can be treated with antibiotics.

Most bacterial infections will generally begin with flulike symptoms, which can make it quite difficult for health care providers to identify whether the cause is a biologic attack or a natural epidemic.

Words of Wisdom

Because humans are acceptable hosts and vectors for many viruses and bacteria, use standard precautions at all times. If you fail to use standard precautions, you may not only become a host for a virus, but you may spread it as well. Remember, a virus spreads from person to person to survive, and many infectious diseases present like common colds.

Inhalation and Cutaneous Anthrax (*Bacillus anthracis*)

Anthrax is caused by deadly bacteria that lay dormant in a spore (protective shell). When exposed to the optimal temperature and moisture, the germ will be released from the spore. The routes of entry for anthrax bacteria are inhalation, cutaneous, and gastrointestinal (from consuming food that contains spores) **Figure 40-13**. The inhalational form, or pulmonary anthrax, is the most deadly and often presents as a severe cold. Pulmonary anthrax is associated with a 90% death rate if untreated. Antibiotics can be used to treat anthrax successfully. There is also a vaccine to prevent anthrax infections **Table 40-6**.

Plague (Bubonic/Pneumonic)

The 14th century plague that ravaged Asia, the Middle East, and finally Europe (the Black Death) killed an estimated 33 to 42 million people. Later on, in the early 19th century, almost 20 million people in India and China died due to plague. The plague's natural vectors are infected rodents and fleas. When a person is bitten by an infected flea or comes into contact with an infected rodent (or the waste of the rodent), the person can contract bubonic plague.

Figure 40-13 Cutaneous anthrax.

Courtesy of James H. Steele/CDC.

Table 40-5 Characteristics of Viral Hemorrhagic Fevers

Dissemination	Direct contact with infected body fluids; can be aerosolized for use in an attack
Communicability	Moderate from person to person or contaminated items
Route of entry	Direct contact with infected body fluids
Signs and symptoms	Sudden onset of fever, weakness, muscle pain, headache, and sore throat; all followed by vomiting and, as the virus runs its course, internal and external bleeding
Medical management	Standard precautions; no specific treatment; provide supportive care (ABCs) and treat for shock and hypotension, if present

Table 40-6 Characteristics of Anthrax

Dissemination	Aerosol
Communicability	Only in the cutaneous form (rare)
Route of entry	Inhalation of spore, skin contact with spore, or direct contact with skin wound (cutaneous)
Signs and symptoms	Flulike symptoms, fever, respiratory distress with tachycardia, shock, pulmonary edema, and respiratory failure after 3 to 5 days of flulike symptoms
Medical management	Inhalation: Standard precautions, oxygen, ventilatory support if in pulmonary edema or respiratory failure, and transport Cutaneous: Standard precautions, apply dry sterile dressing to prevent accidental contact with wound and fluids

Bubonic plague infects the **lymphatic system** (a passive circulatory system in the body that bathes the tissues in lymph and works with the immune system). When this occurs, the patient's **lymph nodes** (area of the lymphatic system where infection-fighting cells are housed) become infected and grow. The glands of the nodes will grow large (up to the size of a tennis ball) and round, forming **buboes** Figure 40-14. If left untreated, the infection may spread through the body, leading to sepsis and possibly death. This form of plague is not contagious and is not likely to be seen in a bioterrorist incident.

Pneumonic plague is a lung infection, also known as plague pneumonia, that results from inhalation of plague bacteria. This form of the disease is contagious and has a much higher death rate than the bubonic form Table 40-7.

Figure 40-14 **A.** Plague buboe at lymph node under arm. **B.** Plague buboe at lymph node on neck.

A, B: Courtesy of CDC.

Neurotoxins

Neurotoxins are the most deadly substances known to humans. The strongest neurotoxin is 15,000 times more lethal than VX and 100,000 times more lethal than sarin. These toxins are produced from plants, marine animals, molds, and bacteria. The route of entry for these toxins is through ingestion, inhalation from aerosols, or injection. Unlike viruses and bacteria, neurotoxins are not contagious and the onset of symptoms is faster. Although these biologic toxins have immense destructive potential, they have not been used successfully as a WMD.

Botulinum Toxin

The most potent neurotoxin is botulinum, which is produced by bacteria. When introduced into the body, this neurotoxin affects the nervous system's ability to function. Voluntary muscle control diminishes as the toxin spreads. Eventually the toxin causes muscle paralysis that begins at the head and face and spreads downward throughout the body. The patient's accessory muscles and diaphragm will become paralyzed, and the patient will go into respiratory arrest Table 40-8.

Table 40-7	Characteristics of Plague
Dissemination	Aerosol
Communicability	Bubonic: low, only from contact with fluid in buboes Pneumonic: high, from person to person
Route of entry	Ingestion, inhalation, or cutaneous
Signs and symptoms	Fever, headache, muscle pain and tenderness, pneumonia, shortness of breath, extreme lymph node pain and enlargement (bubonic)
Medical management	Standard precautions, provide supportive care (ABCs), oxygen if indicated, and transport

Ricin

While not as deadly as botulinum, **ricin** is still five times more lethal than VX. This toxin is derived from mash that is left from the castor bean **Figure 40-15**. When introduced into the body, ricin causes pulmonary edema and respiratory and circulatory failure leading to death **Table 40-9**.

The clinical picture depends on the route of exposure. The toxin is quite stable and extremely toxic by many routes of exposure, including inhalation. It is likely that 1 to 3 mg of ricin can kill an adult, and the ingestion of one seed can most likely kill a child.

Although all parts of the castor bean are actually poisonous, it is the seeds that are the most toxic. Castor bean ingestion causes a rapid onset of nausea, vomiting, abdominal cramps, and severe diarrhea, followed by vascular collapse. Death usually occurs on the third day in the absence of appropriate medical intervention.

Table 40-8 Characteristics of Botulinum Toxin

Dissemination	Aerosol or food supply sabotage or injection
Communicability	None
Route of entry	Ingestion, inhalation
Signs and symptoms	Dry mouth, intestinal obstruction, urinary retention, constipation, nausea and vomiting, abnormal pupil dilation, blurred vision, double vision, drooping eyelids, difficulty swallowing, difficulty speaking, and respiratory failure as the result of paralysis
Medical management	Provide supportive care (ABCs), oxygen, and transport; provide ventilatory support in case of paralysis of the respiratory muscles; vaccine available

Ricin is least toxic by the oral route. This is probably a result of poor absorption in the gastrointestinal tract, some digestion in the gut, and, possibly, some expulsion of the agent as caused by the rapid onset of vomiting. Ingestion causes local hemorrhage and necrosis of the liver, spleen, kidneys, and gastrointestinal tract. Signs and symptoms appear 4 to 8 hours after exposure.

YOU are the Provider — PART 4

On arriving at the scene, you are directed to the patients by the staging officer. They have been properly decontaminated and placed on a large tarp in a safe location. Patient No. 1 is conscious but disoriented; the front of her shirt is covered with blood and she is in obvious respiratory distress. Patient No. 2 is conscious and alert but is also experiencing respiratory distress; he has numerous lacerations and abrasions on his face. Patient No. 3 is conscious, alert, and ambulatory; he is holding his left arm against his body. Patient No. 4 is unconscious, breathing rapidly, and has burns to her face and neck.

7. On the basis of the number of patients and their apparent conditions, how many ambulances and EMTs should be present at the scene?

Signs and symptoms of ricin ingestion are as follows:

- Fever
- Chills
- Headache
- Muscle aches
- Nausea
- Vomiting
- Diarrhea
- Severe abdominal cramping
- Dehydration
- Gastrointestinal bleeding
- Necrosis of the liver, spleen, kidneys, and gastrointestinal tract

Figure 40-15

These seemingly harmless castor beans contain the key ingredient for ricin, one of the most potent toxins known to humans.

Courtesy of Brian Prechtel/USDA.

Inhaling ricin will cause nonspecific weakness, cough, fever, hypothermia, and hypotension. Symptoms occur about 4 to 8 hours after inhalation, depending on the inhaled dose. The onset of profuse sweating some hours later signifies the termination of the symptoms.

Signs and symptoms of ricin inhalation are as follows:

- Fever
- Chills
- Nausea
- Local irritation of eyes, nose, and throat
- Profuse sweating
- Headache
- Muscle aches
- Nonproductive cough
- Chest pain
- Dyspnea
- Pulmonary edema
- Severe lung inflammation
- Cyanosis
- Seizures
- Respiratory failure

Treat with both respiratory support and cardiovascular support as needed. Early intubation and ventilation, combined with treatment of pulmonary edema, are appropriate. Intravenous fluids and electrolyte replacement are useful to treat the dehydration caused by profound vomiting and diarrhea.

Table 40-10 summarizes the biologic agents.

Words of Wisdom

In a mass-casualty incident, it is important to frequently communicate with your patient. Remember, your patient is probably scared and does not know what is going on. Explain to your patient any delays that are occurring, as well as the actions you are taking, so you may alleviate the patient's fears.

Table 40-9 Characteristics of Ricin

Dissemination	Released into indoor or outdoor air (aerosol) Food and water contamination
Communicability	None
Route of exposure	Inhalation, ingestion, injection
Signs and symptoms	Inhaled: cough, difficulty breathing, tightness in chest, nausea, muscle aches, pulmonary edema, and hypoxia Ingested: nausea and vomiting, internal bleeding, and death Injection: no signs except swelling at the injection site and death
Medical management	Provide supportive care (ABCs); no treatment or vaccine available

Table 40-10 Biologic Agents

Disease	Transmission Person to Person	Incubation Period	Duration of Illness	Lethality (approximate case fatality rates)
Inhalation anthrax	No	1 to 6 d	3 to 5 d (usually fatal if untreated)	High
Pneumonic plague	High	2 to 3 d	1 to 6 d (usually fatal)	High unless treated within 12 to 24 h
Smallpox	High	7 to 17 d (average, 12 d)	4 wk	High to moderate
Viral hemorrhagic fevers	Moderate	4 to 21 d	Death within 7 to 16 d	High to moderate, depending on type of fever
Botulinum poisoning	No	1 to 5 d	Death within 24 to 72 h; lasts months if patient does not die	High without respiratory support
Ricin poisoning	No	18 to 24 h	Death within 10 to 12 d for ingestion	High

Other EMT Roles During a Biologic Event

Syndromic Surveillance

Syndromic surveillance is the monitoring, usually by local or state health departments, of patients presenting to emergency departments and alternative care facilities, the recording of EMS call volume, and the use of over-the-counter medications. Patients with signs and symptoms that resemble influenza are particularly important. Local and state health departments monitor for an unusual influx of patients with these symptoms in hopes of discovering an outbreak early. The role of EMS in syndromic surveillance is valuable in the overall tracking of a biologic terrorist event or infectious disease outbreak. Quality assurance and dispatch operations need to be aware of an unusual number of calls from patients with unexplainable symptom clusters coming from a particular region or community.

Points of Distribution (Strategic National Stockpile)

Points of distribution (PODs) are existing facilities that are used as mass distribution sites for antibiotics, antidotes, vaccinations, and other medications and supplies during an emergency.

Figure 40-16 The Centers for Disease Control and Prevention Strategic National Stockpile can deliver one of many push packs to any location in the country within 12 hours of an emergency.

Courtesy of the Strategic National Stockpile/CDC.

These medications may be released in deliveries called “push packs” by the Centers for Disease Control and Prevention (CDC) Strategic National Stockpile **Figure 40-16**. These push packages have a delivery time of 12 hours anywhere in the country and contain antibiotics, chemical antidotes, antitoxins, life-support medications, intravenous administration supplies, airway maintenance supplies, and medical/surgical items. In some regions, local and state municipalities have started to stockpile their own supplies to reduce the time delay.

EMTs, AEMTs, and paramedics may be called on to assist in the delivery of the medications to the public (depending on local emergency management planning). Your role may include triage, treatment of seriously ill patients, and patient transport to the hospital. Most plans for PODs include at least one ambulance on standby to transport seriously ill patients.

Radiologic/Nuclear Devices

What Is Radiation?

Ionizing radiation is energy that is emitted in the form of rays, or particles. This energy can be found in **radioactive material**, such as rocks and metals. Radioactive material is any material that emits radiation. This material is unstable, and it attempts to stabilize itself by changing its structure in a natural process called **decay**. As the substance decays, it gives off radiation, until it stabilizes. The process of radioactive decay can take from as little as minutes to billions of years; meanwhile, the substance remains radioactive.

The energy that is emitted from a strong radiologic source is **alpha**, **beta**, **gamma (x-ray)**, or **neutron radiation**. Alpha is the least harmful penetrating type of radiation and cannot penetrate through most objects. In fact, a sheet of paper or the body's skin can easily stop it. Beta radiation is slightly more penetrating than alpha and requires a layer of clothing to stop it. Gamma rays travel faster and have more energy than alpha and beta rays. These rays easily penetrate through the human body and require lead or several inches of concrete to prevent penetration. Neutron particles are among the most powerful forms of radiation. Neutrons easily penetrate through lead and require several feet of concrete to stop them **Figure 40-17**.

Sources of Radiologic Material

There are thousands of radioactive materials found on the earth. These materials are generally used for purposes that benefit humankind, such as medicine, killing germs in food (irradiating), and construction. Once radiologic material has been used for its purpose, the material remaining is called radiologic waste. Radiologic waste remains radioactive but has no more usefulness. These materials can be found at the following locations:

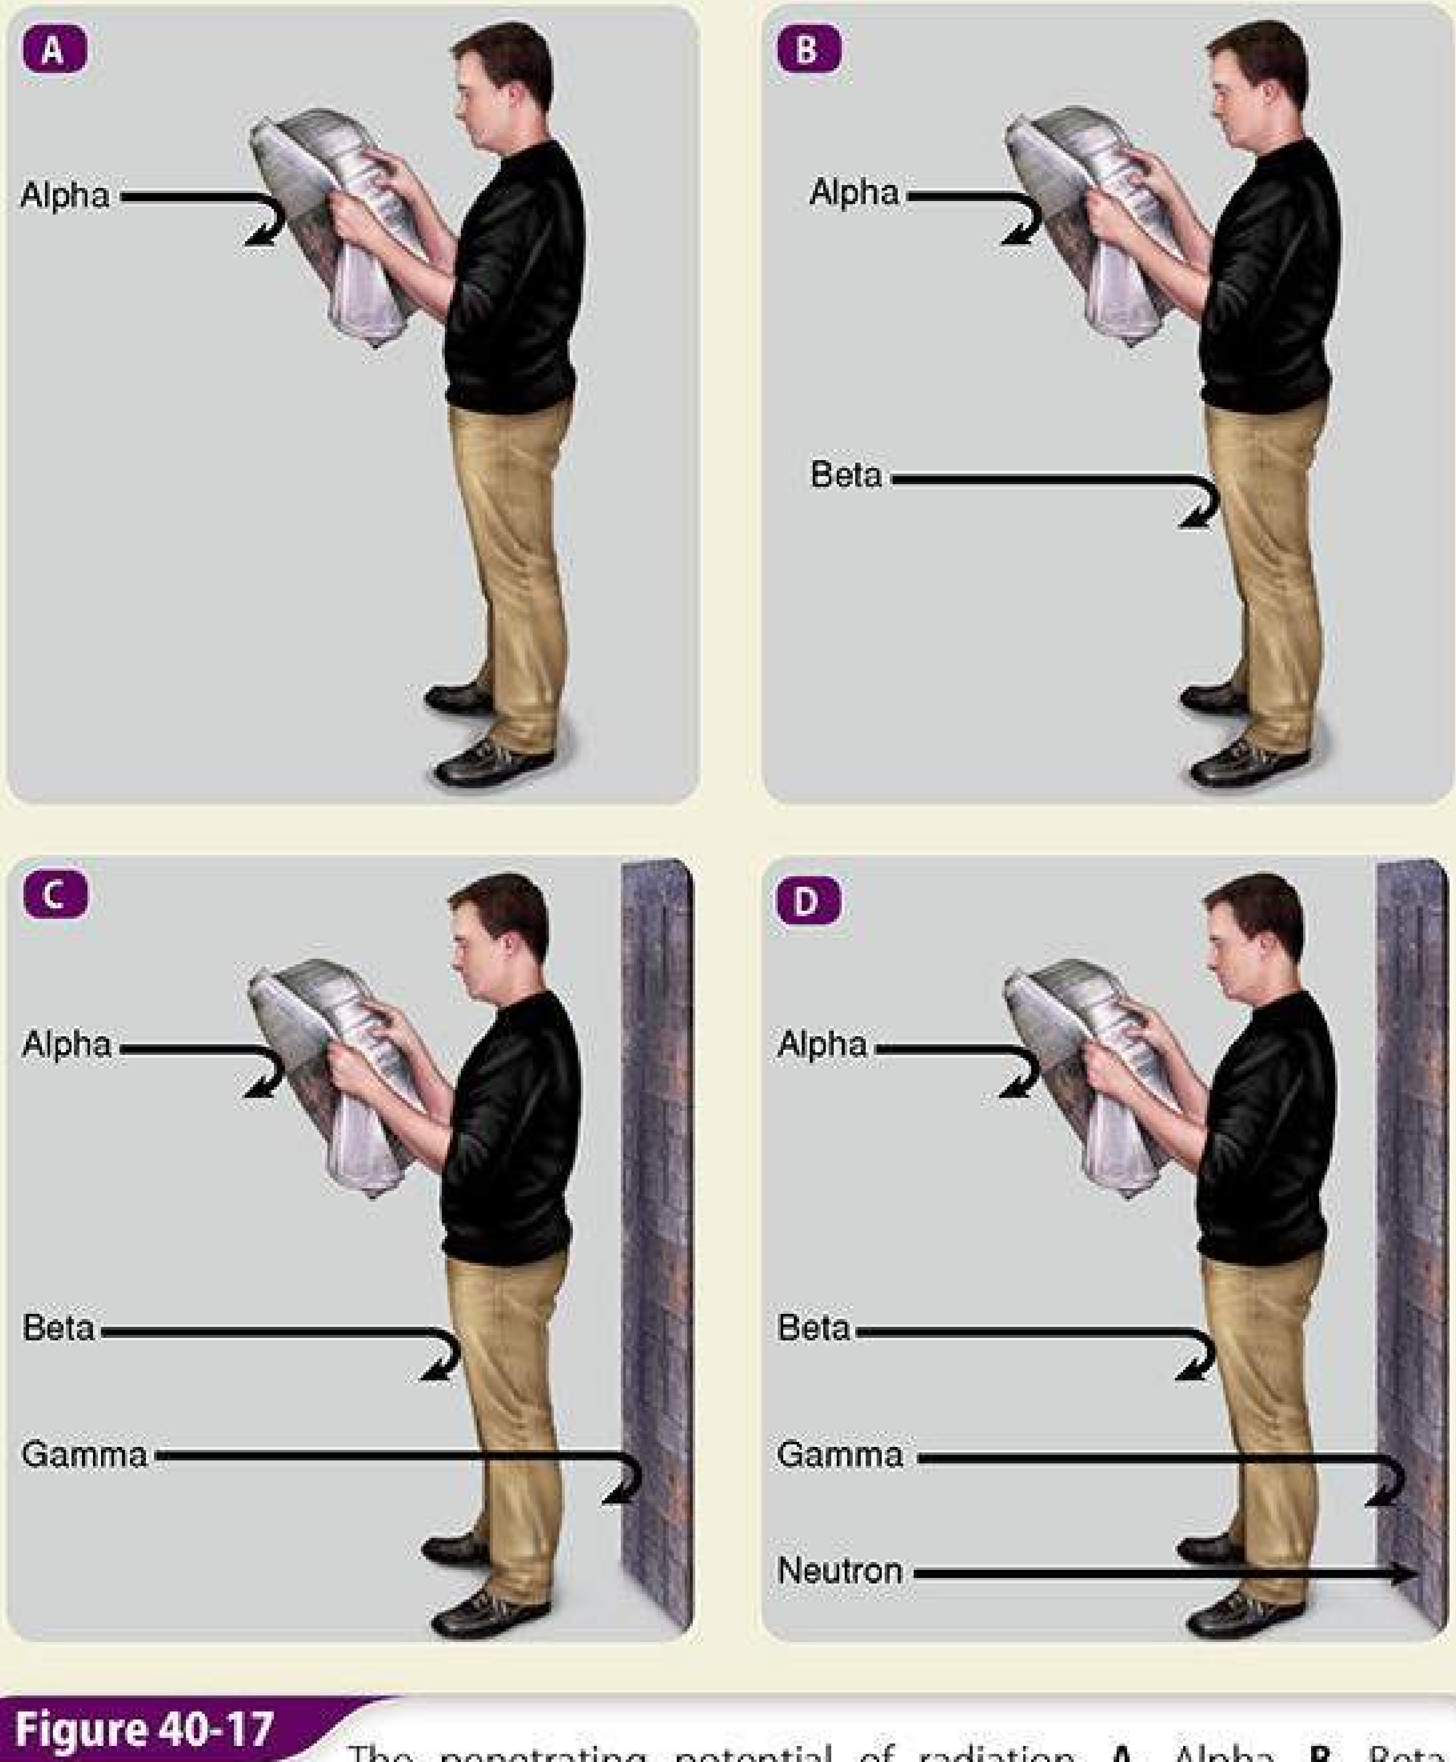

Figure 40-17 The penetrating potential of radiation. **A.** Alpha. **B.** Beta. **C.** Gamma. **D.** Neutron.

- Hospitals and other health care facilities with radiology departments

- Colleges and universities
- Nuclear power plants
- Chemical and industrial sites

Not all radioactive material is tightly guarded, and the waste is often not guarded at all. This makes radioactive material and substances appealing to terrorists.

Radiologic Dispersal Devices (RDD)

A **radiologic dispersal device (RDD)** is any container that is designed to disperse radioactive material. This would generally require the use of a bomb, hence the nickname "**dirty bomb**." A dirty bomb has the potential to cause injury not only as a result of the radioactive material, but also from the explosive material used to deliver it. Just the thought of an RDD creates fear in a population, and so the ultimate goal of some terrorists—fear—is accomplished. In reality, however, the destructive capability of a dirty bomb is limited to the explosives that are attached to it. Therefore, if the explosive is sufficient to kill 10 people without radioactive material, it will also kill 10 people with the radioactive material added. There may be long-term injuries and illness associated with the use of an RDD, yet not much more than the bomb by itself would create. In short, the dirty bomb is an ineffective WMD.

Nuclear Energy

Nuclear energy is artificially made by altering (splitting) radioactive atoms. The result is an immense amount of energy that usually takes the form of heat. Nuclear material is used in medicine, weapons, naval vessels, and power plants. Nuclear material gives off all forms of radiation, including neutrons (the most deadly type). Like radioactive material, when nuclear material is no longer useful it becomes waste that is still radioactive.

Nuclear Weapons

The destructive energy of a nuclear explosion is unlike any other weapon in the world. That is why nuclear weapons are kept in only secure facilities throughout the world. There are nations that have ties to terrorists and that have actively attempted to build nuclear weapons. However, as yet, these nations do not have the ability to deliver a nuclear weapon, such as a missile or bomb.

There is also the deterrent of complete mutual annihilation. Therefore, the likelihood of a nuclear attack is extremely remote.

Unfortunately, however, since the collapse of the former Soviet Union, the whereabouts of many small nuclear devices is unknown. These small suitcase-sized nuclear weapons are called **Special Atomic Demolition Munitions (SADM)**. The SADM, or "suitcase nuke," was designed to destroy individual targets, such as important buildings, bridges, tunnels, and large ships. Some of these are believed to be missing. Information or updates on the whereabouts of these devices have not been made public.

Symptomatology

Patients exposed to a known or suspected source of excessive radiation are considered victims of acute radiation toxicity. The effects of radiation exposure will vary depending on the amount of radiation received and the route of entry. Radiation can be introduced into the body by all routes of entry as well as through the body (irradiation). Patients can inhale radioactive dust from nuclear fallout or from a dirty bomb or have radioactive liquid absorbed into their body through their skin. Once inside the body, the radiation source will irradiate the person from within rather than from an external source (such as x-ray equipment). Some common signs of acute radiation sickness are listed in Table 40-11. Additional injuries will occur with a nuclear blast such as thermal and blast trauma, trauma from flying objects, and eye injuries.

Table 40-11	Common Signs of Acute Radiation Toxicity
Low exposure	Nausea, vomiting, diarrhea, dizziness, headache
Moderate exposure	First-degree burns, hair loss, compromised immune system (death of white blood cells), and cancer
Severe exposure	Second- and third-degree burns, cancer, and death

Medical Management

Being exposed to a radiation source does not make a patient contaminated or radioactive. However, when patients have a radioactive source on their bodies (such as debris from a dirty bomb), they are contaminated and must be initially cared for by a HazMat responder. Once the patient is decontaminated and there is no threat to you, you may begin treating the ABCs and treat the patient for any burns or trauma. As always, wear appropriate PPE. Secure in plastic bags any body fluids obtained from the patient. Place all body fluids in containers and properly disposed of them with other potentially radioactive waste.

Protective Measure

There are no suits or protective gear designed to completely shield you from radiation. The people who work in high-risk areas wear specific protection like lead-lined suits; however, this equipment is not available to EMTs. The best ways to protect yourself from the effects of radiation are to use time and distance and shield yourself using buildings and walls for protection. Do not enter a HazMat area unless you are trained as a HazMat responder and have proper training in the use of self-contained breathing apparatus.

- **Time.** Radiation has a cumulative effect on the body. The less time that you are exposed to the source, the less the effects will be. If you realize the patient is near a radiation source, leave the area immediately.
- **Distance.** Radiation is limited as to how far it can travel. Depending on the type of radiation, moving only a few feet is often enough to remove you from immediate danger. Alpha radiation cannot travel more than a few inches but gamma rays can travel hundreds or thousands of meters. Take this into account when responding to a nuclear or radiologic incident and make certain that responders are stationed far enough away from the incident.
- **Shielding.** Remember, the path of all radiation can be stopped by a specific object. It will be impossible for you to recognize the type of radiation being emitted or even from which direction it is coming. Therefore, always assume you are dealing with the strongest form of radiation and use concrete shielding (such as buildings or walls) between yourself and the incident. The importance of shielding cannot be overemphasized.

Incendiary and Explosive Devices

Incendiary and explosive devices come in various shapes and sizes. Incendiary devices are weapons used to start fires. Terrorists use flamethrowers, chemicals, Molotov cocktails, or other explosive devices for this purpose. Although you are not required to recognize all of the possible types of explosive devices, including improvised explosive devices (IED), it is important for you to be able to identify an object you believe is a potential device, notify the proper authorities, and safely evacuate the area. Always remember that there is the possibility of a secondary device when you are responding to the scene of an incendiary or explosive device call.

Mechanisms of Injury

The type and severity of wounds sustained from incendiary and explosive devices primarily depend on the patient's distance from the epicenter of the explosion. Patients close to the epicenter of the explosion are likely to suffer from all wound-causing agents of the munitions. Patients who are farther away from the epicenter are likely to experience a combination of blast injuries from the explosion and penetrating trauma injuries from primary and secondary projectiles created by the explosion.

YOU are the Provider **PART 5**

The patients have been triaged and appropriately treated. After the transportation officer notifies the receiving facilities about the patients' injuries and their exposure to radiation, they are transported. After decontaminating yourselves and the ambulance, you and your crew discuss the incident, including terrorism in general.

8. What type of terrorist group was most likely responsible for this incident?
9. What level of knowledge of terrorism and weapons of mass destruction should you possess?

Blast injuries occur in a number of ways.

- **Primary blast injury**. Due solely to the direct effects of the pressure wave on the body. The injury from the primary blast is seen almost exclusively in the hollow organs of the body—the lungs, intestines, and inner ears. An injury to the lungs causes the greatest morbidity and mortality.
- **Secondary blast injury**. Penetrating or non-penetrating injury that results from being struck by flying debris, such as ordnance projectiles or secondary missiles, that has been set in motion by the explosion. Objects are propelled by the force of the blast and strike the victim, causing injury.
- **Tertiary blast injury**. Results from whole-body displacement and subsequent traumatic impact with environmental objects (eg, trees, buildings, and vehicles). Other indirect effects include crush injury from the collapse of structures (buildings, bunkers, or tunnels).
- **Quaternary blast injury**. Any other injury caused by a blast occurs in this way. This includes toxic inhalation of combustion gases, burns, a medical emergency (like a myocardial infarction) sustained while fleeing the scene of an explosion, and even a mental health disorder that develops immediately after or days to weeks after detonation of an explosive device.

The Physics of an Explosion

When a substance is detonated, a solid or liquid is chemically converted into large volumes of gas under high pressure with resultant explosive energy release. Propellants, like gunpowder, are explosives designed to release energy relatively slowly compared with high-energy explosives, which are designed to detonate very quickly. This generates a pressure pulse in the shape of a spherical blast wave that expands in all directions from the point of explosion. Flying debris and high winds commonly cause conventional blunt and penetrating trauma.

Tissues at Risk

Hollow organs such as the middle ear, lungs, and gastrointestinal tract are most susceptible to pressure changes. The junction between tissues of different densities and exposed tissues such as the head and neck are prone to injury as well. The ear is the organ system most sensitive to blast injuries. The patient may report ringing or pain in the ears or some loss of hearing, and blood may be visible in the ear canal. Permanent hearing loss is possible.

Primary **pulmonary blast injuries** occur as contusions and hemorrhages. When the explosion occurs in an open space, the patient's side that is toward the explosion is usually injured, but the injury can be bilateral when the patient is located in a confined space. The patient may report tightness or pain in the chest and may cough up blood and have tachypnea or other signs of respiratory distress. Subcutaneous emphysema (crackling under the skin) over the chest may be palpated, indicating the presence of a pneumothorax. Pneumothorax is common and may require emergency decompression.

Solid organs are relatively protected from shockwave injury but may be injured by secondary missiles or a hurled body. Hollow organs, however, may be injured by similar mechanisms as lung tissue. Petechiae, or pinpoint hemorrhages that show up on the skin, to large hematomas are the most visible sign.

According to the CDC, blast lung is the most common cause of death from blast injury. Neurologic injuries and head trauma are also common causes of fatality from blast injury. Subarachnoid (beneath the arachnoid layer covering the brain) and subdural (beneath the outermost covering of the brain) hematomas are often seen. Permanent or transient neurologic deficits may be secondary to concussion, intracerebral bleeding, or air embolism. Instant but transient unconsciousness, with or without retrograde amnesia, may be initiated not only by head trauma, but also by cardiovascular problems. Bradycardia and hypotension are common after an intense pressure wave from an explosion.

Extremity injuries, including traumatic amputations, are common and patients may die of massive hemorrhage without the rapid application of a tourniquet.

YOU are the Provider — SUMMARY

1. On the basis of the dispatch information, how should you approach this incident?

The fact that a vehicle has crashed into an abortion clinic and exploded should raise your index of suspicion that this incident is the result of terrorism because, in most cases, vehicles rarely “explode” when they crash into something. In this incident, the explosion could have been meant to disperse a weaponized chemical. If you suspect a terrorist event has occurred, there are certain actions you need to take. When responding to the scene, take a route that is uphill and upwind from the incident scene if feasible, keeping in mind that wind direction and speed can change very quickly. Do not enter the scene where the incident has occurred; stage your ambulance in a safe location and wait for further information from law enforcement or the incident commander. If the incident command system (ICS) has not already been established, establish command and ensure adequate resources are dispatched including those with the capacity to assess and manage potential safety threats.

2. What indicators suggest that an incident is the result of terrorism?

Information from dispatch, such as the location and type of incident, the number of patients, and victims’ statements may be the first indicators that an incident is the result of terrorism. For example, is the incident location a monument, government building, or a specific structure such as a temple, church, or abortion clinic? Are there multiple patients with similar symptoms, such as difficulty breathing? Are victims fleeing the scene making statements, such as “Everyone is passing out,” or “There was a loud explosion.”

3. On the basis of the HazMat team’s findings, what has most likely occurred?

The presence of radiation in the area following an explosion indicates that a radiologic dispersal device (RDD) was used. The destructive power of an RDD is limited to the explosive that is attached to it; a bomb that is powerful enough to kill 10 people without radioactive material will also kill 10 people when the radioactive material is added. Injury and death caused by an RDD are the result of the explosive pressure wave and blunt and penetrating trauma—just like any other explosion. The addition of radiation, although not likely to cause immediate health problems, could result in people experiencing long-term injury or illness depending on the type and amount of radiation involved, the means of exposure (eg, absorption, inhalation, or ingestion), and the length of exposure.

4. What should be done first to ensure the scene is safe for you and other EMS personnel to enter?

The HazMat team has identified radiation in the area of the incident; however, you have not received information regarding what has been done to make the scene safe for you to enter. Therefore, *do not* enter the scene until you have been given specific instructions by the HazMat team! Exposure to a radiation source does not make a patient contaminated or radioactive; however, if the patient has a radioactive source on his or her body, such as debris from a dirty bomb, the patient is contaminated and must be initially decontaminated by HazMat personnel. Once the patients have been properly decontaminated and moved to a safe area, you will be allowed to begin the processes of assessment and treatment.

5. Given the situation, what are some unique concerns about this incident?

In the past, terrorists have been known to plant additional explosives (secondary devices) that were set to detonate after the initial device. Secondary devices are primarily intended to injure emergency responders and secure media coverage. These devices may not be in the same location as the primary device. The secondary device could be a package or briefcase that has been planted across the street or it could be an electronic device, such as a cell phone, that is designed to detonate when activated.

Although the HazMat team has secured the scene initially, you must realize that the scene can easily become unsafe. Do not rely on others to keep you safe; it is *your* responsibility to constantly reassess the scene for indicators of danger. A subtle change in wind direction during an incident involving radiation or an increase in the number of patients who are contaminated can place you in danger.

6. What types of injuries should you expect to encounter?

Although the victims may experience the effects of radiation exposure (eg, skin burns), depending on the amount of radiation exposure, their most immediately life-threatening injuries will be the result of the explosion itself.

The severity of the injuries during an explosion depends primarily on the location of the victims relative to the epicenter of the blast; the closer they are to the explosion, the more severe their injuries will be. Injuries resulting from explosions may range from severe burns, blunt and penetrating trauma, crush injuries, and inhalation injury. It is important to note that life-threatening injuries can occur to victims who are outside of the blast epicenter. For example, a person standing some distance from the explosion can easily sustain a penetrating injury to the chest, head, or abdomen when he or she is struck by flying debris.

7. On the basis of the number of patients and their apparent conditions, how many ambulances and EMTs should be present at the scene?

Your general impression of the scene has revealed that there are four patients—one of whom appears to be unconscious. Even though the other three patients are conscious, this does not mean that they do not have life-threatening injuries.

Assume all four patients have critical injuries until they have been triaged. One ambulance and two EMTs can effectively care for only one critically injured patient at a time. Therefore, there should be a total of four ambulances and eight EMTs at the scene—two EMTs and one ambulance per patient.

8. What type of terrorist group was most likely responsible for this incident?

In this incident, a single actor crashed his vehicle into an abortion clinic and detonated a dirty bomb in the process. This behavior suggests a single-issue terrorist who felt strongly enough about his cause to destroy a clinic, release radiation to induce further injury, and take his own life in the process.

Abortion has been a topic of great debate for many years, and terrorism has been used by antiabortion groups in the past. Several abortion clinics were bombed in Atlanta; other attacks have occurred when a gunman opened fire on clinic employees.

9. What level of knowledge of terrorism and weapons of mass destruction should you possess?

You are not expected to be an expert in terrorism and weapons of mass destruction (WMDs). However, you are expected to be aware of the various types of threats—just like any other citizen—and recognize certain indicators of terrorism when responding to an incident. As an EMT, you should possess a basic working knowledge of the different types of WMDs that terrorists could use; signs and symptoms and treatment of victims of WMDs; measures to take to ensure personal safety and safety of the patient; and knowledge of the ICS.

Prep Kit

Ready for Review

- As a result of the increase in terrorist activity, it is possible that you, as an EMT could witness a terrorist event. You must be mentally and physically prepared for the possibility of a terrorist event.
- Types of groups that tend to use terrorism include religious extremist groups/doomsday cults, extremist political groups, cyber terrorists, and single-issue groups.
- A weapon of mass destruction (WMD) is any agent designed to bring about mass death, casualties, and/or massive damage to property and infrastructure (bridges, tunnels, airports, and seaports). These can be biologic, nuclear, incendiary, chemical, and explosive weapons (B-NICE).

- Indicators that may give you clues as to whether the emergency is the result of a terrorist attack include the type of location, type of call, number of patients, victims' statements, and preincident indicators.
- If you suspect that a terrorist or an event involving a WMD has occurred, ensure that the scene is safe. If you have any doubt that it may not be safe, do not enter. Wait for assistance.
- Terrorists may set secondary devices that are designed to explode after the initial bomb, thus injuring responders and media coverage. Constantly assess and reassess the scene for safety.
- Chemical agents are manufactured liquid, gas, or solid substances that can have devastating effects on living organisms.
- Persistency and volatility describe how long the agent will stay on the surface before it evaporates, and the route of exposure is how the agent most effectively enters the body.
- Biologic agents are organisms that cause disease.
- Biologic agents include viruses such as smallpox and those that cause viral hemorrhagic fevers; bacteria such as those that cause anthrax and plague; and neurotoxins such as botulinum toxin and ricin.
- Nuclear or radiologic weapons produced from radioactive waste material can create a massive amount of destruction.
- Ionizing radiation is energy that can enter the human body and cause damage.
- Explosive and incendiary devices come in various shapes and sizes. It is important to be able to identify an object you believe is a potential device and notify the proper authorities, while safely evacuating the area.

Vital Vocabulary

aging The process by which the temporary bond between the organophosphate and acetylcholinesterase undergoes hydrolysis, resulting in a permanent covalent bond.

alpha A type of energy that is emitted from a strong radiologic source; it is the least harmful penetrating type of radiation and cannot travel more than a few inches or penetrate most objects.

anthrax A disease caused by deadly bacteria *(Bacillus anthracis)* that lay dormant in a spore (protective shell); the germ is released from the spore when exposed to the optimal temperature and moisture. The routes of entry are inhalation, cutaneous, and gastrointestinal (from consuming food that contains spores).

Antidote Treatment Nerve Agent Auto-Injector (ATNAA) A nerve agent antidote kit containing atropine and pralidoxime chloride; delivered as a single dose through one needle.

bacteria Microorganisms that reproduce by binary fission. These single-cell creatures reproduce rapidly. Some can form spores (encysted variants) when environmental conditions are harsh.

beta A type of energy that is emitted from a strong radiologic source; is slightly more penetrating than alpha and requires a layer of clothing to stop it.

B-NICE A memory device to recall the types of weapons of mass destruction: biologic, nuclear, incendiary, chemical, and explosive.

botulinum Produced by bacteria, this is the most potent neurotoxin known. When introduced into the body, this neurotoxin affects the nervous system's ability to function and causes botulism.

buboes Enlarged lymph nodes (up to the size of a tennis ball) that are characteristic in people infected with the bubonic plague.

bubonic plague Bacterial infection that effects the lymphatic system. It is transmitted by infected rodents and fleas and characterized by acute malaise, fever, and the formation of tender, enlarged, inflamed lymph nodes that appear as lesions, called buboes. Also called the Black Death.

chlorine (Cl) The first chemical agent ever used in warfare. It has a distinct odor of bleach and creates a green haze when released as a gas. Initially it produces upper airway irritation and a choking sensation.

contact hazard The term used to describe danger posed by a chemical whose primary route of entry into the body is through the skin; posed by a hazardous agent that gives off very little or no vapors; also called a skin hazard.

contagious An infectious disease that spreads from one human to another; communicable.

covert An act in which the public safety community generally has no prior knowledge of the time, location, or nature of the attack.

cross-contamination Occurs when a person is contaminated by an agent as a result of coming into contact with another contaminated person.

cyanide An agent that affects the body's ability to use oxygen. It is a colorless gas that has an odor similar to almonds. The effects begin on the cellular level and are very rapidly seen at the organ and system levels.

decay A natural process in which a material that is unstable attempts to stabilize itself by changing its structure.

dirty bomb Name given to an explosive radiologic dispersal device.

disease vector An animal that spreads a disease, once infected, to another animal.

dissemination The means by which a terrorist will spread an agent, for example, by poisoning the water supply or aerosolizing the agent into the air or ventilation system of a building.

domestic terrorism Terrorism that is carried out by people in their own country.

DuoDote Auto-Injector A nerve agent antidote kit containing atropine and pralidoxime chloride; delivered as a single dose through one needle.

G agents Early nerve agents that were developed by German scientists in the period after World War I and into World War II. There are three such agents: sarin, soman, and tabun.

gamma (x-ray) A type of energy that is emitted from a strong radiologic source that travels faster and has more energy than alpha and beta rays. These rays easily penetrate through the human body and require lead or several inches of concrete to prevent penetration.

incubation The period of time between a person being exposed to an agent to the first time when symptoms appear.

international terrorism Terrorism that is carried out by people in a country other than their own; also known as cross-border terrorism.

ionizing radiation Energy that is emitted in the form of rays, or particles.

LD_{50} The standard measure of the dose amount of an agent or substance that will kill 50% of a population who are exposed to this level.

lewisite (L) A blistering agent that has a rapid onset of symptoms and produces immediate, intense pain and discomfort on contact.

lymph nodes The area of the lymphatic system where infection-fighting cells are housed.

lymphatic system A passive circulatory system in the body that transports a plasmalike liquid called lymph, a thin fluid that bathes the tissues of the body.

miosis Excessively constricted pupil; often bilateral after exposure to nerve agents.

mutagen A substance that mutates, damages, and changes the structures of DNA in the body's cells.

nerve agents A class of chemical called organo-phosphates; they function by blocking an essential enzyme in the nervous system, which causes the body's organs to become overstimulated and burn out.

neurotoxins Biologic agents that are the most deadly substances known to humans; they include botulinum toxin and ricin.

neutron radiation The type of energy that is emitted from a strong radiologic source, involving particles that are among the most powerful forms of radiation; the particles easily penetrate through lead and require several feet of concrete to stop them.

off-gassing The release of an agent after exposure, for example from a person's clothes that have been exposed to the agent.

persistency Describes how long a chemical agent will stay on a surface before it evaporates.

phosgene A pulmonary agent that is a product of combustion, resulting from a fire at a textile factory or house or from metalwork or burning Freon. It is a very potent agent that has a delayed onset of symptoms, usually hours.

phosgene oxime (CX) A blistering agent that has a rapid onset of symptoms and produces immediate, intense pain and discomfort on contact.

pneumonic plague A lung infection, also known as plague pneumonia, that is the result of inhalation of plague-causing bacteria.

points of distribution (PODs) Existing facilities used as mass distribution sites for antibiotics, antidotes, vaccinations, and other medications and supplies during an emergency.

primary blast injury Injuries caused by an explosive pressure wave on the hollow organs of the body.

pulmonary blast injuries Pulmonary trauma resulting from short-range exposure to the detonation of high-energy explosives.

quaternary blast injury A blast injury that falls into one of the following categories: burns, crush injuries, toxic inhalation, medical emergencies, or mental health disorders.

radioactive material Any material that emits radiation.

radiologic dispersal device (RDD) Any container that is designed to disperse radioactive material.

ricin A neurotoxin derived from mash that is left from the castor bean; causes pulmonary edema and respiratory and circulatory failure leading to death.

route of exposure The manner by which a toxic substance enters the body.

sarin (GB) A nerve agent that is one of the G agents; a highly volatile colorless and odorless liquid that turns from liquid to gas within seconds to minutes at room temperature.

secondary blast injury A penetrating or nonpenetrating injury caused by ordnance projectiles or secondary missiles.

secondary device A secondary explosive used by terrorists, set to explode after the initial bomb.

smallpox A highly contagious disease; it is most contagious when blisters begin to form.

soman (GD) A nerve agent that is one of the G agents; twice as persistent as sarin and five times as lethal; it has a fruity odor, as a result of the type of alcohol used in the agent, and is a contact and an inhalation hazard that can enter the body through skin absorption and through the respiratory tract.

Special Atomic Demolition Munitions (SADM) Small suitcase-sized nuclear weapons that were designed to destroy individual targets, such as important buildings, bridges, tunnels, and large ships.

state-sponsored terrorism Terrorism that is funded and/or supported by nations that hold close ties with terrorist groups.

sulfur mustard (H) A vesicant; it is a brownish, yellowish oily substance that is generally considered very persistent; has the distinct smell of garlic or mustard and, when released, is quickly absorbed into the skin and/or mucous membranes and begins an irreversible process of damaging the cells. Also called mustard gas.

syndromic surveillance The monitoring, usually by local or state health departments, of patients presenting to emergency departments and alternative care facilities, the recording of EMS call volume, and the use of over-the-counter medications.

tabun (GA) A nerve agent that is one of the G agents; is 36 times more persistent than sarin and approximately half as lethal; has a fruity smell and is unique because the components used to manufacture the agent are easy to acquire and the agent is easy to manufacture.

tertiary blast injury An injury from whole-body displacement and subsequent traumatic impact with environmental objects.

V agent (VX) One of the G agents; it is a clear, oily agent that has no odor and looks like baby oil; more than 100 times more lethal than sarin and is extremely persistent.

vapor hazard The term used to describe danger posed by an agent that enters the body through the respiratory tract.

vesicants Blister agents; the primary route of entry for this agent is through the skin.

viral hemorrhagic fevers (VHF) A group of diseases caused by viruses that include the Ebola, Rift Valley, and yellow fevers, among others. This group of viruses causes the blood in the body to seep out from the tissues and blood vessels.

viruses Germs that require a living host to multiply and survive.

volatility How long a chemical agent will stay on a surface before it evaporates.

weapon of mass casualty (WMC) Any agent designed to bring about mass death, casualties, and/or massive damage to property and infrastructure (bridges, tunnels, airports, and seaports); also known as a weapon of mass destruction (WMD).

weapon of mass destruction (WMD) Any agent designed to bring about mass death, casualties, and/or massive damage to property and infrastructure (bridges, tunnels, airports, and seaports); also known as a weapon of mass casualty (WMC).

weaponization The creation of a weapon from a biologic agent generally found in nature and that causes disease; the agent is cultivated, synthesized, and/or mutated to maximize the target population’s exposure to the germ.

Assessment
in Action

You and your partner are dispatched to stand by for a suspected WMD incident in the federal courthouse. You are aware that a controversial trial is currently in session. This morning, a suspected IED exploded in the packed courtroom, resulting in multiple injuries. You are staged a few blocks away from the incident with police, fire, and other ambulances. The police bomb squad is assessing the scene to ensure it is safe to approach. When you are cleared to enter, the scene is chaotic. Many of the injured are now lying outside on the lawn in front of the courthouse. Police report that those closest to the IED were either critically injured or killed. Incident command is promptly established, and you are immediately assigned to the treatment site.

1. Staging for this suspected WMD incident should be:

   A. upwind and uphill from the incident.
   B. upwind and downhill from the incident.
   C. downwind and uphill from the incident.
   D. downwind and downhill from the incident.

2. Why is it important to follow the requests of the incident commander?

   A. The incident commander best understands incident needs.
   B. It is federal law to follow the ICS structure for patient care.
   C. The incident commander leads the fire department, not EMS.
   D. The incident commander represents a higher level of care.

3. A 35-year-old patient is holding his ear and moaning. What is your most serious concern for this patient?

   A. Ringing or pain in the ears

B. Possibility of associated pulmonary injury
C. Blood in the ear canal
D. Possibility of hearing loss

4. A 67-year-old patient reports tightness in his chest. The patient is coughing up blood and is in respiratory distress. During the physical assessment, you notice subcutaneous emphysema. What is the condition most likely to be?

   A. Exacerbation of asthma
   B. Myocardial infarction
   C. Pulmonary embolism
   D. Pulmonary blast injury

5. A 50-year-old patient is lying on the grass with petechiae (pinpoint hemorrhages on the skin). This patient may have:

   A. hollow organ injury.
   B. solid organ injury.
   C. neurologic injury.
   D. psychologic injury.

6. You perform a physical assessment on the 50-year-old patient with petechiae. Assessing for traumatic impact from flying debris is most important in the:

   A. extremities.
   B. head and neck.
   C. back.
   D. buttocks.

7. You continue the physical assessment on the 50-year-old patient. You find flying debris in the patient's lower back, leading you to suspect that there may be internal damage to the:

   A. hollow organs.
   B. solid organs.
   C. extremities.
   D. head.

8. What are the differences between primary, secondary, and tertiary blast injuries?

9. Other than the specific effects of blast injury, what other kinds of things should you assess a patient for who is involved in a WMD incident?

10. Explain how pulmonary WMD agents inflict damage and the signs and symptoms of exposure.

The Team Approach to Health Care

41 A Team Approach to Health Care

CHAPTER 41

A Team Approach to Health Care

National EMS Education Standard Competencies

There are no National EMS Education Standard Competencies for this chapter.

Knowledge Objectives

1. Define continuum of care. (p 1489)
2. List the five essential elements of a group. (p 1491)
3. Explain the advantages of a team over a group; include the advantages of regularly training and practicing together. (pp 1490–1491)
4. List the five essential elements of a team. (pp 1491–1493)
5. Explain how crew resource management (CRM) can be useful in the prehospital environment. (pp 1493–1494)
6. List the five critical elements necessary to ensure effective transfer of patient care from one provider to another. (pp 1494–1495)
7. List the five steps a receiving health care provider should perform when taking a patient care report (PCR). (p 1495)
8. Describe the four-step process of assisting with advanced life support (ALS) skills. (p 1495)
9. Discuss the importance of preoxygenation when performing endotracheal (ET) intubation. (p 1496)
10. Describe the six steps of the BE MAGIC intubation procedure. (pp 1497–1499)
11. Describe the signs that indicate a complication with an intubated patient. (p 1500)
12. Explain the importance of ensuring patient comfort during a vascular access procedure. (pp 1500, 1502)
13. Describe the steps EMTs can take to troubleshoot interpersonal conflicts. (pp 1503–1504)

Skills Objectives

There are no skills objectives for this chapter.

Introduction

As an EMT, you are a critical member of the emergency health care team that includes not only first responders, paramedics, and other EMTs, but also physicians, nurses, and other personnel who will help care for your patient throughout the duration of his or her injury or illness **Figure 41-1**. You play a pivotal role bringing emergency medicine into patients' homes, assisting with advanced patient care skills, and ensuring the effective transfer of patient care to emergency department (ED) staff when you arrive at the hospital.

As an EMT, you will need to do more than acquire clinical knowledge and master necessary skills. You must also learn to be an effective team member. Essentially, this means communicating and collaborating with others who may have different backgrounds and levels of expertise than you have. By working as a team, emergency health care providers—from the first responders in the field to the physicians in the hospital—can improve patient and provider safety and deliver better emergency care. For basic life support (BLS) and advanced life support (ALS) providers to perform well together, each team member must share a common goal and demonstrate excellent communication skills. This chapter will provide an overview of the team health care approach and discuss how diversity among providers' backgrounds, skills, and abilities can strengthen a team. The chapter will also discuss how to assist with advanced skills and manage interpersonal conflict.

Figure 41-1 As an EMT, you will work with various health care providers along the continuum of care.

The positive impact of effective teamwork on the delivery of health care is highlighted by such programs as The World Health Organization's *Being a Team Player* and in the American Heart Association's *Chain of Survival*.

An Era of Team Health Care

Today, it is understood that for the delivery of EMS to be effective, health care providers must work together toward a unified goal of patient care excellence. Historically, however, this was not always the case. Previous models of emergency care often consisted of providers who worked separately, passing the patient from one individual or group to the next. Gradually, emergency health care providers recognized that by working as a unified team from first patient contact to patient discharge, it was possible to improve individual and team performance, patient and provider safety and, ultimately, patient outcome. This concept is known as the **continuum of care**.

Community Paramedicine and Mobile Integrated Healthcare Teams

Community paramedicine and **mobile integrated healthcare (MIH)** teams may be the best example of the team concept of continuum of care. Recall from Chapter 1, *EMS Systems,* that in the MIH model, health care is provided within the community rather than at a physician's office or hospital. The success of MIH programs have shown that EMS providers, working as a unified team with in-hospital and other community health care providers, can improve patient outcomes, increase patient satisfaction, and reduce health care costs.

Differences Among Teams

The structure and effectiveness of emergency health care teams differ from system to system. EMS providers may be trained as Emergency Medical Responders (EMRs) or may be BLS- or ALS-certified. They may be volunteers or full-time employees, and they may be based in police or fire departments, hospitals, or private agency settings. Multiple EMS agencies across different regions or response districts may respond to the same 9-1-1 call. Because of the variety of providers, agencies, and systems involved in each call, it may be difficult for all of the providers to function as one unified team. For instance, you may find it challenging to share patient assessment information and integrate newly arriving providers into ongoing care. As the chapter will discuss, such challenges can be overcome by ensuring effective communication and mutual respect. In this case, as new responders arrive, it is helpful to think of them as "joining the team" as opposed to "taking over."

Types of Teams

Depending on the EMS system in which you work, you may consistently interact with the same team members. Other systems may require emergency health care providers to assemble their teams "on the fly" for each individual call.

Regular Teams

Some EMS systems rely on regular teams. In this model, EMTs consistently interact with the same partner or team and often become familiar with the other emergency health care providers and hospital staff with whom they frequently interact. Regular teams often train together. Team members who frequently train and work together are more likely to move smoothly from one step in the procedure to the next, performing as one seamless unit. By contrast, team members who train and work together less often may need more explicit verbal direction to accomplish their tasks, potentially leading to patient care delays.

Temporary Teams

Temporary teams are common in volunteer EMS systems. In this model, EMTs work with providers with whom they do not regularly interact, or may not even know. This creates a special challenge. For a temporary team to function effectively, providers must work within an environment that supports and promotes collaboration rather than competition. It is crucial to have a clear understanding of the roles, responsibilities, and capabilities of each team member. One of the best ways to accomplish this is to train together when possible.

Special Teams

Some EMS systems form special teams whose members have particular knowledge, skills, abilities, equipment, and/or training to serve a specialized role within the larger emergency health care team. Examples include:

- Fire Team
- Rescue Team
- Hazardous Materials (HazMat) Team
- Tactical EMS Team
- Special Event EMS Team
- EMS Bike Team
- In-Hospital Patient Care Technicians
- MIH Technicians

Groups Versus Teams

Do not assume any gathering of EMS providers responding together on a call is a “team.” True emergency response teams have better interaction, performance, and patient outcomes than groups of health care providers who do not share a team dynamic.

Groups

The National Incident Management System (NIMS) defines a group as “The organizational level that divides the incident according to functional levels of operation. Groups perform special functions, often across geographic boundaries.” When operating under NIMS, EMS providers may often work as a group in this sense. In the context of this chapter, the term *group* is used in the more general sense.

YOU are the Provider **PART 1**

At 0905 hours, you are dispatched to a private home at 6 Catoonah Street for a 72-year-old man who is “unresponsive.” The dispatcher has no additional information to provide. An EMR crew from the fire department has been dispatched and will likely arrive before you. The weather is clear and sunny, the temperature is 82°F (27.8°C), and the traffic is light. Your response time to the scene is approximately 6 minutes.

1. How will you work together as a team with the EMRs?
2. How will members of this team decide who will perform each role?

You must be able to distinguish between a group of providers gathered together on an emergency call and a true team. In the context of EMS, a **group** consists of individual health care providers working independently to help the patient. Some examples of EMS groups are triage, treatment, and transport groups at a mass-casualty incident. In contrast, a **team** consists of a group of health care providers who are assigned specific roles and are working interdependently in a coordinated manner under a designated leader.

In 1945, the Research Center for Group Dynamics first defined the five essential elements of a group that people must share. These elements include:

- A common goal
- An image of themselves as “a group”
- A sense of continuity of the group (an understanding that the group may work together more than once, even in a slightly different configuration)
- A set of shared values (how the group wants to get things done)
- Different roles within the group (often self-assigned)

Once a group has formed, the ability to function as a true emergency response team depends on the way in which its members work together.

Dependent, Independent, and Interdependent Groups

Dependent

In dependent groups, each individual is told what to do, and often how to do it, by his or her supervisor or group leader. Group members rely on the group leader for task assignments, troubleshooting, and virtually all decisions, thus limiting the group’s ability to adapt and deliver critical medical care in an uncontrolled field environment.

Independent

In independent groups, each individual is responsible for his or her own area (either a physical space or set of tasks). Members of an independent group may receive support and guidance from a supervisor or group leader, but do not have to wait for an assignment before taking action as they would in a dependent group. Although independent group members may work on the same patient, each person is focused on individual goals (starting an intravenous [IV] line, splinting an arm, etc), rather than on working together to achieve a unified goal. The classic example of a poor outcome of independent group work is the perfectly splinted and packaged trauma patient, who is dead on arrival at the ED from a poorly managed airway that no one had noticed.

Interdependent

EMTs and other health care providers who work interdependently are functioning as a true team. While each provider may still be assigned to a particular area or task, everyone in an interdependent group works together with shared responsibilities, accountability, and a common goal (the best possible patient outcome), as opposed to focusing on the goals of their own individual areas.

Effective Team Performance

Building on the five essential elements of a group, you will learn the five essential elements that health care providers must share to perform as an effective team.

A Shared Goal

Every health care provider on the team, from EMT to paramedic to emergency physician, must be committed to a common goal—typically, the best possible patient outcome. While this may seem like common sense, evidence of providers not working as a team can be heard in such alarming phrases as, “Why take the time to splint the patient if they’re only going to undo it in the ED?” and “There was no point in doing good CPR if the paramedic wasn’t even trying to save the patient.”

Clear Roles and Responsibilities

To achieve a common goal, each provider must know what needs to be done and what is expected of him or her. An excellent example of this is the pit crew approach to cardiopulmonary resuscitation (CPR) for cardiac arrest situations **Figure 41-2**. The term originated in motor racing, in which teams of technicians rapidly assess and repair vehicles in a matter of seconds. Similarly, pit crew CPR consists of defining each intervention that needs to be addressed during cardiac arrest (compressions, defibrillation, airway management, vascular access, medications) and training providers *before* the call to rapidly identify, prioritize, and take over any areas that are not being addressed as soon as they arrive on scene. The effectiveness of pit crew CPR is dependent on defining clear roles and responsibilities among team members. It is an outstanding example of how training together can allow providers with different certifications from different agencies to rapidly come together as a team to improve outcomes for critically ill patients.

Figure 41-2 In the pit crew CPR model, providers train how to rapidly identify, prioritize, and take over any areas that are not being addressed as soon as they arrive on scene.

Diverse and Competent Skill Sets

As discussed, EMS providers often have varying levels of certification or licensure. Think of these diverse backgrounds and skill sets not as obstacles, but as opportunities to fill roles and responsibilities within a high-performing team. Again, the best way for a team to be effective during an emergency call is to practice with one another and become familiar with each other's tools, techniques, capabilities, and preferences, so that each team member is competent *before* the call comes in.

Effective Collaboration and Communication

For team members to collaborate successfully, you must communicate effectively with one another. Four important elements of team communication include:

YOU are the Provider **PART 2**

When you arrive on scene, a frantic bystander waves you inside. She tells you, "It's my husband! He isn't breathing!" As you walk to the front door, the fire officer meets you and tells you two EMRs are already inside caring for the patient. The scene is safe. Inside you find the patient, an older man, lying in a supine position on the floor of the living room. He is being ventilated with a bag-valve mask (BVM) by one EMR as another EMR performs a reassessment. As you approach the patient with your equipment bag, airway kit, and automatic external defibrillator (AED), the EMR looks up and tells you, "We've lost a pulse." He immediately starts chest compressions while you prepare the AED.

Recording Time: 2 Minutes

Appearance	Motionless
Level of consciousness	Unconscious and unresponsive
Airway	Open; maintained by fire department EMRs
Breathing	Absent; BVM ventilations at a rate of 1 breath every 5 seconds
Circulation	No pulse; skin, cool and pale; CPR has been started

3. Which roles will need to be assigned to perform cardiac arrest resuscitation?

4. The AED analyzes the patient's heart rhythm and advises you to deliver a shock. How can your team maximize patient perfusion and minimize "hands-off" time during this part of the cardiac arrest?

- **A clear message.** Speak calmly, confidently, and concisely so that the information delivered or the action requested is clear to your listeners.
- **Closed loop communication.** When a team member speaks, you should repeat the message back to him or her. This technique helps confirm that you heard and understand the message, and will act on it.
- **Courtesy.** All team members expect and deserve to be spoken to politely.
- **Constructive intervention.** Sometimes it is necessary for you to respectfully question or correct team members (or the team leader) if you believe a mistake has been or is about to be made. This technique is not only allowed and encouraged—it is essential for effective team performance.

Supportive and Coordinated Leadership

The **team leader** is the team member who provides role assignments, coordination, oversight, centralized decision making, and support for the team to accomplish their goals and achieve desired results. The team leader is often defined by policy, procedure, or statute. He or she may be the most senior provider in the group or the person with the highest level certification. A team leader who simply commands others is not leading a team; he or she is simply directing a dependent group. A key differentiation between a team leader and a group leader is that a team leader helps the individual team members to not only do their jobs (provides support) but also to work together (facilitates coordination). In this way, a team leader helps the team produce a better outcome than is possible with a simple group. Team leaders also foster communication and team dynamics using concepts such as crew resource management and team **situational awareness** (the knowledge and understanding of one's surroundings and the ability to recognize potential threats to safety).

Crew Resource Management

Crew resource management (CRM) is, in short, a way for team members to work together with the team leader to develop and maintain a shared understanding of the emergency situation. CRM allows team members with different skill sets to collaborate and communicate, fulfill their roles and responsibilities, and achieve the shared goal of the best possible patient outcome **Figure 41-3**. The concept of CRM says that each member is responsible for maintaining awareness of the current patient situation and sharing any critical information with the team leader. Likewise, the team leader is responsible for listening to any critical information provided by you or other team members, and incorporating it into his or her decision making.

Figure 41-3 Collaboration and communication are crucial aspects of crew resource management.

In the loud and often hectic environment in which EMS providers work, when you believe there is an immediate or potential problem that must be brought to the attention of the team leader, CRM recommends use of the PACE mnemonic:

P *Probe.* Look or ask to confirm the problem.

A *Alert.* Communicate the problem to the team leader.

C *Challenge.* If the issue is not corrected, then clearly challenge the team's present course of action that is leading to the problem. For example, "Lieutenant, I think this additional action should be taken. Do you agree?"

E *Emergency.* If the problem is clear and critical (such as an immediate safety issue), then immediately communicate the emergency to the entire team.

The CRM concept does not mean you are free to ignore the chain of command within the incident command system or NIMS structure. It means you are empowered to provide the team leader and other team members with immediate feedback in the event of a potential threat to patient or crew safety. It means the team, as a whole, recognizes the importance of every individual's input and that the team is committed to creating open lines of communication. CRM empowers people to speak clearly and concisely when they detect a problem or potential problem.

Transfer of Patient Care

While effective health care teams work together from first patient contact to patient discharge, clearly not all providers will be present throughout the entire continuum of care. At several points along the continuum, the patient's care will be transferred, or "handed off," from one unit of providers on the team to another. These transfers introduce the possibility of critical patient care errors, especially when they occur several times and in different settings along the continuum of care. Effective teams minimize the number of transfers during patient care, and adhere to strict and careful guidelines when such transfers are unavoidable.

Just like in a relay race, a proper transfer of patient care will allow the team to keep moving forward with patient care. When incorrect information is handed off, information is miscommunicated, or care is interrupted, the team is forced to move backward, resulting in a loss of valuable time and effort. For this reason, it is important for you to trust other team members—even those who work at different levels or for different agencies. For example, if an EMR reports a patient had a syncopal episode, but the patient is now alert, then do not assume the EMR's information is incorrect.

General Guidelines

If possible, a single person, the team leader, should coordinate the patient's transfer of care and report the patient information. Whenever the verbal transfer of care occurs, all team members should do their best to ensure the following:

1. **Uninterrupted critical care.** Whenever possible, the team member giving the report and the team member taking the report should hand off lifesaving care (such as performing chest compressions) to another team member, allowing them to focus on the transfer of care.
2. **Minimal interference.** The transfer of patient care should occur in a location with the least interference possible.
3. **Respectful interaction.** Each team member involved in the transfer must be respectful of members' different roles and recognize the importance of each role.
4. **Common priorities.** Both the team member giving the report and the team member taking the report must focus on their common priorities (critical assessment findings and patient care) vital for the best possible patient outcome.

YOU are the Provider — PART 3

After the AED reanalyzes and advises a shock, you clear the patient and deliver the defibrillation, quickly directing the two EMRs to rotate compressors and continue CPR. As the EMRs continue compressions and BVM ventilations, the paramedics arrive.

Recording Time: 5 Minutes	
Respirations	Absent; ventilations are being assisted
Pulse	Absent; fire department EMR performing CPR
Skin	Cool and cyanotic
Blood pressure	Not obtainable; the patient has no pulse
Oxygen saturation (SpO_2)	Not obtainable; the patient has no pulse

While your partner gathers a medical history from the patient's wife and the fire officer collects the patient's medications, one of the paramedics asks you to assist her in setting up to intubate the patient.

5. What can you do to assist the paramedic with intubation of the patient?
6. When should you give the patient's medical history and medication list to the paramedic?

5. **Common language or system.** Whenever possible, a mutually agreed-upon and standardized patient handoff format should be used.

See Chapter 4, *Communications and Documentation*, for information on PCRs.

Words of Wisdom

Whether it be from a bystander, an EMR, or a fellow EMT, when taking a patient handoff report, the receiving care provider should do the following:

- **Eye Contact.** Make eye contact with the individual giving a report. This helps both providers to stop other noncritical work and focus on the transfer of information and patient care.
- **Environment.** The very nature of EMS means we do not have the level of control over the environment that we would like. However, when taking a report, make every effort to create or move to an environment that is quieter and less distracting.
- **Ensure Understanding.** Ask any questions to ensure you understand what was reported.
- **Sum up.** Quickly summarize the critical components of the handoff to allow the reporting team member to correct any misunderstandings and to reinforce the information to the new team members taking over patient care.
- **Supplement.** Obtain any relevant paperwork or other materials that will be helpful for communicating information to the next set of health care providers.

BLS and ALS Providers Working Together

In the world of prehospital emergency care, BLS and ALS care cannot exist without each other. For example, if a patient experiences sudden cardiac arrest, then BLS care (high-quality CPR and defibrillation) are the core interventions around which ALS providers build their resuscitative efforts. It would be a mistake to think of BLS care as only the “first steps” of ALS care. As an EMT, you may begin BLS efforts early, but keep in mind that BLS efforts must continue throughout the continuum of care. To successfully stabilize and treat the patient’s condition, you must carefully coordinate your efforts with the advanced tools and techniques used by ALS providers. Remember, excellent communication skills and teamwork are essential elements of emergency medicine. Each member of the EMS team must work in harmony with one goal in mind—high-quality patient care.

Where BLS Care Ends and ALS Care Begins

Many patient care skills can be considered advanced; however, the tools and techniques that you can use as an EMT versus those that are reserved for ALS providers vary from system to system. What may be a “paramedic only” skill in your EMS system may be common for an Advanced Emergency Medical Technician (AEMT) or EMT to perform in another.

As discussed in Chapter 3, *Medical, Legal, and Ethical Issues*, it is your responsibility to understand what is allowed by the scope of practice, standard of care, and local protocols where you work. If you work outside these bounds, such as performing a skill for which you are not authorized, then you risk legal liability. This liability is not reduced because you were unaware you were “not supposed to do that.”

It is just as important to understand that, as a key part of the emergency team, there are many ways in which you can assist paramedics and other ALS providers with advanced procedures.

For an EMS team to effectively perform an advanced skill, they should train and practice together. While a good EMT knows what he or she is allowed to do in assisting with an advanced procedure, a great EMT has the foundational knowledge to understand the procedure. Most important, you must understand that when using any advanced tool or technique, the focus is always on achieving a goal (solving a clinical problem) rather than simply completing a procedure.

Assisting With ALS Skills

As an EMT, there are many different ALS skills with which you may be able to assist. The exact list of ALS procedures and how they are to be performed will vary from system to system. In general, assisting follows a four-step process: (1) patient preparation, (2) equipment set up, (3) performing the procedure, and (4) continuing care.

Assisting With Placement of Advanced Airways

Endotracheal (ET) intubation is the insertion of a tube into the trachea to maintain and protect the airway. The ET tube can be inserted through the mouth or through the nose. In either case, the ET tube passes directly through the larynx between the vocal cords and then into the trachea. You may also be asked to assist with the placement of other advanced airway devices.

Patient Preparation

The first step in preparing a patient for ET intubation is oxygenation. Recall from Chapter 10, *Airway Management*, that **oxygenation** is the process of loading oxygen molecules onto hemoglobin molecules in the bloodstream. Good oxygenation often includes BVM ventilation (including the use of an oral or nasal airway) and ensuring a proper seal, ventilation rate, volume of ventilation, and time for patient exhalation. Oxygen enters the bloodstream through the process of diffusion. The more oxygen that is available in the alveoli, the longer the patient can maintain adequate gas exchange in the lungs while the intubation procedure is being performed **Figure 41-4**. This critical phase of the intubation procedure is called **preoxygenation**.

Maintain a high-flow nasal cannula on the patient during the preoxygenation phase and leave the nasal cannula in place during the intubation attempt, a period of time when BVM ventilation and chest rise and fall is not possible. This technique, called **apneic oxygenation**, allows for continuous oxygen delivery down the airways during all phases of the intubation procedure.

Preoxygenation is a critical step in advanced airway management. Always follow your local protocols regarding the sequence of this procedure.

Equipment Set Up

Equipment sets vary depending on local protocols, provider preference, and whether **direct laryngoscopy** or **video laryngoscopy** will be used. (Direct laryngoscopy is visualization of the vocal cords with a laryngoscope, while video laryngoscopy is visualization of the vocal cords using a video camera and monitor.) These differences emphasize why it is important for team members to train and practice together. Typically, intubation equipment sets include:

- Personal protective equipment (PPE), including face mask and eye shield
- Suction unit with rigid, tonsil-tip (Yankauer) and nonrigid, whistle-tip (French) catheters
- Laryngoscope handle and blade (sized for the patient)
- Magill forceps
- ET tube (sized for the patient)

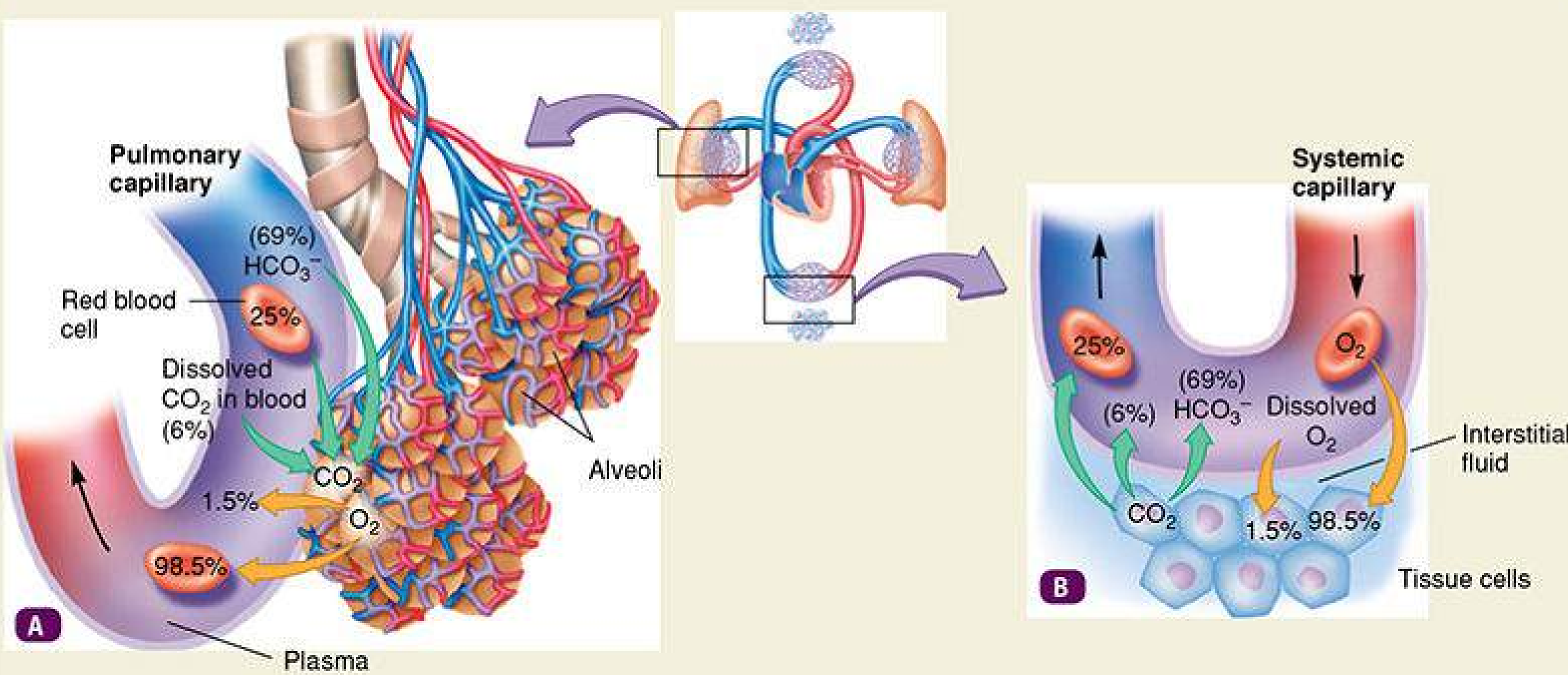

Figure 41-4 **A.** Alveolar-capillary exchange. Oxygen-rich air enters the alveoli, where it crosses into the bloodstream. Carbon dioxide leaves the blood and enters the alveoli. **B.** Capillary cellular exchange. Throughout the body, carbon dioxide from the cells enters the capillaries, and oxygen leaves the capillaries and enters the cells. Carbon dioxide is returned to the lungs in red blood cells (25%), in the form of bicarbonate (69%), and dissolved in blood (6%).

- Stylette or tube introducer (**gum elastic bougie**)

- Water-soluble lubricant
- 10-mL syringe
- Confirmation device(s), including waveform end-tidal CO_2 monitors and/or colorimetric device
- Commercial ET tube securing device
- Alternate airway management devices, such as a supraglottic airway and/or cricothyrotomy kit

Words of Wisdom

When assembling the intubation equipment, you may have time to take extra steps, such as opening the ET tube package, lubricating the end of the ET tube with the water-soluble lubricant, attaching the 10-mL syringe, testing the cuff and pilot balloon, and checking the laryngoscope's light source.

Performing the Procedure

While the details of endotracheal intubation may vary depending on available equipment, difficulties encountered, and provider preference, you can remember the six typical steps by using the **BE MAGIC** mnemonic:

B Perform *BVM* preoxygenation.

E *Evaluate* for airway difficulties.

M *Manipulate* the patient.

A *Attempt* first-pass intubation.

GI Use a supra*Glottic* or *Intermediate* airway if unable to intubate.

C *Confirm* successful intubation/*Correct* any issues.

BVM preoxygenation. As discussed previously, it is crucial that you adequately preoxygenate the patient before the intubation procedure, especially critical patients **Figure 41-5**. Do not hyperventilate the patient during the preoxygenation phase, because this may cause gastric distention and increase the risk of aspiration. Hyperventilation may also cause hypotension. Focus on maintaining a good seal, achieving chest rise and fall, and delivering breaths at a rate appropriate for the patient's age (1 breath every 6 seconds for an adult, and 1 breath every 3 to 5 seconds for an infant or child).

Evaluate for airway difficulties. While you preoxygenate the patient, an ALS provider should evaluate the patient to identify any factors that will present difficulties during the procedure—for example, trauma or anatomic deformities to the airway. It is crucial that difficulties be identified before the procedure begins. You may assist with this process, as well as the preparation of any equipment that will be needed to address the problem(s).

Figure 41-5 One EMT or the paramedic may prepare the intubation equipment while another EMT continues to ventilate and preoxygenate the patient.

Manipulate the patient. Before the procedure can begin, position the patient so that the ALS provider can visualize the vocal cords. Use towels, blankets, and pillows to ramp, position, and otherwise manipulate the patient so that the first attempted intubation will be successful. The ideal position is achieved when the patient's ear canal is on the same horizontal plane as his or her sternal notch, known as the sniffing position Figure 41-6.

Attempt intubation. When the ALS provider is ready to begin the intubation attempt, remove the oral airway and disconnect the mask from the bag in preparation for connecting the bag to the ET tube. Always keep the mask and airway within reach in case the first attempt is unsuccessful and you need to ventilate the patient with the BVM once more. Likewise, keep suction equipment at hand in case you need to suction the patient's airway. The ALS provider will begin by inserting the laryngoscope blade into the patient's mouth and will use it to move structures in the airway, such as the tongue and epiglottis, to gain a view of the vocal cords through which the ET tube will pass Figure 41-7.

Special Populations

It may be difficult for the ALS provider to visualize the vocal cords in bariatric and pediatric patients or patients with suspected cervical spine injuries. Expect to have particularly hands-on involvement with these patients. It is usually necessary to open (undo) a cervical collar to perform intubation. As the cervical collar is opened, you may be asked to maintain cervical spine immobilization while an ALS provider attempts intubation. Good communication and coordination between team members is critical during these advanced procedures.

Figure 41-6 The sniffing position: Position the patient so that the ear canal is on the same horizontal plane as the sternal notch.

Figure 41-7 The ALS provider will use the laryngoscope blade to visualize the target of the vocal cords through which the ET tube will pass.

The ALS provider may ask you for assistance in manipulating the patient's larynx (external laryngeal manipulation) or otherwise positioning the patient for a better view **Figure 41-8**. You may also be asked to hand over the ET tube, gum elastic bougie, suction catheter, or other equipment to the ALS provider.

Supraglottic or intermediate airway. Should the intubation attempts fail, it may be your responsibility to prepare and hand over the supraglottic or intermediate airway device or, in systems where it is allowed, you may place the airway devices themselves **Figure 41-9**.

Confirm intubation/correct issues. If the intubation procedure appears successful, then work with your team to confirm intubation success. You may attach the end-tidal waveform CO_2 detector in line between the ET tube and the bag. You may also either ventilate the patient while another provider checks for positive breath sounds in the absence of gastric sounds, or you may listen while another team member ventilates **Figure 41-10**. A successfully intubated patient should have bilateral breath sounds present and gastric (or epigastric) sounds should be absent. Either absence of breath sounds or presence of gastric sounds suggests the ET tube was improperly inserted into the esophagus. If the intubation is confirmed as successful, then you may assist in securing the ET tube **Figure 41-11**. If the intubation cannot be confirmed, or if the ET tube appears to be properly placed but airway or breathing issues remain, then you may assist other team members in correcting these issues.

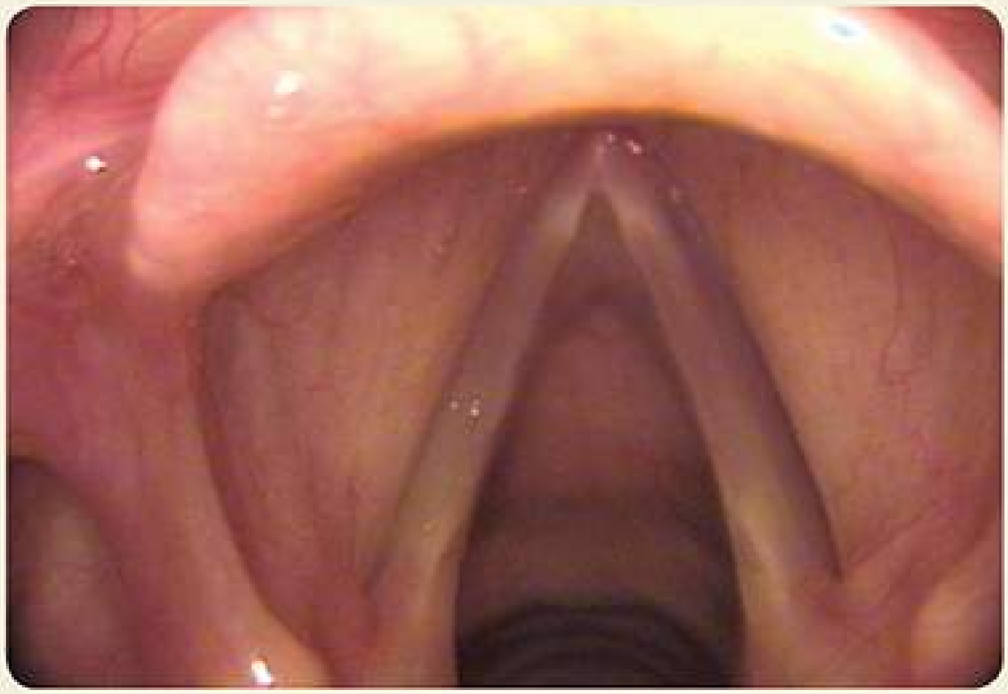

Figure 41-8 The cuff of the ET tube must pass through the vocal cords. The ALS provider will attempt to directly visualize this, but may be able to intubate even if the cords are not visible.

Courtesy of James P. Thomas, M.D. (voicedoctor.net).

Words of Wisdom

An ALS provider may place an oral airway back into the patient’s mouth after a successful intubation attempt to prevent the patient from biting down on the ET tube.

Figure 41-9 Supraglottic airway devices. **A.** The King LT is a single lumen supraglottic airway device. **B.** The laryngeal mask airway device. **C.** The i-gel airway device.

Figure 41-10 Ventilate while listening for breath sounds to confirm successful placement of the ET tube.

Figure 41-11 Ensure the ET tube does not move while it is being secured or at any point during patient care.

Words of Wisdom

The position of the ET tube is unstable before the tube is secured with tape or a mechanical device. Make sure the ET tube is not dislodged by movement at this point in the procedure, or at any time during patient care.

Continuing Care

Once an intubation attempt has been confirmed as successful, the job of airway management is not over for the EMS team. You must continue to observe all of the patient's monitor readings, as well as monitor for signs of potential complications, including:

- **Absence of an end-tidal CO_2 level.** Alert team members if the end-tidal CO_2 waveform suddenly disappears. (This is a sign the ET tube may have shifted out of the proper position.)
- **Decreasing SpO_2 level.** Alert team members if the SpO_2 level begins to drop, especially below 94%. (This is a sign the ET tube may have shifted out of the proper position.)
- **Increasing resistance when ventilating.** The person assigned the task of ventilation should monitor for increasing resistance when the bag is squeezed for ventilation. When increasing resistance is felt, it could indicate a critical airway or breathing problem that must be addressed, such as the advanced airway device has been mistakenly placed into the esophagus rather than into the trachea, referred to as esophageal intubation. When the ET tube is placed in the esophagus, ventilation results in air being pumped into the stomach, which increases the size of the patient's stomach and leads to gastric distention.
- **Other physical signs of poor ventilation and perfusion.** Physical signs include pale skin and cyanosis.
- **Improper positioning or dislodgement of the ET tube.** Each time the patient is moved, it is important to reassess the placement of the ET tube. Verify proper ET tube position by ensuring breath sounds are present, gastric sounds are absent, an end-tidal CO_2 waveform is visible during ventilation, SpO_2 values are stable or rising, and the ET tube is secured at the proper depth marking Figure 41-12.

Vascular Access

Vascular access is a procedure that gains access to a patient's circulatory system in order to inject or remove fluids, medicines, or blood products. Vascular access is usually obtained through an intravenous catheter placed in a vein, but sometimes through a needle or catheter placed in an artery or a needle placed into bone.

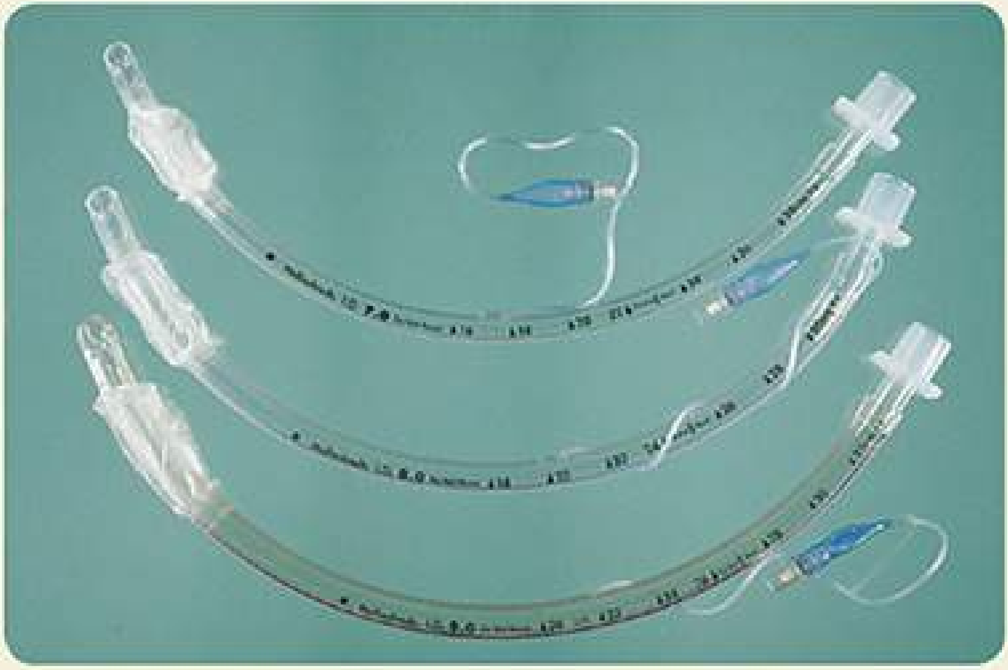

Figure 41-12 Centimeter markings on the ET tube are used to ensure insertion to the appropriate depth.

Patient Preparation

The first step in preparing a patient for a vascular access procedure may involve positioning the patient and other EMS equipment so the ALS provider has enough room to make the attempt. Patient preparation may also involve explaining the procedure, and the reason for it, to the patient. You must ensure the patient is comfortable and calm so that he or she is less likely to move during the procedure.

Equipment Set Up

IV equipment sets vary depending on local protocols as well as EMS agency and provider preference. Regardless, regular team training, practice, and familiarity with the equipment involved in vascular access procedures can make an enormous difference in team performance and patient care. In the case of vascular access, you may be asked to gather the equipment and/or assemble some parts of the vascular access system, including spiking (inserting a needle into) the bag of IV solution.

While vascular access may involve either IV or intraosseous (IO) access, the procedure and equipment list will be generally the same:

- PPE, including properly sized gloves
- A properly sized bag or syringe of the IV solution (selected by the ALS provider)
- IV tubing and drip set (selected by the ALS provider)
  - Macrodrip set (10 to 15 gtt [drops]/mL) for general use and trauma
  - Microdrip set (60 gtt/mL) for medication infusion

- Skin preparation pads, typically alcohol prep pads and/or betadine solution
- Adhesive tape, torn into several pieces about 1 inch (2.5 cm) in length, to help secure the tubing to the patient's body
- Gauze, 2 × 2 inches (50 × 50 mm) or 4 × 4 inches (101 × 101 mm)
- Commercial IV securing system (a device to help secure the tubing instead of, or together with, adhesive tape; optional)
- IV "pigtail" catheter (a small section of IV tubing that connects to the hub of the IV catheter and can be easily connected and disconnected from the primary IV tubing; optional)
- If IV access:
  - Venous constricting band (sometimes referred to as a venous tourniquet)
  - IV catheter (size selected by the ALS provider)

Words of Wisdom

Clean, Sterile, and Aseptic Technique

Some advanced procedures are considered invasive because they involve creating openings in the body or inserting devices in the body. During invasive procedures, you must utilize the appropriate technique (clean, aseptic, or sterile), to prevent the spread of infection—especially if the patient is already sick.

Clean technique refers to minimizing the amount of pathogens or "unclean" materials that you pick up or transfer through the use of routine handwashing, nonsterile protective gloves, etc.

Aseptic technique is often used for fast, invasive procedures such as starting an IV line and refers to techniques and procedures that help ensure that pathogens are not introduced anywhere in the procedure (such as sterilization of equipment or use of antiseptics or disinfectants).

Sterile technique is often used during long, highly invasive surgical procedures and involves thorough decontamination, as well as the use of sterile fields around the procedure and full-scale, sterile PPE.

When you assist with ALS skills such as spiking an IV bag, it is important for you to use aseptic technique. Ensure that no nonsterile items (nonsterile gloves, the outside of the IV bag, the patient's skin, etc) come in contact with the sterile parts of the IV system (the tubing spike, the IV bag port, the end of the IV tubing, etc).

- If IO access:
  - IO needle (size selected by the ALS provider)
  - Mechanical IO driver or insertion device (depending on IO system)

Spiking the Bag

An ALS provider may ask you to spike the IV bag. To spike the bag with the administration set, follow these steps.

Begin by removing the rubber pigtail found on the end of the IV bag by pulling on it. The bag is still sealed and will not leak until the piercing spike of the IV administration set punctures this port. Remove the protective cover from the sterile piercing spike **Figure 41-13**.

Next, slide the spike into the IV bag port until you see fluid enter the drip chamber **Figure 41-14**. Invert the bag. Squeeze and release the drip chamber until about half full. Unclamp the tubing (to allow fluid into the tubing to prime the line and flush the air out of the tubing).

Let the fluid flow until air bubbles are removed from the line before turning the roller clamp wheel to stop the flow.

Next, go back and check the drip chamber; it should be only half filled. The fluid level must be visible to calculate drip rates. If the fluid level is too low, then squeeze the IV bag until it fills. If the chamber is too full, then invert the IV bag and squeeze the chamber to empty the fluid back into the bag. Hang the bag in the appropriate location with the end of the IV tubing easily accessible.

Figure 41-13 Remove the pigtail from the port on the IV bag and the cover from the spike on the administration set.

Choose the drip set indicated by the ALS provider, and attach it to the fluid bag indicated by the ALS provider. Fill the drip chamber halfway by squeezing it Figure 41-15. Flush or "bleed" the tubing to remove any air bubbles by opening the roller clamp Figure 41-16. Make sure no bubbles are floating in the tubing.

Saline locks (buff caps) are access devices used to maintain an active IV site without running fluids through the vein Figure 41-17. Saline locks, also called heparin caps and heparin locks, are used primarily for patients who do not need additional fluids but may need rapid medication delivery. Procedures will vary based on local protocol, available equipment, and provider preference. One way to set up a saline lock is to attach it to the end of an IV catheter and fill it with approximately 2 mL of normal saline to keep blood from clotting at the end of the catheter. Saline remains in the port without entering the vein.

Figure 41-14 Slide the spike into the IV bag port.

Figure 41-15 Prepare the solution and tubing to be used. Fill the drip chamber halfway by squeezing it.

Figure 41-16 Flush or "bleed" the tubing to remove any air bubbles by opening the roller clamp.

Performing the Procedure

While the ALS provider is establishing IV or IO access, you may help to stabilize (or in some instances, restrain) the patient's limbs or simply hold the patient's hand and provide him or her comfort **Figure 41-18**. You may also be asked to assist the ALS provider by handing over equipment as requested.

Figure 41-17

A saline lock is attached to the end of an intravenous catheter and filled with approximately 2 mL of normal saline.

Continuing Care

Once vascular access is established, continue patient care by observing the access site for swelling, bleeding, discoloration, or leaking. Also, observe the IV tubing to see if it is improperly blocked, clamped, kinked, or if the bag of IV solution is empty **Figure 41-19**.

Figure 41-18 While the ALS provider starts the IV line, you can help ensure that the patient's arm does not move.

Figure 41-19 Observe for the accumulation of blood, IV fluid, or air in the area of the insertion site.

Troubleshooting Team Conflicts

As outlined in this chapter, applying the principles of effective emergency health care teams will help to minimize interpersonal conflicts. However, because most emergency health care teams consist of highly trained, enthusiastic, and dedicated people, it is inevitable that conflict will arise from time to time. When conflict occurs, keep in mind the following five techniques:

YOU are the Provider — PART 4

The patient is intubated and has an IV line established. Before any medications are administered, the patient regains a pulse, even though he remains unconscious. You transport the patient to the local hospital, which is only a few minutes away. The paramedic gives a radio report while en route.

Recording Time: 17 Minutes	
Level of consciousness	Unconscious and unresponsive
Respirations	6 breaths/min (baseline); ventilations are being assisted
Pulse	104 beats/min
Skin	Pale and cyanotic
Blood pressure	104/80 mm Hg
Spo_2	92% (with assisted ventilation)

Upon arrival, you bring the patient into the resuscitation room where the ED members of your team await.

7. In the ED, if the paramedic is giving the handoff report, then who will ensure that patient care is continued during the transfer of care?
8. During the transfer of patient care, at what point is the EMS unit of the team relieved of responsibility for caring for the patient?

- **The patient comes first.** Regardless of interpersonal conflicts that may arise, the patient's needs must always come first.

- **Do not engage.** If the problem causing the conflict does not directly and immediately impact patient care, then do not engage. Have the discussion after the call, when more positive communication may be possible.
- **Keep your cool.** Maintain your composure. If you feel that the conflict is over a critical component of patient care, then follow the PACE mnemonic discussed previously. If it is not, then begin by taking a deep breath and slowly counting to 10.
- **Separate the person from the issue.** If the conflict arises from the behavior of another team member and the conflict cannot be delayed or avoided, then focus on the behavior itself rather than the individual.
- **Choose your battles.** Remember, there is strength in the diversity of team members. Not everyone will work in exactly the same way, and that is a good thing. Avoid engaging in conflict over minor issues in patient care that center around one provider "style" over another.

YOU are the Provider — SUMMARY

1. How will you work together as a team with the EMRs?

Because the EMRs will arrive at the scene before you, they will have begun patient care. When you arrive, begin by making contact with the EMR in charge while your partner assists the other EMRs. You should gather information about the patient's current condition as well as the care that has already been provided, so you understand the patient care priorities as well as which roles need to be filled and what tasks need to be completed. This information-gathering step will allow you to seamlessly integrate into the patient care team for the call already in progress.

2. How will members of this team decide who will perform each role?

Throughout the emergency call, provider roles and responsibilities will change as patient needs and available resources change. In some cases, certain roles will need to be filled by providers with specific levels of expertise or advanced certifications. In other cases, local protocol will often require the highest-certified or most senior provider to be the team leader. Be aware that it will not always be necessary (and may even set the team back) for an arriving responder to take over simply because they have a higher certification. For example, if you arrive on this scene to find the patient in respiratory arrest with an EMR already providing ventilations, then it may not be helpful to stop the EMR and have him hand over the procedure. The most helpful way, assuming there are no higher patient priorities at that time, would be for you to step into another necessary, but as of yet unfilled, role.

3. Which roles will need to be assigned to perform cardiac arrest resuscitation?

At this point in the call, there are seven providers on scene: the fire officer, the EMR who is ventilating, the EMR who is performing chest compressions, you, your partner, the paramedic, and the paramedic's partner.

The highest-priority role (providing high-quality cardiac compressions) has already been filled by the EMR from the fire department. However, be aware that it may be necessary to relieve a provider who has been doing CPR for more than a few minutes, because he or she may become fatigued and start to perform ineffective compressions. Your partner can fulfill this role.

The second highest-priority role is to apply and use a cardiac monitor or AED. If only two responders are on scene, then the provider in this role will be the team leader. In this scenario, the paramedic can fulfill this role.

Depending on local protocol, the next role is to manage the patient's airway and breathing. If the person filling this role is a BLS provider, then he or she will utilize a BVM, oxygen, and airway adjuncts as allowed by local protocol. If an ALS provider arrives, then he or she may assume this role from a BLS provider. In this scenario, this role has already been filled by the second EMR.

If advanced providers are available, then the next role is to gain vascular access and administer medication. In this situation, the paramedic's partner can fulfill this role.

If enough providers are available, then a fifth role is that of team leader. His or her tasks include gathering patient history and assessment information, formulating a resuscitation plan, and coordinating all of the other roles. Here, the fire officer can fulfill this role.

4. The AED analyzes the patient's heart rhythm and advises you to deliver a shock. How can your team maximize patient perfusion and minimize "hands off" time during this part of the cardiac arrest?

The provider performing CPR (the EMR) should resume compressions immediately after the shock is delivered, without having to be directed to do so by the team leader.

In general, methods for minimizing "hands off" time will depend greatly on the amount of training and practice the providers on the resuscitation team have had prior to the call. After any defibrillation, CPR should resume immediately after the shock is delivered, regardless of the patient's cardiac rhythm—unless the patient has obvious signs of circulation (such as movement, breathing, or speaking). In a well-coordinated team, all team members should understand this priority, even if the team members hold different levels of certifications or are from different organizations. However, team members who have not practiced or worked together before are likely to wait until they are given specific direction from a team leader because they do not know what to expect next. In cardiac resuscitation, this can lead to delays in the resumption of CPR, which negatively affects the patient's chances of successful resuscitation.

5. What can you do to assist the paramedic with intubation of the patient?

The intubation procedure will typically follow the BE MAGIC mnemonic process, but the specific steps will depend on several factors, including your level of training and provider preference. As with any ALS procedure, assisting with intubation typically follows the four-step process of patient preparation, equipment set up, performing the procedure, and continuing care.

In this case, patient preparation is complete, because proper BVM ventilation has been ongoing. The paramedic may wish to evaluate the patient for difficult airway issues while you set up the intubation equipment, or the paramedic may wish to set up the equipment.

You will most surely assist in the continuation of care, especially if you fill the role of airway and breathing provider. You will continue to observe end-tidal CO_2 level, SpO_2 level, and other monitor readings. You should watch out for indicators of pending or immediate airway issues, such as gastric inflation, increasing resistance when squeezing the BVM, and signs of poor patient ventilation or perfusion.

6. When should you give the patient's medical history and medication list to the paramedic?

As a single ALS provider arriving on scene of a cardiac resuscitation, the paramedic will have a number of roles that he or she may need to fill. The most obvious role is that of team leader. However, a dilemma the paramedic may face is that he or she may be the only one able to complete certain ALS level tasks such as cardiac rhythm interpretation, obtaining vascular access, and medication administration.

As a result, the exact answer to this question will depend on the specifics of the situation. Generally, most ALS providers assuming the role of team leader upon arrival will want an immediate report of priority patient concerns, priority assessment, medical history, and key interventions that have been performed. This brief, priority-only report is typically verbal, not written. Therefore, in this case, you should provide a verbal report to the paramedic as soon as possible upon her arrival.

While not always possible, it is recommended that the full patient demographics, medical history, medication list, and other pertinent information be written down in a clear format and turned over to the paramedic team leader for additional reference, and then turned over to the team members upon arrival at the ED.

7. In the ED, if the paramedic is giving the handoff report, then who will ensure that patient care is continued during the transfer of care?

It is important for other team members to avoid interrupting or causing interference with the hand-off report. It is just as important for team members to ensure that priority treatments (think ABCs) are continued during the transfer of care until treatments are assumed by the receiving team members.

It is for this reason that many team-focused patient handoff protocols specify that all priority treatments must be completely taken over by the receiving team before the handoff report is given. This ensures that the team's complete attention can be given to the person (in this case, the paramedic) providing the report. Many protocols even include a specific, so-called moment of silence to ensure that the report is given only once and that all team members received the information. This is especially important during critical care handoffs such as this cardiac arrest, but this concept can also apply to severe trauma, and "alert" situations such as STEMI, stroke, and sepsis.

8. During the transfer of patient care, at what point is the EMS unit of the team relieved of responsibility for

caring for the patient?

It is crucial for team members to ensure that patient care continues through any transition of team members, from the time you arrive on scene to join the team to the moment you hand off care to your team members in the ED.

Once the handoff is complete, it is important for you to ask if your team members in the ED have any remaining questions or need anything else from you. Do not make assumptions. Ask explicit questions aloud, such as “Do you have any questions?” and “Is there anything else that you need from me?” You should receive a clear response from the team members to whom you are handing off patient care.

EMS Patient Care Report (PCR)

Date: 7-20-17	**Incident No.:** 0101855	**Nature of Call:** Unresponsive		**Location:** 6 Catoonah St.	
Dispatched: 0905	**En Route:** 0905	**At Scene:** 0912	**Transport:** 0925	**At Hospital:** 0932	**In Service:** 1000

Patient Information

Age: 72 **Sex:** M **Weight (in kg [lb]):** 90 kg estimated (198 lb)	**Allergies:** Cipro **Medications:** Avastatin **Past Medical History:** Lung cancer **Chief Complaint:** Cardiac arrest

Vital Signs

Time: 0910	**BP:** Unable to obtain	**Pulse:** 71	**Respirations:** 8	**Spo_2:** 82%
Time: 0912	**BP:** N/A	**Pulse:** 0	**Respirations:** 0	**Spo_2:** N/A
Time: 0919	**BP:** N/A	**Pulse:** 0	**Respirations:** 0	**Spo_2:** N/A
Time: 0925	**BP:** N/A	**Pulse:** 0	**Respirations:** 0	**Spo_2:** N/A
Time: 0931	**BP:** 104/80	**Pulse:** 104	**Respirations:** 6 baseline, ventilations assisted	**Spo_2:** 92%, ventilations assisted

EMS Treatment (circle all that apply)

Oxygen @ 15 L/min via (circle one): **NC NRM BVM**		**Assisted Ventilation**	**Airway Adjunct**	**CPR**
Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** Assisted with ET intubation and vascular access

Narrative

Unit 118-1 co-dispatched with fire department EMRs and paramedic unit to a private residence for a 72-year-old male "unresponsive patient." Upon arrival patient was reported to be in respiratory arrest under care of EMRs. Upon reassessment patient found to be pulseless and apneic. CPR initiated by EMRs. AED applied by EMS. Shock advised and delivered. CPR continued rotating compressors every 2 minutes. Patient history of lung cancer obtained from spouse. Paramedic arrival at 0915. EMS assisted with advanced airway placement and vascular access. Before medications were administered, patient regained pulse, but remained unconscious. Patient loaded for transport with assistance of EMRs. Patient transported without further change in status or additional treatment. Paramedic gave radio report en route. Upon arrival at ED, care was assumed by ED staff. Verbal report was given to attending physician (team leader). Written patient history and medications were given to RN (resuscitation team recorder). ED staff confirmed no further questions. Transfer of care complete at 0935. Unit 118-1 cleared the hospital and returned to service at 1000 hrs.
End of report

Prep Kit

Ready for Review

- Emergency health care providers must know how to work effectively as a unified team, from first patient contact to patient discharge. Ensuring consistent patient care across all team members is known as the continuum of care.
- While some EMS systems will allow EMTs to work together in regular teams, others will require providers to assemble their teams "on the fly" for each call (temporary teams). It is especially important for team members to train and practice together if they are from different organizations.
- An effective team must work interdependently toward a shared goal (best possible patient outcome) instead of focusing on individual, task-based goals (such as splinting an arm or starting an IV line).
- An effective team must have clearly defined roles and responsibilities. The diverse and highly competent team members must communicate and collaborate efficiently under supported and coordinated leadership.
- An effective team must have a team leader to coordinate and guide decision making. For this to be possible, every member must be responsible for maintaining individual situational awareness and conveying critical information to each other and to the team leader.
- For all emergency health care providers to work together successfully, they must be well versed in efficient patient handoff techniques.
- The ALS skills with which you may assist will vary from EMS system to EMS system, but you will generally follow a four-step process: (1) patient preparation, (2) equipment set up, (3) performing the procedure, and (4) continuing care.

Vital Vocabulary

apneic oxygenation A technique in which oxygen administered via a high-flow nasal cannula is left in place during an intubation attempt, allowing for continuous oxygen delivery into the airways during all phases of the procedure.

aseptic technique A technique that helps ensure pathogens are not introduced anywhere in the procedure through the sterilization of equipment and use of antiseptics or disinfectants; often used for fast, invasive procedures, such as starting an IV line.

clean technique A technique in which the amount of pathogens or unclean materials picked up or transferred during a procedure is minimized through the use of routine handwashing and non-sterile protective gloves.

community paramedicine A health care model in which experienced paramedics receive advanced training to equip them to provide additional services in the prehospital environment, such as health evaluations, monitoring of chronic illnesses or conditions, and patient advocacy.

continuum of care The concept of consistent patient care across the entire health care team from first patient contact to patient discharge; working together with a unified goal, results in improved individual and team performance, better patient and provider safety, and improved patient outcome.

crew resource management (CRM) A set of procedures for use in environments where human error can have disastrous consequences. It empowers people within a team to communicate effectively with one another with a goal of improving team situational awareness, patient and crew safety, and overall communication.

direct laryngoscopy Visualization of the airway with a laryngoscope.

endotracheal (ET) intubation Insertion of an endotracheal tube directly through the larynx between the vocal cords and into the trachea to maintain and protect an airway.

esophageal intubation Improper placement of an advanced airway device into the esophagus rather than into the trachea.

group In the context of EMS, a collection of individual health care providers working independently to help the patient.

gum elastic bougie A flexible device that is inserted between the glottis under direct laryngoscopy; the endotracheal tube is threaded over the device, facilitating its entry into the trachea.

mobile integrated healthcare (MIH) A method of delivering health care that involves providing health care within the community rather than at a physician's office or hospital.

oxygenation The process of loading oxygen molecules onto hemoglobin molecules in the bloodstream.

preoxygenation The process of providing oxygen, often in combination with ventilation, prior to intubation in order to raise the oxygen levels of body tissues; a critical step in advanced airway management. This extends the time during which an advanced airway can be placed in an apneic patient, because the more oxygen that is available in the alveoli, the longer the patient can maintain adequate gas exchange in the lungs during the procedure.

saline locks (buff caps) Special types of intravenous devices filled with a small amount of normal saline to keep blood from clotting at the end of the catheter, allowing an IV site to be maintained without running fluids through the vein; also called heparin caps and heparin locks.

situational awareness Knowledge and understanding of one's surroundings and the ability to recognize potential risks to the safety of the patient or EMS team.

sterile technique A technique that involves thorough decontamination, as well as the use of sterile fields around the procedure and full-scale, sterile PPE; often used during long, highly invasive surgical procedures.

team In the context of EMS, a group of health care providers who are assigned specific roles and are working interdependently in a coordinated manner under a designated leader.

team leader The team member who provides role assignments, coordination, oversight, centralized decision making, and support for the team to accomplish their goals and achieve desired results.

vascular access A procedure that gains access to a patient's circulatory system in order to inject or remove fluids, medicines, or blood products. Vascular access is usually obtained through an intravenous catheter placed in a vein, but sometimes through a needle or catheter placed in an artery or a needle placed into bone.

video laryngoscopy Visualization of the vocal cords, and thereby placement of the endotracheal tube that is facilitated by use of a video camera and monitor.

Assessment *in Action*

You are dispatched to a private residence where a 48-year-old woman is lying supine on the bathroom floor. She is alone in the house. The patient is unresponsive, not breathing, and has a weak pulse. You secure her airway with an oral airway and ventilate her with a BVM at a rate of one breath every 5 seconds. An ALS transport ambulance arrives. The paramedic and her AEMT partner enter the house and approach you and the patient. You continue BVM ventilations. The paramedic prepares to intubate and the AEMT prepares to start an IV line.

1. At what point should you give your verbal report?

   A. Over the radio, prior to arrival of the ambulance
   B. Face to face, inside of the house
   C. Face to face, outside of the house
   D. Over the radio, after the ambulance leaves

2. Now that the ambulance has arrived, who will be the team leader?

   A. You, because you were the first provider on scene
   B. The AEMT, because the paramedic will be too busy intubating the patient
   C. The paramedic, because she is the highest-level provider on scene
   D. The hospital physician, because he provides medical control

3. After giving your report, which of the following roles is the most appropriate for you to assume?

   A. The role of team leader
   B. Assistant to the paramedic
   C. Assistant to the AEMT
   D. Request from the team leader

4. The paramedic asks you to assist her with intubation. Your first step should be to:

   A. prepare the patient by continuing to ventilate.
   B. assemble the equipment that the paramedic will need.

C. assist the paramedic as she places the ET tube.
D. care for and monitor the patient once she has been intubated.

5. The paramedic asks you to help position the patient to facilitate intubation. What is the best way to position the patient?

A. Raise the patient's legs.
B. Lift the patient's neck.
C. Help pad under the patient's shoulders.
D. Turn the patient on her side.

6. As you ventilate the intubated patient, which of the following observations would cause you to immediately alert the team leader?

A. Ventilation is causing the chest to rise.
B. The patient's cyanosis is disappearing.
C. The oxygen saturation level is now at 94%.
D. The BVM is offering more resistance.

7. After the paramedic relieves you of your task, you offer to assist the AEMT. He tells you he does not need any help, even though he is clearly having difficulty establishing an IV line. You should:

A. immediately inform the team leader that the AEMT needs help.
B. call the AEMT's supervisor.
C. not engage; calmly speak to the AEMT about the situation after the call.
D. not engage; assist the AEMT with the IV line.

8. After your other tasks are completed, you search the house for a medication list or other relevant medical information. To whom should you give this information?

A. The team leader
B. The AEMT
C. The physician at the ED
D. The patient's family

9. As the paramedic and AEMT prepare to transport, they begin to have a disagreement as to how best to package the patient. As they discuss this, you notice the paramedic is no longer ventilating the patient at the appropriate rate. How should you proceed?

10. How might you improve your team dynamic with the other providers in the future?

Glossary

abandonment Unilateral termination of care by the EMT without the patient's consent and without making provisions for transferring care to another medical professional with the skills and training necessary to meet the needs of the patient.

abdomen The body cavity that contains the major organs of digestion and excretion. It is located below the diaphragm and above the pelvis.

abdominal aortic aneurysm (AAA) A rapidly fatal condition in which the walls of the aorta in the abdomen weaken and blood leaks into the layers of the vessel, causing it to bulge.

abdominal-thrust maneuver The preferred method to dislodge a severe airway obstruction in adults and children; also called the Heimlich maneuver.

abduction Motion of a limb away from the midline.

abrasion Loss or damage of the superficial layer of skin as a result of a body part rubbing or scraping across a rough or hard surface.

abruptio placenta Premature separation of the placenta from the wall of the uterus.

absorption The process by which medications travel through body tissues until they reach the bloodstream.

access Gaining entry to an enclosed area and reaching a patient.

accessory muscles The secondary muscles of respiration. They include the neck muscles (sternocleidomastoids), the chest pectoralis major muscles, and the abdominal muscles.

acetabulum The depression on the lateral pelvis where its three component bones join, in which the femoral head fits snugly.

acidosis A pathologic condition that results from the accumulation of acids in the blood and body tissues.

acromioclavicular (AC) joint A simple joint where the bony projections of the scapula and the clavicle meet at the top of the shoulder.

action The therapeutic effect of a medication on the body.

activated charcoal An oral medication that binds and adsorbs ingested toxins in the gastrointestinal tract for treatment of some poisonings and medication overdoses. It is ground into a very fine powder that provides the greatest possible surface area for binding medications that have been taken by mouth; it is carried on the EMS unit.

active compression-decompression CPR A technique that involves compressing the chest and then actively pulling it back up to its neutral position or beyond (decompression); may increase the amount of blood that returns to the heart, and thus, the amount of blood ejected from the heart during the compression phase.

activities of daily living The basic activities a person usually accomplishes during a normal day, such as eating, dressing, and bathing.

acute abdomen A condition of sudden onset of pain within the abdomen, usually indicating peritonitis; immediate medical or surgical treatment is necessary.

acute coronary syndrome A group of symptoms caused by myocardial ischemia; includes angina and myocardial infarction.

acute myocardial infarction (AMI) A heart attack; death of heart muscle following obstruction of blood flow to it; in this context the attack is "new" or "happening right now."

acute stress reactions Reactions to stress that occur during a stressful situation.

Adam's apple A firm prominence of cartilage that forms the upper part of the larynx. It is more prominent in men than in women. Also called the thyroid cartilage.

addiction A state of overwhelming obsession or physical need to continue the use of a substance.

adduction Motion of a limb toward the midline.

adenosine triphosphate (ATP) The nucleotide involved in energy metabolism; used to store energy.

adolescents Children between ages 12 to 18 years.

adrenal glands Endocrine glands located on top of the kidneys that release adrenaline when stimulated by the sympathetic nervous system.

adrenergic Pertaining to nerves that release the neurotransmitter norepinephrine, or noradrenaline (such as adrenergic nerves, adrenergic response); also pertains to the receptors acted on by norepinephrine.

adsorption The process of binding or sticking to a surface.

advance directive Written documentation that specifies medical treatment for a competent patient should the patient become unable to make decisions; also called a living will or health care directive.

advanced EMT (AEMT) An individual who has training in specific aspects of advanced life support, such as intravenous therapy, and the administration of certain emergency medications.

advanced life support (ALS) Advanced lifesaving procedures, including cardiac monitoring, administration of intravenous fluids and medications, and the use of advanced airway adjuncts. EMTs may be trained in some of these areas.

adventitious breath sounds Abnormal breath sounds such as wheezing, stridor, rhonchi, and crackles.

aerobic metabolism Metabolism that can proceed only in the presence of oxygen.

afterload The force or resistance against which the heart pumps.

aging The process by which the temporary bond between the organophosphate and acetylcholinesterase undergoes hydrolysis, resulting in a permanent covalent bond.

agonal gasps Occasional, gasping breaths that occur after the heart has stopped; seen in dying patients.

agonist A medication that causes stimulation of receptors.

air ambulances Fixed-wing and rotary-wing (known as helicopters) aircrafts that have been modified for medical care; used to evacuate and transport patients with life-threatening injuries to treatment facilities.

air embolism The presence of air in the veins, which can lead to cardiac arrest if it enters the heart.

airborne transmission The spread of an organism via droplets or dust.

airway The upper airway tract or the passage above the larynx, which includes the nose, mouth, and throat.

alkalosis The buildup of excess base (lack of acids) in the body fluids.

allergen A substance that causes an allergic reaction.

allergic reaction The body's exaggerated immune response to an internal or surface agent.

alpha A type of energy that is emitted from a strong radiologic source; it is the least harmful penetrating type of radiation and cannot travel more than a few inches or penetrate most objects.

alpha-adrenergic receptors Portions of the nervous system that, when stimulated, can cause constriction of blood vessels.

altered mental status Any deviation from alert and oriented to person, place, time, and event, or any deviation from a patient's normal baseline mental status; may signal disease in the central nervous system or elsewhere in the body.

alveolar minute volume The volume of air moved through the lungs in 1 minute minus the dead space; calculated by multiplying tidal volume (minus dead space) and respiratory rate.

alveolar ventilation The volume of air that reaches the alveoli. It is determined by subtracting the amount of dead space air from the tidal volume.

alveoli The air sacs of the lungs in which the exchange of oxygen and carbon dioxide takes place.

ambient temperature The temperature of the surrounding environment.

ambulance A specialized vehicle for treating and transporting sick and injured patients.

American Standard Safety System A safety system for large oxygen cylinders, designed to prevent the accidental attachment of a regulator to a cylinder containing the wrong type of gas.

Americans With Disabilities Act (ADA) Comprehensive legislation that is designed to protect people with disabilities against discrimination.

amniotic sac The fluid-filled, baglike membrane in which the fetus develops.

amputation An injury in which part of the body is completely severed.

anaerobic metabolism The metabolism that takes place in the absence of oxygen; the main by-product is lactic acid.

anaphylactic shock Severe shock caused by an allergic reaction.

anaphylaxis An extreme, life-threatening, systemic allergic reaction that may include shock and respiratory failure.

anatomic position The position of reference in which the patient stands facing forward, arms at the side, with the palms of the hands forward.

anemic Describes a condition in which the patient has too few red blood cells, resulting in a decreased ability to transport oxygen throughout the body via the bloodstream.

aneurysm An abnormal enlargement of the wall of a blood vessel that results from weakening of the vessel wall.

angina pectoris Transient (short-lived) chest discomfort caused by partial or temporary blockage of blood flow to the heart muscle; also called *angina*.

angioedema Localized areas of swelling beneath the skin, often around the eyes and lips, but it can also involve other body areas as well.

anisocoria Naturally occurring uneven pupil size.

antagonist A medication that binds to a receptor and blocks other medications.

anterior The front surface of the body; the side facing you in the standard anatomic position.

anterograde (posttraumatic) amnesia Inability to remember events after an injury.

anthrax A disease caused by deadly bacteria (*Bacillus anthracis*) that lay dormant in a spore (protective shell); the germ is released from the spore when exposed to the optimal temperature and moisture. The routes of entry are inhalation, cutaneous, and gastrointestinal (from consuming food that contains spores).

antidote A substance that is used to neutralize or counteract a poison.

Antidote Treatment Nerve Agent Auto-Injector (ATNAA) A nerve agent antidote kit containing atropine and pralidoxime chloride; delivered as a single dose through one needle.

antivenin A serum that counteracts the effect of venom from an animal or insect.

aorta The main artery leaving the left side of the heart, which receives blood from the left ventricle and delivers it to all the other arteries that carry blood to the tissues of the body.

aortic aneurysm A weakness in the wall of the aorta that makes it susceptible to rupture.

aortic valve The one-way valve that lies between the left ventricle and the aorta and keeps blood from flowing back into the left ventricle after the left ventricle ejects its blood into the aorta; one of four heart valves.

apex (apices) The pointed extremity of a conical structure.

Apgar score A scoring system for assessing the status of a newborn that assigns a number value to each of five areas.

aphasia The inability to understand and/or produce speech.

apnea Absence of spontaneous breathing.

apneic oxygenation A technique in which oxygen administered via a high-flow nasal cannula is left in place during an intubation attempt, allowing for continuous oxygen delivery into the airways during all phases of the procedure.

apparent life-threatening event (ALTE) An event that causes unresponsiveness, cyanosis, and apnea in an infant, who then resumes breathing with stimulation.

appendicitis Inflammation or infection of the appendix.

appendicular skeleton The portion of the skeletal system that comprises the arms, legs, pelvis, and shoulder girdle.

appendix A small, tubular structure that is attached to the lower border of the cecum in the lower right quadrant of the abdomen.

applied ethics The manner in which principles of ethics are incorporated into professional conduct.

arterial air embolism Air bubbles in the arterial blood vessels.

arterioles The smallest branches of arteries leading to the vast network of capillaries.

arteriosclerosis A disease that causes the arteries to thicken, harden, and calcify.

artery A blood vessel, consisting of three layers of tissue and smooth muscle, that carries blood away from the heart.

articular cartilage A pearly white layer of specialized cartilage covering the articular surfaces (contact surfaces on the ends) of bones in synovial joints.

artifact A tracing on an ECG that is the result of interference, such as patient movement, rather than the heart's electrical activity.

ascites Fluid in the abdomen.

aseptic technique A technique that helps ensure pathogens are not introduced anywhere in the procedure, achieved by sterilization of equipment, or use of antiseptics or disinfectants; often used for fast, invasive procedures such as starting an IV line.

aspiration In the context of airway, the introduction of vomitus or other foreign material into the lungs.

aspirin (acetylsalicylic acid or ASA) A medication that is an antipyretic (reduces fever), analgesic (reduces pain), anti-inflammatory (reduces inflammation), and a potent inhibitor of platelet aggregation (clumping).

assault Unlawfully placing a patient in fear of bodily harm.

asthma An acute spasm of the smaller air passages, called bronchioles, associated with excessive mucus production and with swelling of the mucous lining of the respiratory passages.

asystole The complete absence of all heart electrical activity.

ataxic respirations Irregular, ineffective respirations that may or may not have an identifiable pattern.

atelectasis Collapse of the alveolar air spaces of the lungs.

atherosclerosis A disorder in which cholesterol and calcium build up inside the walls of the blood vessels, forming plaque, eventually leading to a partial or complete blockage of blood flow.

atrium One of two (right and left) upper chambers of the heart. The right receives blood from the vena cava and delivers it to the right ventricle. The left receives blood from pulmonary veins and delivers it to the left ventricle.

aura A sensation experienced before a seizure; serves as a warning sign that a seizure is about to occur.

auscultate To listen to sounds within an organ with a stethoscope.

autism spectrum disorder (ASD) A group of complex disorders of brain development, characterized by difficulties in social interaction, repetitive behaviors, and verbal and nonverbal communication.

automated external defibrillator (AED) A device that detects treatable life-threatening cardiac arrhythmias (ventricular fibrillation and ventricular tachycardia) and delivers the appropriate electrical shock to the patient.

automatic transport ventilator (ATV) A ventilation device attached to a control box that allows the variables of ventilation to be set. It frees the EMT to perform other tasks while the patient is being ventilated.

automaticity The ability of cardiac muscle cells to contract without stimulation from the nervous system.

autonomic nervous system The part of the nervous system that regulates involuntary activities of the body, such as heart rate, blood pressure, and digestion of food.

AVPU scale A method of assessing the level of consciousness by determining whether the patient is awake and alert, responsive to verbal stimuli or pain, or unresponsive; used principally early in the assessment process.

avulsion An injury in which soft tissue is torn completely loose or is hanging as a flap.

axial loading injuries Injuries in which load is applied along the vertical or longitudinal axis of the spine, which results in load being transmitted along the entire length of the vertebral column; for example, falling from a height and landing on the feet in an upright position.

axial skeleton The part of the skeleton comprising the skull, spinal column, and rib cage.

B-NICE A memory device to recall the types of weapons of mass destruction: biologic, nuclear, incendiary, chemical, and explosive.

backboard A long, flat board made of rigid, rectangular material that is used to provide support to a patient who is suspected of having a hip, pelvic, spinal, or lower extremity injury; also called a spine board, trauma board, and longboard.

bacteria Microorganisms that reproduce by binary fission. These single-cell creatures reproduce rapidly. Some can form spores (encysted variants) when environmental conditions are harsh.

bacterial vaginosis An overgrowth of bacteria in the vagina; characterized by itching, burning, or pain, and possibly a “fishy” smelling discharge.

bag-valve mask (BVM) A device with a one-way valve and a face mask attached to a ventilation bag; when attached to a reservoir and connected to oxygen, it delivers more than 90% supplemental oxygen.

ball-and-socket joint A joint that allows internal and external rotation, as well as bending.

bariatrics A branch of medicine concerned with the management (prevention or control) of obesity and allied diseases.

barotrauma Injury caused by pressure to enclosed body surfaces, for example, from too much pressure in the lungs.

barrier device A protective item, such as a pocket mask with a valve, that limits exposure to a patient’s body fluids.

base station Any radio hardware containing a transmitter and receiver that is located in a fixed place.

basic life support (BLS) Noninvasive emergency lifesaving care that is used to treat medical conditions, including airway obstruction, respiratory arrest, and cardiac arrest.

basilar skull fractures Usually occur following diffuse impact to the head (such as falls, motor vehicle crashes); generally result from extension of a linear fracture to the base of the skull and can be difficult to diagnose with a radiograph.

basket stretcher A rigid stretcher commonly used in technical and water rescues that surrounds and supports the patient yet allows water to drain through holes in the bottom; also called a Stokes litter.

battery Unlawfully touching a patient or providing emergency care without consent.

Battle sign Bruising behind an ear over the mastoid process that may indicate a skull fracture.

behavior How a person functions or acts in response to his or her environment.

behavioral crisis The point at which a person's reactions to events interfere with activities of daily living; this becomes a psychiatric emergency when it causes a major life interruption, such as attempted suicide.

bends A painful condition seen in divers who ascend too quickly, in which gas, especially nitrogen, forms bubbles in blood vessels and other tissues; also called decompression sickness.

beta A type of energy that is emitted from a strong radiologic source; is slightly more penetrating than alpha and requires a layer of clothing to stop it.

beta-adrenergic receptors Portions of the nervous system that, when stimulated, can cause an increase in the force of contraction of the heart, an increased heart rate, and bronchial dilation.

biceps The large muscle that covers the front of the humerus.

bilateral A body part or condition that appears on both sides of the midline.

bile ducts The ducts that convey bile between the liver and the intestine.

bills of lading The shipping papers used for transport of chemicals over roads and highways; also referred to as freight bills.

bioethics The study of ethics related to issues that arise in health care.

birth canal The vagina and cervix.

blanch To turn white.

blind spots Areas of the road that are blocked from your view by your vehicle or mirrors.

blood pressure (BP) The pressure that the blood exerts against the walls of the arteries as it passes through them.

bloodborne pathogens Pathogenic microorganisms that are present in human blood and can cause disease in humans. These pathogens include, but are not limited to, hepatitis B virus and human immunodeficiency virus (HIV).

bloody show A small amount of blood in the vagina that appears at the beginning of labor and may include a plug of pinktinged mucus that is discharged when the cervix begins to dilate.

blow-out fracture A fracture of the orbit or of the bones that support the floor of the orbit.

blunt trauma An impact on the body by objects that cause injury without penetrating soft tissues or internal organs and cavities.

body mechanics The relationship between the body's anatomical structures and the physical forces associated with lifting, moving, and carrying; the ways in which the body moves to achieve a specific action.

botulinum Produced by bacteria, this is the most potent neurotoxin known. When introduced into the body, this neurotoxin affects the nervous system's ability to function and causes botulism.

brachial artery The major vessel in the upper extremities that supplies blood to the arm.

bradycardia A slow heart rate, less than 60 beats/min.

bradypnea Slow respiratory rate; in a child it is an ominous sign that indicates impending respiratory arrest.

brain The controlling organ of the body and center of consciousness; functions include perception, control of reactions to the environment, emotional responses, and judgment.

brain stem The area of the brain between the spinal cord and cerebrum, surrounded by the cerebellum; controls functions that are necessary for life, such as respiration.

breach of confidentiality Disclosure of information without proper authorization.

breath sounds An indication of air movement in the lungs, usually assessed with a stethoscope.

breath-holding syncope Loss of consciousness caused by a decreased breathing stimulus.

breech presentation A delivery in which the buttocks come out first.

bronchial breath sounds Normal breath sounds made by air moving through the bronchi.

bronchioles Subdivision of the smaller bronchi in the lungs; made of smooth muscle and dilate or constrict in response to various stimuli.

bronchiolitis Inflammation of the bronchioles that usually occurs in children younger than 2 years and is often caused by the respiratory syncytial virus.

bronchitis An acute or chronic inflammation of the lung that may damage lung tissue; usually associated with cough and production of sputum and, depending on its cause, sometimes fever.

buboes Enlarged lymph nodes (up to the size of a tennis ball) that are characteristic in people infected with the bubonic plague.

bubonic plague Bacterial infection that affects the lymphatic system. It is transmitted by infected rodents and fleas and characterized by acute malaise, fever, and the formation of tender, enlarged, inflamed lymph nodes that appear as lesions, called buboes. Also called the Black Death.

bulk storage containers Any container other than nonbulky storage containers such as fixed tanks, highway cargo tanks, rail tank cars, totes, and intermodal tanks. These are typically found in manufacturing facilities and are often surrounded by a secondary containment system to help control an accidental release.

burns Injuries in which soft-tissue damage occurs as a result of thermal heat, frictional heat, toxic chemicals, electricity, or nuclear radiation.

calcaneus The heel bone.

capillaries The small blood vessels that connect arterioles and venules; various substances pass through capillary walls, into and out of the interstitial fluid, and then on to the cells.

capillary refill A test that evaluates distal circulatory system function by squeezing (blanching) blood from an area such as a nail bed and watching the speed of its return after releasing the pressure.

capillary vessels The tiny blood vessels between the arterioles and venules that permit transfer of oxygen, carbon dioxide, nutrients, and waste between body tissues and the blood.

capnography A noninvasive method to quickly and efficiently provide information on a patient's ventilatory status, circulation, and metabolism; effectively measures the concentration of carbon dioxide in expired air over time.

capnometry The use of a capnometer, a device that measures the amount of expired carbon dioxide.

carbon dioxide Carbon dioxide is a component of air and typically makes up 0.3% of air at sea level; also a waste product exhaled during expiration by the respiratory system.

carbon dioxide retention A condition characterized by a chronically high blood level of carbon dioxide in which the respiratory center no longer responds to high blood levels of carbon dioxide.

carbon monoxide An odorless, colorless, tasteless, and highly poisonous gas that results from incomplete oxidation of carbon in combustion.

carboys Glass, plastic, or steel containers, ranging in volume from 5 to 15 gallons (19 to 57 L).

cardiac arrest When the heart fails to generate effective and detectable blood flow; pulses are not palpable in cardiac arrest, even if muscular and electrical activity continues in the heart.

cardiac muscle The heart muscle.

cardiac output (CO) A measure of the volume of blood circulated by the heart in 1 minute, calculated by multiplying the stroke volume by the heart rate.

cardiac tamponade (pericardial tamponade) Compression of the heart as the result of buildup of blood or other fluid in the pericardial sac, leading to decreased cardiac output.

cardiogenic shock A state in which not enough oxygen is delivered to the tissues of the body, caused by low output of blood from the heart. It can be a severe complication of a large acute myocardial infarction, as well as other conditions.

cardiopulmonary resuscitation (CPR) The combination of chest compressions and rescue breathing used to establish adequate ventilation and circulation in a patient who is not breathing and has no pulse.

carina Point at which the trachea bifurcates (divides) into the left and right mainstem bronchi.

carotid artery The major artery that supplies blood to the head and brain.

cartilage The smooth connective tissue that forms the support structure of the skeletal system and provides cushioning between bones; also forms the nasal septum and portions of the outer ear.

casualty collection area An area set up by physicians, nurses, and other hospital staff near a major disaster scene where patients can receive further triage and medical care.

cataracts Clouding of the lens of the eye or its surrounding transparent membranes.

cavitation A phenomenon in which speed causes a bullet to generate pressure waves, which cause damage distant from the bullet's path.

cecum The first part of the large intestine, into which the ileum opens.

cellular telephone A low-power portable radio that communicates through an interconnected series of repeater stations called "cells."

Centers for Disease Control and Prevention (CDC) The primary federal agency that conducts and supports public health activities in the United States. It is part of the US Department of Health and Human Services.

central nervous system (CNS) The brain and spinal cord.

central pulses Pulses that are closest to the core (central) part of the body where the vital organs are located; include the carotid, femoral, and apical pulses.

cerebellum One of the three major subdivisions of the brain, sometimes called the little brain; coordinates the various activities of the brain, particularly fine body movements.

cerebral edema Swelling of the brain.

cerebral palsy A group of disorders characterized by poorly controlled body movement.

cerebrospinal fluid (CSF) Fluid produced in the ventricles of the brain that flows in the subarachnoid space and bathes the meninges.

cerebrovascular accident (CVA) An interruption of blood flow to the brain that results in the loss of brain function; also called a stroke.

cerebrum The largest part of the three subdivisions of the brain, sometimes called the gray matter; made up of several lobes that control movement, hearing, balance, speech, visual perception, emotions, and personality.

certification A process in which a person, an institution, or a program is evaluated and recognized as meeting certain predetermined standards to provide safe and ethical patient care.

cervical spine The portion of the spinal column consisting of the first seven vertebrae that lie in the neck.

cervix The lower third, or neck, of the uterus; it is the narrowest portion of the uterus and opens into the vagina.

channel An assigned frequency or frequencies that are used to carry voice and/or data communications.

Chemical Transportation Emergency Center (CHEMTREC) An agency that assists emergency responders in identifying and handling hazardous materials transport incidents.

chemoreceptors Monitor the levels of O_2, CO_2, and the pH of the cerebrospinal fluid and then provide feedback to the respiratory centers to modify the rate and depth of breathing based on the body's needs at any given time.

chest compression fraction The total percentage of time during a resuscitation attempt in which active chest compressions are being performed.

chief complaint The reason a patient called for help; also, the patient's response to questions such as "What's wrong?" or "What happened?"

child abuse A general term applying to all forms of abuse and neglect of children.

chlamydia A sexually transmitted disease caused by the bacterium *Chlamydia trachomatis*.

chlorine (Cl) The first chemical agent ever used in warfare. It has a distinct odor of bleach and creates a green haze when released as a gas. Initially it produces upper airway irritation and a choking sensation.

cholecystitis Inflammation of the gallbladder.

chordae tendineae Thin bands of fibrous tissue that attach to the valves in the heart and prevent them from inverting.

chronic bronchitis Irritation of the major lung passageways from infectious disease or irritants such as smoke.

chronic obstructive pulmonary disease (COPD) A slow process of dilation and disruption of the airways and alveoli caused by chronic bronchial obstruction.

chyme The substance that leaves the stomach. It is a combination of all of the eaten foods with added stomach acids.

circulatory system The complex arrangement of connected tubes, including the arteries, arterioles, capillaries, venules, and veins, that moves blood, oxygen, nutrients, carbon dioxide, and cellular waste throughout the body.

clavicle The collar bone; it is lateral to the sternum and anterior to the scapula.

clean technique A technique in which the amount of pathogens or unclean materials picked up or transferred is minimized through the use of routine handwashing, nonsterile protective gloves, etc.

cleaning The process of removing dirt, dust, blood, or other visible contaminants from a surface.

closed abdominal injury An injury in which there is soft-tissue damage inside the body but the skin remains intact.

closed chest injury An injury to the chest in which the skin is not broken, usually caused by blunt trauma.

closed fracture Any break in a bone in which the overlying skin is not broken.

closed head injury Injury in which the brain has been injured but the skin has not been broken and there is no obvious bleeding.

closed incident An incident that is contained; all casualties are accounted for.

closed injuries Injuries in which damage occurs beneath the skin or mucous membrane but the surface of the skin remains intact.

closed-ended questions Questions that can be answered in short or single word responses.

coagulation The formation of a clot to plug an opening in an injured blood vessel and stop bleeding.

coccyx The last three or four vertebrae of the spine; the tail bone.

cold zone A safe area at a hazardous materials incident for the agencies involved in the operations. The incident commander, the command post, EMS providers, and other support functions necessary to control the incident should be located in this zone. Also referred to as the clean zone or the support zone.

colostomy A surgical procedure to create an opening (stoma) between the colon and the surface of the body.

coma A state of profound unconsciousness from which the patient cannot be roused.

combining vowel The vowel used to combine two word roots or a word root and suffix.

command In incident command, the position that oversees the incident, establishes the objectives and priorities, and develops a response plan.

command post The location of the incident commander at the scene of an emergency and where command, coordination, control, and communication are centralized.

commotio cordis A blunt chest injury caused by a sudden, direct blow to the chest that occurs only during the critical portion of a person's heartbeat.

communicable disease A disease that can be spread from one person or species to another.

communication The transmission of information to another person—verbally or through body language.

community paramedicine A health care model in which experienced paramedics receive advanced training to equip them to provide additional services in the prehospital environment, such as health evaluations, monitoring of chronic illnesses or conditions, and patient advocacy.

compartment syndrome Swelling within a confined anatomic compartment that produces dangerous pressure, characterized by extreme pain, decreased pain sensation, pain on stretching of affected muscles, and decreased power.

compensated shock The early stage of shock, in which the body can still compensate for blood loss.

compensatory damages Damages awarded in a civil lawsuit that are intended to restore the plaintiff to the same condition that he or she was in prior to the incident.

competent Able to make rational decisions about personal well-being.

complex access Entry that requires special tools and training and includes the use of force.

compliance The ability of the alveoli to expand when air is drawn in during inhalation.

concealment The use of objects to limit a person's visibility of you.

concussion A temporary loss or alteration of part or all of the brain's abilities to function without actual physical damage to the brain.

conduction The loss of heat by direct contact (eg, when a body part comes into contact with a colder object).

conductive hearing loss Hearing loss caused by a faulty transmission of sound waves.

congestive heart failure (CHF) A disorder in which the heart loses part of its ability to effectively pump blood, usually as a result of damage to the heart muscle and usually resulting in a backup of fluid into the lungs.

conjunctiva The delicate membrane that lines the eyelids and covers the exposed surface of the eye.

conjunctivitis Inflammation of the conjunctiva.

consent In the context of EMS, permission to render care.

contact burn A burn caused by direct contact with a hot object.

contact hazard The term used to describe danger posed by a chemical whose primary route of entry into the body is through the skin; posed by a hazardous agent that gives off very little or no vapors; also called a skin hazard.

contagious An infectious disease that spreads from one human to another; communicable.

container Any vessel or receptacle that holds material, including storage vessels, pipelines, and packaging.

contamination The presence of infectious organisms on or in objects such as dressings, water, food, needles, wounds, or a patient's body; also, the presence of foreign bodies such as dirt, gravel, or metal.

continuous positive airway pressure (CPAP) A method of ventilation used primarily in the treatment of critically ill patients with respiratory distress; can prevent the need for endotracheal intubation.

continuous quality improvement (CQI) A system of internal and external reviews and audits of all aspects of an EMS system.

continuum of care The concept of consistent patient care across the entire health care team from first patient contact to patient discharge; working together with a unified goal, results in improved individual and team performance, better patient and provider safety, and improved patient outcome.

contraindications Conditions that make a particular medication or treatment inappropriate because it would not help, or may actually harm, a patient.

contributory negligence A legal defense that may be raised when the defendant feels that the conduct of the plaintiff somehow contributed to any injuries or damages that were sustained by the plaintiff.

control zones Areas at a hazardous materials incident that are designated as hot, warm, or cold, based on safety issues and the degree of hazard found there.

contusion A bruise from an injury that causes bleeding beneath the skin without breaking the skin; also see ecchymosis.

convection The loss of body heat caused by air movement (eg, a breeze blowing across the body).

conventional reasoning A type of reasoning in which a child looks for approval from peers and society.

core temperature The temperature of the central part of the body (eg, the heart, lungs, and vital organs).

cornea The transparent tissue layer in front of the pupil and iris of the eye.

coronal plane An imaginary plane where the body is divided into front and back parts.

coronary arteries The blood vessels that carry blood and nutrients to the heart muscle.

coup-contrecoup brain injury A brain injury that occurs when force is applied to the head and energy transmission through brain tissue causes injury on the opposite side of original impact; coup injury occurs at the point of impact; contrecoup injury occurs on the opposite side of impact, as the brain rebounds.

cover The tactical use of an impenetrable barrier for protection.

covert An act in which the public safety community generally has no prior knowledge of the time, location, or nature of the attack.

CPR board A device that provides a firm surface under the patient's torso.

crackles Crackling, rattling breath sounds signaling fluid in the air spaces of the lungs; formerly called rales.

cranium The area of the head above the ears and eyes; the skull. It contains the brain.

credentialing An established process to determine the qualifications necessary to be allowed to practice a particular profession, or to function as an organization.

crepitus A grating or grinding sensation caused by fractured bone ends or joints rubbing together; also air bubbles under the skin that produce a crackling sound or crinkly feeling.

crew resource management (CRM) A set of procedures for use in environments where human error can have disastrous consequences. It empowers people within a team to communicate effectively with one another with a goal of improving team situational awareness, patient and crew safety, and overall communication.

cricoid cartilage A firm ridge of cartilage that forms the lower part of the larynx.

cricothyroid membrane A thin sheet of fascia that connects the thyroid and cricoid cartilages that make up the larynx.

critical incident stress management (CISM) A process that confronts the responses to critical incidents and defuses them, directing the emergency services personnel toward physical and emotional equilibrium.

cross-contamination Occurs when a person is contaminated by an agent as a result of coming into contact with another contaminated person.

croup An inflammatory disease of the upper respiratory system that may cause a partial airway obstruction and is characterized by a barking cough; usually seen in children.

crowning The appearance of the fetus's head at the vaginal opening during labor.

crush syndrome Significant metabolic derangement that develops when crushed extremities or body parts remain trapped for prolonged periods. This can lead to renal failure and death.

crushing injury An injury that occurs when a great amount of force is applied to the body.

cultural imposition When one person imposes his or her beliefs, values, and practices on another because he or she believes his or her ideals are superior.

cumulative stress reactions Prolonged or excessive stress.

cushion of safety Keeping a safe distance between your vehicle and any vehicles around you.

cyanide An agent that affects the body's ability to use oxygen. It is a colorless gas that has an odor similar to almonds. The effects begin on the cellular level and are very rapidly seen at the organ and system levels.

cyanosis A blue-gray skin color that is caused by a reduced level of oxygen in the blood.

cylinders Portable, compressed gas containers used to hold liquids and gases such as nitrogen, argon, helium, and oxygen. They have a range of sizes and internal pressures.

cystitis Inflammation of the bladder.

danger zone (hot zone) An area where people can be exposed to hazards such as electric wires, sharp metal edges, broken glass, toxic substances, lethal radiation, fire, or hazardous materials.

DCAP-BTLS A mnemonic for assessment in which each area of the body is evaluated for Deformities, Contusions, Abrasions, Punctures/penetrations, Burns, Tenderness, Lacerations, and Swelling.

dead space The portion of the tidal volume that does not reach the alveoli and thus does not participate in gas exchange; in some contexts, any portion of the airway that does contain air and cannot participate in gas exchange, such as the trachea and bronchi.

decay A natural process in which a material that is unstable attempts to stabilize itself by changing its structure.

deceleration The slowing of an object.

decision-making capacity Ability to understand and process information and make a choice regarding appropriate medical care.

decompensated shock The late stage of shock when blood pressure is falling.

decompression sickness A painful condition seen in divers who ascend too quickly, in which gas, especially nitrogen, forms bubbles in blood vessels and other tissues; see bends.

decontaminate To remove or neutralize radiation, chemical, or other hazardous material from clothing, equipment, vehicles, and personnel.

decontamination The process of removing or neutralizing radioactive, chemical, or other hazardous material from clothing, equipment, vehicles, patients, and responders and properly disposing of it.

decontamination area The designated area in a hazardous materials incident where all patients and responders must be decontaminated before going to another area.

decubitus ulcers Sores caused by the pressure of skin against a surface for long periods; can range from a pink discoloration of the skin to a deep wound that may invade into bone or organs; also known as bedsores.

dedicated line A special telephone line that is used for specific point-to-point communications; also known as a *hotline*.

deep Farther inside the body and away from the skin.

deep venous thrombosis The formation of a blood clot within the larger veins of an extremity, typically following a period of prolonged immobilization.

defamation The communication of false information about a person that is damaging to that person's reputation or standing in the community.

defibrillate To shock a fibrillating (chaotically beating) heart with specialized electric current in an attempt to restore a normal, rhythmic beat.

dehydration Loss of water from the tissues of the body.

delayed stress reactions Reactions to stress that occur after a stressful situation.

delirium A sudden change in mental status that is generally acute and reversible, characterized by disorientation, inability to focus, inattention, inability to think logically, memory loss, striking changes in personality and affect, hallucinations, delusions, or a decreased level of consciousness.

delirium tremens (DTs) A severe withdrawal syndrome seen in alcoholics who are deprived of ethyl alcohol; characterized by restlessness, fever, sweating, disorientation, agitation, and seizures; can be fatal if untreated.

dementia The slow onset of progressive disorientation, shortened attention span, and loss of cognitive function; this condition is generally chronic and irreversible.

demobilization The process of directing responders to return to their facilities when work at a disaster or masscasualty incident has finished, at least for those particular responders.

dependent edema Swelling in the part of the body closest to the ground, caused by collection of fluid in the tissues; a possible sign of congestive heart failure.

dependent lividity Blood settling to the lowest point of the body, causing discoloration of the skin; a definitive sign of death.

depositions Oral questions asked of parties and witnesses under oath.

depression A persistent mood of sadness, despair, and discouragement; may be a symptom of many different mental and physical disorders, or it may be a disorder on its own.

dermis The inner layer of the skin, containing hair follicles, sweat glands, nerve endings, and blood vessels.

designated officer The individual in the department who is charged with the responsibility of managing exposures and infection control issues.

developmental disability Insufficient development of the brain, resulting in some level of dysfunction or impairment.

diabetes mellitus A metabolic disorder in which the ability to metabolize carbohydrates (sugars) is impaired, usually because of a lack of insulin.

diabetic ketoacidosis (DKA) A form of hyperglycemia in uncontrolled diabetes in which certain acids accumulate when insulin is not available.

diamond carry A carrying technique in which one provider is located at the head end of the stretcher or backboard, one at the foot end, and one at each side of the patient; each of the two providers at the sides uses one hand to support the stretcher or backboard so that all are able to face forward as they walk.

diaphoretic Characterized by light or profuse sweating.

diaphragm A muscular dome that forms the undersurface of the thorax, separating the chest from the abdominal cavity. Contraction of this (and the chest wall muscles) brings air into the lungs. Relaxation allows air to be expelled from the lungs.

diastole The relaxation, or period of relaxation, of the heart, especially of the ventricles.

diastolic pressure The pressure that remains in the arteries during the relaxing phase of the heart's cycle (diastole) when the left ventricle is at rest.

diffusion A process in which molecules move from an area of higher concentration to an area of lower concentration.

digestion The processing of food that nourishes the individual cells of the body.

dilation Widening of a tubular structure such as a coronary artery.

diphtheria An infectious disease in which a membrane forms, lining the pharynx; this lining can severely obstruct the passage of air into the larynx.

direct contact Exposure or transmission of a communicable disease from one person to another by physical contact.

direct ground lift A lifting technique that is used for patients who are found lying supine on the ground with no suspected spinal injury.

direct laryngoscopy Visualization of the airway with a laryngoscope.

dirty bomb Name given to an explosive radiologic dispersal device.

disaster A widespread event that disrupts community resources and functions, in turn threatening public safety, citizens' lives, and property.

discovery The phase of a civil lawsuit where the plaintiff and defense obtain information from each other that will enable the attorneys to have a better understanding of the case, which will assist in negotiating a possible settlement or in preparing for trial. This phase includes depositions, interrogatories, and demands for production of records.

disease vector An animal that spreads a disease, once infected, to another animal.

disinfection The killing of pathogenic agents by direct application of chemicals.

dislocation Disruption of a joint in which ligaments are damaged and the bone ends are no longer in contact.

displaced fracture A fracture in which bone fragments are separated from one another, producing deformity in the limb.

dissecting aneurysm A condition in which the inner layers of an artery, such as the aorta, become separated, allowing blood (at high pressures) to flow between the layers.

dissemination The means by which a terrorist will spread an agent, for example, by poisoning the water supply or aerosolizing the agent into the air or ventilation system of a building.

distal Further from the trunk or nearer to the free end of the extremity.

distracting injury Any injury that prevents the patient from noticing other injuries he or she may have, even severe injuries; for example, a painful femur or tibia fracture that prevents the patient from noticing back pain associated with a spinal fracture.

distributive shock A condition that occurs when there is widespread dilation of the small arterioles, small venules, or both.

diverticulitis Inflammation in small pockets at weak areas in the muscle walls.

diving reflex The slowing of the heart rate caused by submersion in cold water.

do not resuscitate (DNR) orders Written documentation by a physician giving permission to medical personnel not to attempt resuscitation in the event of cardiac arrest.

documentation The recorded portion of the EMT's patient interaction, either written or electronic. This becomes part of the patient's permanent medical record.

domestic terrorism Terrorism that is carried out by people in their own country.

dorsal The posterior surface of the body, including the back of the hand.

dorsalis pedis artery The artery on the anterior surface of the foot between the first and second metatarsals.

dose The amount of medication given on the basis of the patient's size and age.

Down syndrome A genetic chromosomal defect that can occur during fetal development and that results in intellectual impairment as well as certain physical characteristics, such as a round head with a flat occiput and slanted, wide-set eyes.

drag Resistance that slows a projectile, such as air.

drowning The process of experiencing respiratory impairment from submersion or immersion in liquid.

drums Barrel-like containers used to store a wide variety of substances, including food-grade materials, corrosives, flammable liquids, and grease. May be constructed of low-carbon steel, polyethylene, cardboard, stainless steel, nickel, or other materials.

DuoDote Auto-Injector A nerve agent antidote kit containing atropine and pralidoxime chloride; delivered as a single dose through one needle.

duplex The ability to transmit and receive simultaneously.

durable power of attorney for health care A type of advance directive executed by a competent adult that appoints another individual to make medical treatment decisions on his or her behalf, in the event that the person making the appointment loses decision-making capacity.

duty to act A medicolegal term relating to certain personnel who either by statute or by function have a responsibility to provide care.

dysarthria Slurred speech.

dysbarism injuries Any signs and symptoms caused by the difference between the surrounding atmospheric pressure and the total gas pressure in various tissues, fluids, and cavities of the body.

dyspnea Shortness of breath or difficulty breathing.

dysrhythmia An irregular or abnormal heart rhythm.

early adult A young adult age 19 to 40 years.

ecchymosis A buildup of blood beneath the skin that produces a characteristic blue or black discoloration as the result of an injury; also see contusion.

eclampsia Severe hypertension in a pregnant woman, resulting in seizures (convulsions).

ectopic pregnancy A pregnancy that develops outside the uterus, typically in a fallopian tube.

edema The presence of abnormally large amounts of fluid between cells in body tissues, causing swelling of the affected area.

elder abuse Any action on the part of an older person's family member, caregiver, or other associated person that takes advantage of the older person's person, property, or emotional state.

emancipated minor A person who is under the legal age in a given state but, because of other circumstances, is legally considered an adult.

embolus A blood clot or other substance in the circulatory system that travels to a blood vessel where it causes a blockage.

embryo The early stage of development after the fertilization of the egg (first 10 weeks).

emergency A serious situation, such as injury or illness that threatens the life or welfare of a person or group of people and requires immediate intervention.

emergency doctrine The principle of law that permits a health care provider to treat a patient in an emergency situation when the patient is incapable of granting consent because of an altered level of consciousness, disability, the effects of drugs or alcohol, or the patient's age.

emergency medical care Immediate care or treatment.

emergency medical dispatch (EMD) A system that assists dispatchers in selecting appropriate units to respond to a particular call for assistance and provides callers with vital instructions until the arrival of EMS crews.

emergency medical responder (EMR) The first trained professional, such as a police officer, firefighter, lifeguard, or other rescuer, to arrive at the scene of an emergency to provide initial medical assistance.

emergency medical services (EMS) A multidisciplinary system that represents the combined efforts of several professionals and agencies to provide prehospital emergency care to the sick and injured.

emergency medical technician (EMT) An individual who has training in basic life support, including automated external defibrillation, use of a definitive airway adjunct, and assisting patients with certain medications.

emergency move A move in which the patient is dragged or pulled from a dangerous scene before assessment and care are provided.

Emergency Response Guidebook (ERG) A preliminary action guide for first responders operating at a hazardous materials incident in coordination with the US Department of Transportation's labels and placards marking system. Jointly developed by the DOT, the Secretariat of Communications and Transportation of Mexico, and Transport Canada.

emesis Vomiting.

emphysema A disease of the lungs in which there is extreme dilation and eventual destruction of the pulmonary alveoli with poor exchange of oxygen and carbon dioxide; it is one form of chronic obstructive pulmonary disease.

EMT-administered medication Administration of a medication by the EMT directly to the patient.

endocrine glands Glands that secrete or release chemicals that are used inside the body.

endocrine system The complex message and control system that integrates many body functions, including the release of hormones; also regulates metabolism and maintains homeostasis.

endometrium The lining of the inside of the uterus.

end-tidal CO_2 The amount of carbon dioxide present at the end of an exhaled breath.

endotracheal (ET) intubation Insertion of an endotracheal tube directly through the larynx between the vocal cords and into the trachea to maintain and protect an airway.

enteral medications Medications that enter the body through the digestive system.

entrapment To be caught (trapped) within a vehicle, room, or container with no way out or to have a limb or other body part trapped.

envenomation The act of injecting venom.

enzymes Substances designed to speed up the rate of specific biochemical reactions.

epidemic Occurs when new cases of a disease in a human population substantially exceed the number expected based on recent experience.

epidermis The outer layer of skin, which is made up of cells that are sealed together to form a watertight protective covering for the body.

epidural hematoma An accumulation of blood between the skull and the dura mater.

epiglottis A thin, leaf-shaped valve that allows air to pass into the trachea but prevents food and liquid from entering.

epiglottitis A disease in which the epiglottis becomes inflamed and enlarged and may cause an upper airway obstruction.

epilepsy A disorder in which abnormal electrical discharges occur in the brain, causing seizure and possible loss of consciousness.

epinephrine A substance produced by the body (commonly called adrenaline) that has a vital role in the function of the sympathetic nervous system; also, a drug produced by pharmaceutical companies, that increases pulse rate and blood pressure; the drug of choice for an anaphylactic reaction. It also eases breathing problems by decreasing muscle tone of the bronchiole tree.

epistaxis A nosebleed.

esophageal intubation The improper placement of an advanced airway device into the esophagus rather than into the trachea.

esophagus A collapsible tube that extends from the pharynx to the stomach; muscle contractions propel food and liquids through it to the stomach.

ethics The philosophy of right and wrong, of moral duties, and of ideal professional behavior.

ethnocentrism When a person considers his or her own cultural values as more important when interacting with people of a different culture.

eustachian tube A branch of the internal auditory canal that connects the middle ear to the oropharynx.

evaporation The conversion of water or another fluid from a liquid to a gas.

evisceration The displacement of organs outside of the body.

excited delirium A serious behavioral condition in which a person exhibits agitated behavior combined with disorientation, hallucinations, or delusions; also called agitated delirium or exhaustive mania.

exhalation The passive part of the breathing process in which the diaphragm and the intercostal muscles relax, forcing air out of the lungs.

expiratory reserve volume The amount of air that can be exhaled following a normal exhalation; average volume is about 1,200 mL in the average adult man.

exposure A situation in which a person has had contact with blood, body fluids, tissues, or airborne particles in a manner that suggests disease transmission may occur.

expressed consent A type of consent in which a patient gives verbal or nonverbal authorization for provision of care or transport.

extension The straightening of a joint.

external auditory canal The ear canal; leads to the tympanic membrane.

external respiration The exchange of gases between the lungs and the blood cells in the pulmonary capillaries; also called pulmonary respiration.

extremity lift A lifting technique that is used for patients who are supine or in a sitting position with no suspected extremity or spinal injuries.

extrication Removal of a patient from entrapment or a dangerous situation or position, such as removal from a wrecked vehicle, industrial incident, or collapsed building.

extrication supervisor In incident command, the person appointed to determine the type of equipment and resources needed for a situation involving extrication or special rescue; also called the rescue officer.

eyes forward position A head position in which the patient's eyes are looking straight ahead and the head and torso are in line.

fallopian tubes The tubes that extend from the uterus to the region of the ovary and through which the ovum passes from the ovary to the uterus; the primary location for fertilization of the ovum.

false imprisonment The confinement of a person without legal authority or the person's consent.

false motion Movement that occurs in a bone at a point where there is no joint, indicating a fracture; also called free movement.

fascia The fiberlike connective tissue that covers arteries, veins, tendons, and ligaments.

febrile seizures Seizures that result from sudden high fevers; most often seen in children.

Federal Communications Commission (FCC) The federal agency that has jurisdiction over interstate and international telephone and telegraph services and satellite communications, all of which may involve EMS activity.

femoral artery The major artery of the thigh, a continuation of the external iliac artery. It supplies blood to the lower abdominal wall, external genitalia, and legs. It can be palpated in the groin area.

femoral head The proximal end of the femur, articulating with the acetabulum to form the hip joint.

femur The thighbone; the longest and one of the strongest bones in the body.

fetal alcohol syndrome A condition caused by the consumption of alcohol by a pregnant woman; characterized by growth and physical problems, mental retardation, and a variety of congenital abnormalities.

fetus The developing, unborn infant inside the uterus, from 10 weeks after fertilization until birth.

fibula The outer and smaller bone of the two bones of the lower leg.

finance In incident command, the position in an incident responsible for accounting of all expenditures.

first-responder vehicles Specialized vehicles used to transport EMS equipment and personnel to the scenes of medical emergencies.

flail chest A condition in which three or more ribs are fractured in two or more places or in association with a fracture of the sternum so that a segment of the chest wall is effectively detached from the rest of the thoracic cage.

flame burn A burn caused by an open flame.

flank The region below the rib cage and above the hip.

flash burn A burn caused by exposure to very intense heat, such as in an explosion.

flexible stretcher A stretcher that is a rigid carrying device when secured around a patient but can be folded or rolled when not in use.

flexion The bending of a joint.

flutter valve A one-way valve that allows air to leave the chest cavity but not return; formed by taping three sides of an occlusive dressing to the chest wall, leaving the fourth side open as a valve; may also be part of a commercial vented occlusive dressing.

focused assessment A type of physical assessment typically performed on patients who have sustained nonsignificant mechanisms of injury or on responsive medical patients. This type of examination is based on the chief complaint and focuses on one body system or part.

fontanelles Areas where the neonate's or infant's skull has not fused together; usually disappear at approximately 18 months of age.

foodborne transmission The contamination of food or water with an organism than can cause disease.

foramen magnum A large opening at the base of the skull through which the brain connects to the spinal cord.

forcible restraint The act of physically preventing an individual from initiating any physical action.

four-person log roll The recommended procedure for moving a patient with a suspected spinal injury from the ground to a long backboard or other spinal immobilization device.

Fowler position An inclined position in which the head of the bed is raised.

fracture A break in the continuity of a bone.

freelancing When individual units or different organizations make independent and often inefficient decisions about the next appropriate action.

freight bills The shipping papers used for transport of chemicals along roads and highways; also referred to as bills of lading.

frontal bone The portion of the cranium that forms the forehead.

frostbite Damage to tissues as the result of exposure to cold; frozen or partially frozen body parts.

full-thickness (third-degree) burns Burns that affect all skin layers and may affect the subcutaneous layers, muscle, bone, and internal organs, leaving the area dry, leathery, and white, dark brown, or charred.

functional disorder A disorder in which there is no known physiologic reason for the abnormal functioning of an organ or organ system.

fundus The dome-shaped top of the uterus.

G agents Early nerve agents that were developed by German scientists in the period after World War I and into World War II. There are three such agents: sarin, soman, and tabun.

gag reflex A normal reflex mechanism that causes retching; activated by touching the soft palate or the back of the throat.

gallbladder A sac on the undersurface of the liver that collects bile from the liver and discharges it into the duodenum through the common bile duct.

gamma (x-ray) A type of energy that is emitted from a strong radiologic source that travels faster and has more energy than alpha and beta rays. These rays easily penetrate through the human body and require lead or several inches of concrete to prevent penetration.

gastric distention A condition in which air fills the stomach, often as a result of high volume and pressure during artificial ventilation.

gastroesophageal reflux disease (GERD) A condition in which the sphincter between the esophagus and the stomach opens, allowing stomach acid to move up into the esophagus, usually resulting in a burning sensation within the chest; also called acid reflux.

gel A semiliquid substance that is administered orally in capsule form or through plastic tubes.

general adaptation syndrome The body's response to stress that begins with an alarm response, followed by a stage of reaction and resistance, and then recovery or, if the stress is prolonged, exhaustion.

general impression The overall initial impression that determines the priority for patient care; based on the patient's surroundings, the mechanism of injury, signs and symptoms, and the chief complaint.

generalized tonic-clonic seizure A seizure that features rhythmic back-and-forth motion of an extremity and body stiffness, or extreme twitching of all of the body's muscles, that may last several minutes or more; formerly known as a grand mal seizure.

generic name The original chemical name of a medication (in contrast with one of its proprietary or trade names); the name is not capitalized.

genital system The reproductive system in men and women.

geriatrics The assessment and treatment of disease in someone who is 65 years or older.

germinal layer The deepest layer of the epidermis where new skin cells are formed.

gestational diabetes Diabetes that develops during pregnancy in women who did not have diabetes before pregnancy.

Glasgow Coma Scale (GCS) An evaluation tool used to determine level of consciousness, which evaluates and assigns point values (scores) for eye opening, verbal response, and motor response, which are then totaled; effective in helping predict patient outcomes.

glenoid fossa The part of the scapula that joins with the humeral head to form the glenohumeral joint.

globe The eyeball.

glottis The space in between the vocal cords that is the narrowest portion of the adult's airway; also called the glottic opening.

glucose One of the basic sugars; it is the primary fuel, in conjunction with oxygen, for cellular metabolism.

Golden Hour The time from injury to definitive care, during which treatment of shock and traumatic injuries should occur because survival potential is best; also called the Golden Period.

gonorrhea A sexually transmitted disease caused by *Neisseria gonorrhoeae*.

good air exchange A term used to distinguish the degree of distress in a patient with a mild airway obstruction. With good air exchange, the patient is still conscious and able to cough forcefully, although wheezing may be heard.

Good Samaritan laws Statutory provisions enacted by many states to protect citizens from liability for errors and omissions in giving good faith emergency medical care, unless there is wanton, gross, or willful negligence.

governmental immunity Legal doctrine that can protect an EMS provider from being sued or that may limit the amount of the monetary judgment that the plaintiff may recover; generally applies only to EMS systems that are operated by municipalities or other governmental entities.

greater trochanter A bony prominence on the proximal lateral side of the thigh, just below the hip joint.

gross negligence Conduct that constitutes a willful or reckless disregard for a duty or standard of care.

group In the context of EMS, a collection of individual health care providers working to help the patient.

grunting An "uh" sound heard during exhalation; reflects the child's attempt to keep the alveoli open; a sign of increased work of breathing.

guarding Involuntary muscle contractions (spasm) of the abdominal wall to minimize the pain of movement and protect the inflamed abdomen; a sign of peritonitis.

gum elastic bougie A flexible device that is inserted between the glottis under direct laryngoscopy; the endotracheal tube is threaded over the device, facilitating its entry into the trachea.

hair follicles The small organs that produce hair.

hallucinogen An agent that produce false perceptions in any one of the five senses.

hay fever An allergic response usually to outdoor airborne allergens such as pollen or sometimes indoor allergens such as dust mites or pet dander; also called allergic rhinitis.

hazardous materials Any substances that are toxic, poisonous, radioactive, flammable, or explosive and cause injury or death with exposure.

hazardous materials (HazMat) incident An incident in which a hazardous material is no longer properly contained and isolated.

head tilt–chin lift maneuver A combination of two movements to open the airway by tilting the forehead back and lifting the chin; not used for trauma patients.

health care directive A written document that specifies medical treatment for a competent patient, should he or she become unable to make decisions. Also known as an advance directive or a living will.

health care proxy A type of advance directive executed by a competent adult that appoints another individual to make medical treatment decisions on his or her behalf in the event that the person making the appointment loses decision-making capacity. Also known as a durable power of attorney for health care.

Health Insurance Portability and Accountability Act (HIPAA) Federal legislation passed in 1996. Its main effect in EMS is in limiting availability of patients' health care information and penalizing violations of patient privacy.

heart A hollow muscular organ that pumps blood throughout the body.

heart rate (HR) The number of heartbeats during a specific time (usually 1 minute).

heat cramps Painful muscle spasms usually associated with vigorous activity in a hot environment.

heat exhaustion A heat emergency in which a significant amount of fluid and electrolyte loss occurs because of heavy sweating; also called heat prostration or heat collapse.

heat stroke A life-threatening condition of severe hyperthermia caused by exposure to excessive natural or artificial heat, marked by warm, dry skin; severely altered mental status; and often irreversible coma.

hematemesis Vomited blood.

hematology The study and prevention of blood-related disorders.

hematoma A mass of blood that has collected within damaged tissue beneath the skin or in a body cavity.

hematuria Blood in the urine.

hemiparesis Weakness on one side of the body.

hemophilia A congenital abnormality in which the body is unable to produce clots, which results in uncontrollable bleeding.

hemopneumothorax The accumulation of blood and air in the pleural space of the chest.

hemoptysis The coughing up of blood.

hemorrhage Bleeding.

hemorrhagic stroke A type of stroke that occurs as a result of bleeding inside the brain.

hemostatic agent A chemical compound that slows or stops bleeding by assisting with clot formation.

hemothorax A collection of blood in the pleural cavity.

hepatitis Inflammation of the liver, usually caused by a viral infection, that causes fever, loss of appetite, jaundice, fatigue, and altered liver function.

hernia The protrusion of an organ or tissue through an abnormal body opening.

herpes simplex A common virus that is asymptomatic in 80% of people carrying it, but characterized by small blisters on the lips or genitals in symptomatic infections.

high-level disinfection The killing of pathogenic agents by using potent means of disinfection.

hinge joints Joints that can bend and straighten but cannot rotate; they restrict motion to one plane.

histamines Chemical substances released by the immune system in allergic reactions that are responsible for many of the symptoms of anaphylaxis, such as vasodilation.

history taking A step within the patient assessment process that provides detail about the patient's chief complaint and an account of the patient's signs and symptoms.

hollow organs Structures through which materials pass, such as the stomach, small intestines, large intestines, ureters, and urinary bladder.

homeostasis A balance of all systems of the body.

hormone A chemical substance produced by a gland that regulates the activity of organs and tissues; regulates many body functions, including metabolism, growth, and body temperature.

host The organism or individual that is attacked by the infecting agent.

hot zone The area immediately surrounding a hazardous materials spill or incident site that endangers life and health. All responders working in this zone must wear appropriate protective clothing and equipment. Entry requires approval by the incident commander or other designated officer.

human immunodeficiency virus (HIV) Acquired immunodeficiency syndrome (AIDS) is caused by HIV, which damages the cells in the body's immune system so that the body is unable to fight infection or certain cancers.

humerus The supporting bone of the upper arm.

hydroplaning Occurs when the tires of a vehicle are lifted off the road surface as a result of water "piling up" underneath them, making the vehicle feel as though it is floating.

hydrostatic pressure The pressure of water against the walls of its container.

hymenoptera A family of insects that includes bees, wasps, ants, and yellow jackets.

hypercarbia Increased carbon dioxide level in the bloodstream.

hyperglycemia An abnormally high blood glucose level.

hyperosmolar hyperglycemic nonketotic syndrome (HHNS) A life-threatening condition resulting from high blood glucose that typically occurs in older adults, and which causes altered mental status, dehydration, and organ damage.

hypertension Blood pressure that is higher than the normal range.

hypertensive emergency An emergency situation created by excessively high blood pressure, which can lead to serious complications such as stroke or aneurysm.

hyperthermia A condition in which the body core temperature rises to 101°F (38.3°C) or more.

hyperventilation Rapid or deep breathing that lowers the blood carbon dioxide level below normal; may lead to increased intrathoracic pressure, decreased venous return, and hypotension when associated with BVM use.

hyperventilation syndrome (panic attack) This syndrome occurs in the absence of other physical problems. The respirations of a person who is experiencing this syndrome may be as high as 40 shallow breaths/min or as low as only 20 very deep breaths/min.

hypnotic A sleep-inducing effect or agent.

hypoglycemia An abnormally low blood glucose level.

hypoperfusion A condition in which the circulatory system fails to provide sufficient circulation to maintain normal cellular functions; also called shock.

hypotension Blood pressure that is lower than the normal range.

hypothermia A condition in which the internal or core body temperature falls below 95°F (35°C).

hypovolemic shock A condition in which low blood volume, due to massive internal or external bleeding or extensive loss of body water, results in inadequate perfusion.

hypoxia A dangerous condition in which the body's tissues and cells do not have enough oxygen.

hypoxic drive A condition in which chronically low levels of oxygen in the blood stimulate the respiratory drive; seen in patients with chronic lung diseases.

ileostomy A surgical procedure to create an opening (stoma) between the small intestine and the surface of the body.

ileus Paralysis of the bowel, arising from any one of several causes; stops contractions that move material through the intestine.

ilium One of three bones that fuse to form the pelvic ring.

immune The body's ability to protect itself from acquiring a disease.

immune response The body's response to a substance perceived by the body as foreign.

immune system The body system that includes all of the structures and processes designed to mount a defense against foreign substances and disease-causing agents.

immunology The study of the body's immune system.

impaled objects Objects that penetrate the skin but remain in place.

impedance threshold device (ITD) A valve device placed between the endotracheal tube and a bag-valve mask that limits the amount of air entering the lungs during the recoil phase between chest compressions.

implied consent Type of consent in which a patient who is unable to give consent is given treatment under the legal assumption that he or she would want treatment.

in loco parentis Refers to the legal responsibility of a person or organization to take on some of the functions and responsibilities of a parent.

incident action plan An oral or written plan stating general objectives reflecting the overall strategy for managing an incident.

incident command system (ICS) A system implemented to manage disasters and mass-casualty incidents in which section chiefs, including finance, logistics, operations, and planning, report to the incident commander. Also referred to as the incident management system.

incident commander (IC) The individual who has overall command of the incident in the field.

incision A sharp, smooth cut in the skin.

incontinence Loss of bowel and/or bladder control; may be the result of a generalized seizure.

incubation The period of time between a person being exposed to an agent to the first time when symptoms appear.

index of suspicion Awareness that unseen life-threatening injuries or illness may exist.

indications The therapeutic uses for a specific medication.

indirect contact Exposure or transmission of disease from one person to another by contact with a contaminated object.

infancy The first year of life.

infant A young child age 1 month to 1 year.

infarction Death of a body tissue, usually caused by interruption of its blood supply.

infection The abnormal invasion of a host or host tissues by organisms such as bacteria, viruses, or parasites, with or without signs or symptoms of disease.

infection control Procedures to reduce transmission of infection among patients and health care personnel.

infectious disease A medical condition caused by the growth and spread of small, harmful organisms within the body.

inferior Below a body part or nearer to the feet.

inferior vena cava One of the two largest veins in the body; carries blood from the lower extremities and the pelvic and the abdominal organs to the heart.

influenza A virus that has crossed the animal/human barrier and infected humans and that kills thousands of people every year.

influenza type A Virus that has crossed the animal/human barrier and has infected humans, recently reaching a pandemic level with the H1N1 strain.

informed consent Permission for treatment given by a competent patient after the potential risks, benefits, and alternatives to treatment have been explained.

ingestion Swallowing; taking a substance by mouth.

inhalation The active, muscular part of breathing that draws air into the airway and lungs; also a medication delivery route.

inspiratory reserve volume The amount of air that can be inhaled after a normal inhalation; the amount of air that can be inhaled in addition to the normal tidal volume.

insulin A hormone produced by the islets of Langerhans (endocrine gland located throughout the pancreas) that enables glucose in the blood to enter cells; used in synthetic form to treat and control diabetes mellitus.

intermodal tanks Shipping and storage vessels that can be either pressurized or nonpressurized.

internal respiration The exchange of gases between the blood cells and the tissues.

international terrorism Terrorism that is carried out by people in a country other than their own; also known as cross-border terrorism.

interoperable communications system A communication system that uses voice-over-Internet-protocol (VoIP) technology to allow multiple agencies to communicate and transmit data.

interrogatories Written questions that the defense and plaintiff send to one another.

interstitial space The space in between the cells.

intervertebral disk The cushion that lies between two vertebrae.

intracerebral hematoma Bleeding within the brain tissue (parenchyma) itself; also referred to as an intraparenchymal hematoma.

intracranial pressure (ICP) The pressure within the cranial vault.

intramuscular (IM) injection An injection into a muscle; a medication delivery route.

intranasal (IN) A delivery route in which a medication is pushed through a specialized atomizer device called a mucosal atomizer device (MAD) into the naris.

intraosseous (IO) injection An injection into the bone; a medication delivery route.

intrapulmonary shunting Bypassing of oxygen-poor blood past nonfunctional alveoli to the left side of the heart.

intravenous (IV) injection An injection directly into a vein; a medication delivery route.

intravenous (IV) therapy The delivery of medication directly into a vein.

involuntary activities Actions of the body that are not under a person's conscious control.

involuntary muscle The muscle over which a person has no conscious control. It is found in many automatic regulating systems of the body.

ionizing radiation Energy that is emitted in the form of rays, or particles.

iris The muscle and surrounding tissue behind the cornea that dilate and constrict the pupil, regulating the amount of light that enters the eye; pigment in this tissue gives the eye its color.

ischemia A lack of oxygen that deprives tissues of necessary nutrients, resulting from partial or complete blockage of blood flow; potentially reversible because permanent injury has not yet occurred.

ischemic stroke A type of stroke that occurs when blood flow to a particular part of the brain is cut off by a blockage (eg, a blood clot) inside a blood vessel.

ischium One of three bones that fuse to form the pelvic ring.

jaundice Yellow skin or sclera that is caused by liver disease or dysfunction.

jaw-thrust maneuver Technique to open the airway by placing the fingers behind the angle of the jaw and bringing the jaw forward; used for patients who may have a cervical spine injury.

joint (articulation) The place where two bones come into contact.

joint capsule The fibrous sac that encloses a joint.

joint information center (JIC) An area designated by the incident commander, or a designee, in which public information officers from multiple agencies distribute information about the incident.

jugular vein distention A visual bulging of the jugular veins in the neck that can be caused by fluid overload, pressure in the chest, cardiac tamponade, or tension pneumothorax.

jump kit A portable kit containing items that are used in the initial care of the patient.

JumpSTART triage A sorting system for pediatric patients younger than 8 years or weighing less than 100 pounds (45 kg). There is a minor adaptation for infants because they cannot ambulate on their own.

kidnapping The seizing, confining, abducting, or carrying away of a person by force, including transporting a competent adult for medical treatment without his or her consent.

kidney stones Solid crystalline masses formed in the kidney, resulting from an excess of insoluble salts or uric acid crystallizing in the urine; may become trapped anywhere along the urinary tract.

kidneys Two retroperitoneal organs that excrete the end products of metabolism as urine and regulate the body's salt and water content.

kinetic energy The energy of a moving object.

Kussmaul respirations Deep, rapid breathing; usually the result of an accumulation of certain acids when insulin is not available in the body.

kyphosis A forward curling of the back caused by an abnormal increase in the curvature of the spine.

labia majora Outer fleshy lips covered with pubic hair that protect the vagina.

labia minora Inner fleshy lips devoid of pubic hair that protect the vagina.

labored breathing Breathing that requires greater than normal effort; may be slower or faster than normal and characterized by grunting, stridor, and use of accessory muscles.

laceration A deep, jagged cut in the skin.

lacrimal glands The glands that produce fluids to keep the eye moist; also called tear glands.

lactic acid A metabolic by-product of the breakdown of glucose that accumulates when metabolism proceeds in the absence of oxygen (anaerobic metabolism).

large intestine The portion of the digestive tube that encircles the abdomen around the small bowel, consisting of the cecum, the colon, and the rectum. It helps regulate water balance and eliminate solid waste.

larynx A complex structure formed by many independent cartilaginous structures that all work together; where the upper airway ends and the lower airway begins; also called the voice box.

lateral Parts of the body that lie farther from the midline; also called outer structures.

LD_{50} The standard measure of the dose amount of an agent or substance that will kill 50% of a population who are exposed to this level.

length-based resuscitation tape A tape used to estimate an infant or child's weight on the basis of length; appropriate drug doses and equipment sizes are listed on the tape.

lens The transparent part of the eye through which images are focused on the retina.

lesser trochanter The projection on the medial/superior portion of the femur.

leukotrienes Chemical substances that contribute to anaphylaxis; released by the immune system in allergic reactions.

lewisite (L) A blistering agent that has a rapid onset of symptoms and produces immediate, intense pain and discomfort on contact.

liaison officer In incident command, the person who relays information, concerns, and requests among responding agencies.

libel False and damaging information about a person that is communicated in writing.

licensure The process whereby a competent authority, usually the state, allows people to perform a regulated act.

life expectancy The average number of years a person can be expected to live.

ligament A band of fibrous tissue that connects bones to bones. It supports and strengthens a joint.

lightening The movement of the fetus down into the pelvis late in pregnancy.

limb presentation A delivery in which the presenting part is a single arm or leg.

linear skull fractures Account for 80% of skull fractures; also referred to as nondisplaced skull fractures; commonly occur in the temporal-parietal region of the skull; not associated with deformities to the skull.

liver A large, solid organ that lies in the right upper quadrant immediately below the diaphragm; it produces bile, stores glucose for immediate use by the body, and produces many substances that help regulate immune responses.

load-distributing band (LDB) A circumferential chest compression device composed of a constricting band and backboard that is either electrically or pneumatically driven to compress the heart by putting inward pressure on the thorax.

logistics In incident command, the position that helps procure and stockpile equipment and supplies during an incident.

lumbar spine The lower part of the back, formed by the lowest five nonfused vertebrae; also called the dorsal spine.

lumen The inside diameter of an artery or other hollow structure.

lymph A thin, straw-colored fluid that carries oxygen, nutrients, and hormones to the cells and carries waste products of metabolism away from the cells and back into the capillaries so that they may be excreted.

lymph nodes Tiny, oval-shaped structures located in various places along the lymph vessels that filter lymph.

lymphatic system A passive circulatory system in the body that transports a plasmalike liquid called lymph, a thin fluid that bathes the tissues of the body.

mandible The bone of the lower jaw.

manually triggered ventilation device A fixed flow rate ventilation device that delivers a breath every time its button is pushed; also referred to as a flow-restricted, oxygen-powered ventilation device.

manubrium The upper quarter of the sternum.

mass-casualty incident (MCI) An emergency situation involving three or more patients or that can place great demand on the equipment or personnel of the EMS system or has the potential to produce multiple casualties.

mastoid process The prominent bony mass at the base of the skull about 1 inch posterior to the external opening of the ear.

material safety data sheet (MSDS) A form, provided by manufacturers and compounders (blenders) of chemicals, containing information about chemical composition, physical and chemical properties, health and safety hazards, emergency response, and waste disposal of a specific material; also known as a safety data sheet (SDS).

maxillae The upper jawbones that assist in the formation of the orbit, the nasal cavity, and the palate and hold the upper teeth.

mechanical piston device A device that depresses the sternum via a compressed gas-powered or electric-powered plunger mounted on a backboard.

mechanism of injury (MOI) The forces, or energy transmission, applied to the body that cause injury.

meconium Fetal stool. When appearing as a dark green material in the amniotic fluid, it can indicate distress or disease in the newborn; it can be aspirated into the fetus's lungs during delivery.

MED channels VHF and UHF channels that the Federal Communications Commission has designated exclusively for EMS use.

medial Parts of the body that lie closer to the midline; also called inner structures.

mediastinum Space within the chest that contains the heart, major blood vessels, vagus nerve, trachea, major bronchi, and esophagus; located between the two lungs.

medical control Physician instructions given directly by radio or cell phone (online/direct) or indirectly by protocol/guidelines (off-line/indirect), as authorized by the medical director of the service program.

medical director The physician who authorizes or delegates to the EMT the authority to provide medical care in the field.

medical emergencies Emergencies that are not caused by an outside force; illnesses or conditions.

medication A substance that is used to treat or prevent disease or relieve pain.

medication error Inappropriate use of a medication that could lead to patient harm.

medicolegal Relating to medical jurisprudence (law) or forensic medicine.

medivac Medical evacuation of a patient by helicopter.

medulla oblongata Nerve tissue that is continuous inferiorly with the spinal cord; serves as a conduction pathway for ascending and descending nerve tracts; coordinates heart rate, blood vessel diameter, breathing, swallowing, vomiting, coughing, and sneezing.

melena Black, foul-smelling, tarry stool containing digested blood.

meninges Three distinct layers of tissue that surround and protect the brain and the spinal cord within the skull and the spinal canal.

meningitis An inflammation of the meningeal coverings of the brain and spinal cord; it is usually caused by a virus or a bacterium.

meningococcal meningitis An inflammation of the meningeal coverings of the brain and spinal cord; can be highly contagious.

metabolism (cellular respiration) The biochemical processes that result in production of energy from nutrients within cells.

metered-dose inhaler (MDI) A miniature spray canister through which droplets or particles of medication may be inhaled through the mouth and into the lungs.

methicillin-resistant *Staphylococcus aureus* (MRSA) A bacterium that can cause infections in different parts of the body and is often resistant to commonly used antibiotics; it is transmitted by different routes, including the respiratory route, and can be found on the skin, in surgical wounds, in the bloodstream, lungs, and urinary tract.

midbrain The part of the brain that is responsible for helping to regulate the level of consciousness.

middle adult An adult age 41 to 60 years.

midsagittal plane (midline) An imaginary vertical line drawn from the middle of the forehead through the nose and the umbilicus (navel) to the floor, dividing the body into equal left and right halves.

mild airway obstruction Occurs when a foreign body partially obstructs the patient's airway. The patient is able to move adequate amounts of air, but also experiences some degree of respiratory distress.

minute volume The volume of air that moves in and out of the lungs per minute; calculated by multiplying the tidal volume and respiratory rate; also called minute ventilation.

miosis Excessively constricted pupil; often bilateral after exposure to nerve agents.

miscarriage The spontaneous passage of the fetus and placenta before 20 weeks; also called spontaneous abortion.

mobile data terminal (MDT) A small computer terminal inside the ambulance that directly receives data from the dispatch center.

mobile integrated healthcare (MIH) A method of delivering health care which involves providing health care within the community rather than at a physician's office or hospital.

morality A code of conduct that can be defined by society, religion, or a person, affecting character, conduct, and conscience.

morgue supervisor In incident command, the person who works with area medical examiners, coroners, and law enforcement agencies to coordinate the disposition of dead victims.

Moro reflex An infant reflex in which, when an infant is caught off guard, the infant opens his or her arms wide, spreads the fingers, and seems to grab at things.

motor nerves Nerves that carry information from the central nervous system to the muscles of the body.

mucosal atomizer device (MAD) A device that is used to change a liquid medication into a spray and push it into a nostril.

mucous membranes The linings of body cavities and passages that are in direct or indirect contact with the outside environment.

mucus The watery secretion of the mucous membranes that lubricates the body openings.

multigravida A woman who has had previous pregnancies.

multiplex The ability to transmit audio and data signals through the use of more than one communications channel.

multisystem trauma Trauma that affects more than one body system.

musculoskeletal system The bones and voluntary muscles of the body.

mutagen A substance that mutates, damages, and changes the structures of DNA in the body's cells.

mutual aid response An agreement between neighboring EMS systems to respond to mass-casualty incidents or disasters in each other's region when local resources are insufficient to handle the response.

myocardial contractility The ability of the heart muscle to contract.

myocardial contusion Bruising of the heart muscle.

myocardium The heart muscle.

narcotic A drug that produces sleep or altered mental consciousness.

nares The external openings of the nostrils. A single nostril opening is called a naris.

nasal cannula An oxygen-delivery device in which oxygen flows through two small, tubelike prongs that fit into the patient's nostrils; delivers 24% to 44% supplemental oxygen, depending on the flow rate.

nasal flaring Widening of the nostrils, indicating that there is an airway obstruction.

nasopharyngeal (nasal) airway Airway adjunct inserted into the nostril of an unresponsive patient or a patient with an altered level of consciousness who is unable to maintain airway patency independently.

nasopharynx The nasal cavity, or part of the pharynx that lies above the level of the roof of the mouth; formed by the union of facial bones and protects the respiratory tract from contaminants.

National EMS Scope of Practice Model A document created by the National Highway Traffic Safety Administration (NHTSA) that outlines the skills performed by various EMS providers.

National Incident Management System (NIMS) A Department of Homeland Security system designed to enable federal, state, and local governments and private-sector and nongovernmental organizations to effectively and efficiently prepare for, prevent, respond to, and recover from domestic incidents, regardless of cause, size, or complexity, including acts of catastrophic terrorism.

nature of illness (NOI) The general type of illness a patient is experiencing.

neglect Refusal or failure on the part of the parent or caregiver to provide life necessities.

negligence Failure to provide the same care that a person with similar training would provide.

negligence per se A theory that may be used when the conduct of the person being sued is alleged to have occurred in clear violation of a statute.

Neisseria meningitides A form of bacterial meningitis characterized by rapid onset of symptoms, often leading to shock and death.

neonate A newborn age birth to 1 month.

nephrons The basic filtering units in the kidneys.

nerve agents A class of chemical called organophosphates; they function by blocking an essential enzyme in the nervous system, which causes the body's organs to become overstimulated and burn out.

nervous system The system that controls virtually all activities of the body, both voluntary and involuntary.

neurogenic shock Circulatory failure caused by paralysis of the nerves that control the size of the blood vessels, leading to widespread dilation; seen in patients with spinal cord injuries.

neuropathy A group of conditions in which the nerves leaving the spinal cord are damaged, resulting in distortion of signals to or from the brain.

neurotoxins Biologic agents that are the most deadly substances known to humans; they include botulinum toxin and ricin.

neutron radiation The type of energy that is emitted from a strong radiologic source, involving particles that are among the most powerful forms of radiation; the particles easily penetrate through lead and require several feet of concrete to stop them.

nitroglycerin A medication that increases cardiac perfusion by causing blood vessels to dilate; EMTs may be allowed to assist the patient to self-administer the medication.

noise Anything that dampens or obscures the true meaning of a message.

nonbulk storage vessels Any container other than bulk storage containers such as drums, bags, compressed gas cylinders, and cryogenic containers. These hold commonly used commercial and industrial chemicals such as solvents, industrial cleaners, and compounds.

nondisplaced fracture A simple crack in the bone that has not caused the bone to move from its normal anatomic position; also called a hairline fracture.

nonrebreathing mask A combination mask and reservoir bag system that is the preferred way to give oxygen in the prehospital setting; delivers up to 90% inspired oxygen and prevents inhaling the exhaled gases (carbon dioxide).

norepinephrine A neurotransmitter and drug sometimes used in the treatment of shock; produces vasoconstriction through its alpha-stimulator properties.

nuchal cord An umbilical cord that is wrapped around the fetus's neck.

obesity A complex condition in which a person has an excessive amount of body fat.

obstructive shock Shock that occurs when there is a block to blood flow in the heart or great vessels, causing an insufficient blood supply to the body's tissues.

occiput The most posterior portion of the cranium.

occlusion A blockage, usually of a tubular structure such as a blood vessel.

occlusive dressing An airtight dressing that protects a wound from air and bacteria; a commercial vented version allows air to passively escape from the chest, while an unvented dressing may be made of petroleum jelly-based (Vaseline) gauze, aluminum foil, or plastic.

Occupational Safety and Health Administration (OSHA) The federal regulatory compliance agency that develops, publishes, and enforces guidelines concerning safety in the workplace.

off-gassing The release of an agent after exposure, for example from a person's clothes that have been exposed to the agent.

older adult An adult age 61 years or older.

oncotic pressure The pressure of water to move, typically into the capillary, as the result of the presence of plasma proteins.

open abdominal injury An injury in which there is a break in the surface of the skin or mucous membrane, exposing deeper tissue to potential contamination.

open-book pelvic fracture A life-threatening fracture of the pelvis caused by a force that displaces one or both sides of the pelvis laterally and posteriorly.

open chest injury An injury to the chest in which the chest wall itself is penetrated by a fractured rib or, more frequently, by an external object such as a bullet or knife.

open-ended questions Questions for which the patient must provide detail to give an answer.

open fracture Any break in a bone in which the overlying skin has been broken.

open head injury Injury to the head often caused by a penetrating object in which there may be bleeding and exposed brain tissue.

open incident An incident that is not yet contained; there may be patients to be located and the situation may be ongoing, producing more patients.

open injuries Injuries in which there is a break in the surface of the skin or the mucous membrane, exposing deeper tissue to potential contamination.

open pneumothorax An open or penetrating chest wall wound through which air passes during inspiration and expiration, creating a sucking sound; also referred to as a sucking chest wound.

operations In incident command, the position that carries out the orders of the commander to help resolve the incident.

opiate A subset of the opioid family, referring to natural, non-synthetic opioids.

opioid A synthetically produced narcotic medication, drug, or agent similar to the opiate morphine, but not derived from opium; used to relieve pain.

OPQRST A mnemonic used in evaluating a patient's pain: Onset, Provocation/palliation, Quality, Region/radiation, Severity, and Timing.

optic nerve A cranial nerve that transmits visual information to the brain.

oral By mouth; a medication delivery route.

oral glucose A simple sugar that is readily absorbed by the bloodstream; it is carried on the EMS unit.

orbit The eye socket, made up of the maxilla and zygoma.

organic brain syndrome Temporary or permanent dysfunction of the brain, caused by a disturbance in the physical or physiologic functioning of brain tissue.

orientation The mental status of a patient as measured by memory of person (name), place (current location), time (current year, month, and approximate date), and event (what happened).

oropharyngeal (oral) airway Airway adjunct inserted into the mouth of an unresponsive patient to keep the tongue from blocking the upper airway and to facilitate suctioning the airway, if necessary.

oropharynx A tubular structure that extends vertically from the back of the mouth to the esophagus and trachea; forms the posterior portion of the oral cavity, which is bordered superiorly by the hard and soft palates, laterally by the cheeks, and inferiorly by the tongue.

orthopnea Severe dyspnea experienced when lying down and relieved by sitting up.

osteoporosis A generalized bone disease, commonly associated with postmenopausal women, in which there is a reduction in the amount of bone mass leading to fractures after minimal trauma in either sex.

ovaries The primary female reproductive organs that produce sex hormones and an ovum, or egg, that, if fertilized, will develop into a fetus.

overdose An excessive quantity of a drug that, when taken or administered, can have toxic or lethal consequences.

over-the-counter (OTC) medications Medications that may be purchased directly by a patient without a prescription.

ovulation The process in which an ovum is released from a follicle.

oxygen A gas that all cells need for metabolism; the heart and brain, especially, cannot function without oxygen.

oxygen toxicity A condition of excessive oxygen consumption resulting in cellular and tissue damage.

oxygenation The process of delivering oxygen to the blood by diffusion from the alveoli following inhalation into the lungs.

paging The use of a radio signal and a voice or digital message that is transmitted to pagers (“beepers”) or desktop monitor radios.

palmar The forward facing part of the hand in the anatomic position.

palmar grasp An infant reflex that occurs when something is placed in the infant’s palm; the infant grasps the object.

palpate To examine by touch.

pancreas A flat, solid organ that lies below the liver and the stomach; it is a major source of digestive enzymes and produces the hormone insulin.

pancreatitis Inflammation of the pancreas.

pandemic An outbreak that occurs on a global scale.

paradoxical motion The motion of the portion of the chest wall that is detached in a flail chest; the motion—in during inhalation, out during exhalation—is exactly the opposite of normal chest wall motion during breathing.

paramedic An individual who has extensive training in advanced life support, including endotracheal intubation, emergency pharmacology, cardiac monitoring, and other advanced assessment and treatment skills.

parasympathetic nervous system A subdivision of the autonomic nervous system, involved in control of involuntary functions such as digestion of food and relaxation, mediated largely by the vagus nerve through the chemical acetylcholine.

parenteral medications Medications that enter the body by a route other than the digestive tract, skin, or mucous membranes.

parietal bones The bones that lie between the temporal and occipital regions of the cranium.

parietal pleura Thin membrane that lines the chest cavity.

paroxysmal nocturnal dyspnea Severe shortness of breath, especially at night after several hours of reclining; the person is forced to sit up to breathe.

partial (focal) seizure A seizure affecting a limited portion of the brain.

partial pressure Describes the amount of gas in air or dissolved in fluid, such as blood.

partial-thickness (second-degree) burns Burns that affect the epidermis and some portion of the dermis but not the subcutaneous tissue, characterized by blisters and skin that is white to red, moist, and mottled.

passive ventilation The act of air moving in and out of the lungs during chest compressions.

patella The knee cap; a specialized bone that lies within the tendon of the quadriceps muscle.

patent Open, clear of obstruction.

pathogen A microorganism that is capable of causing disease in a susceptible host.

pathophysiology The study of how normal physiologic processes are affected by disease.

patient-assisted medication When the EMT assists the patient with the administration of his or her own medication.

patient autonomy The right of a patient to make informed choices regarding his or her health care.

patient care report (PCR) The legal document used to record all patient care activities. This report has direct patient care functions but also administrative and quality control functions. Also known as prehospital care reports.

pediatric assessment triangle (PAT) A structured assessment tool used to rapidly form a general impression of the infant or child without touching him or her; consists of assessing appearance, work of breathing, and circulation to the skin.

pediatrics A specialized medical practice devoted to the care of the young.

peer-assisted medication When the EMT administers medication to him or herself or to a partner.

pelvic binder A device to splint the bony pelvis to reduce hemorrhage from bone ends, venous disruption, and pain.

pelvic inflammatory disease (PID) An infection of the fallopian tubes and the surrounding tissues of the pelvis.

penetrating trauma Injury caused by objects, such as knives and bullets, that pierce the surface of the body and damage internal tissues and organs.

penetrating wound An injury resulting from a sharp, piercing object.

peptic ulcer disease An abrasion of the stomach or small intestine.

per os (PO) Through the mouth; a medication delivery route; same as oral.

per rectum (PR) Through the rectum; a medication delivery route.

perfusion The circulation of oxygenated blood through body tissues and vessels.

pericardial effusion A collection of fluid between the pericardial sac and the myocardium.

pericardium The fibrous sac that surrounds the heart.

perineum In a female, the area between the vagina and the anus.

peripheral nervous system (PNS) The part of the nervous system that consists of 31 pairs of spinal nerves and 12 pairs of cranial nerves; these may be sensory nerves, motor nerves, or connecting nerves.

peristalsis The wavelike contraction of smooth muscle by which the ureters or other tubular organs propel their contents.

peritoneal cavity The abdominal cavity.

peritoneum The membrane lining the abdominal cavity (parietal peritoneum) and covering the abdominal organs (visceral peritoneum).

peritonitis Inflammation of the peritoneum.

persistency Describes how long a chemical agent will stay on a surface before it evaporates.

personal protective equipment (PPE) levels Protective equipment that blocks exposure to a pathogen or a hazardous material.

personal protective equipment (PPE) level The amount and type of protective equipment that an individual needs to avoid injury during contact with a hazardous material.

pertinent negatives Negative findings that warrant no care or intervention.

pertussis An airborne bacterial infection that affects mostly children younger than 6 years, in which the patient is feverish and exhibits a “whoop” sound on inspiration after a coughing attack; highly contagious through droplet infection. Also called whooping cough.

pharmacodynamics The process by which a medication works on the body.

pharmacology The study of the properties and effects of medications.

phosgene A pulmonary agent that is a product of combustion, resulting from a fire at a textile factory or house or from metalwork or burning Freon. It is a very potent agent that has a delayed onset of symptoms, usually hours.

phosgene oxime (CX) A blistering agent that has a rapid onset of symptoms and produces immediate, intense pain and discomfort on contact.

phrenic nerve Nerve that innervates the diaphragm; necessary for adequate breathing to occur.

pin-indexing system A system established for portable cylinders to ensure that a regulator is not connected to a cylinder containing the wrong type of gas.

pinna The external, visible part of the ear.

placards Signage required to be placed on all four sides of highway transport vehicles, railroad tank cars, and other forms of hazardous materials transportation; the sign identifies the hazardous contents of the vehicle, using a standardization system with 10¾-inch (27-cm) diamond-shaped indicators.

placenta The tissue attached to the uterine wall that nourishes the fetus through the umbilical cord.

placenta previa A condition in which the placenta develops over and covers the cervix.

planning In incident command, the position that ultimately produces a plan to resolve any incident.

plantar The bottom surface of the foot.

plasma A sticky, yellow fluid that carries the blood cells and nutrients and transports cellular waste material to the organs of excretion.

platelets Tiny, disc-shaped elements that are much smaller than the cells; they are essential in the initial formation of a blood clot, the mechanism that stops bleeding.

pleura The serous membranes covering the lungs and lining the thorax, completely enclosing a potential space known as the pleural space.

pleural effusion A collection of fluid between the lung and chest wall that may compress the lung.

pleural space The potential space between the parietal pleura and the visceral pleura; described as "potential" because under normal conditions, the space does not exist.

pleuritic chest pain Sharp, stabbing pain in the chest that is worsened by a deep breath or other chest wall movement; often caused by inflammation or irritation of the pleura.

pneumonia An infectious disease of the lung that damages lung tissue; its cause can be bacterial, viral, or fungal.

pneumonic plague A lung infection, also known as plague pneumonia, that is the result of inhalation of plague-causing bacteria.

pneumonitis Inflammation of the lung.

pneumothorax A partial or complete accumulation of air in the pleural space.

point tenderness Tenderness that is sharply localized at the site of the injury, found by gently palpating along the bone with the tip of one finger.

points of distribution (PODs) Existing facilities used as mass distribution sites for antibiotics, antidotes, vaccinations, and other medications and supplies during an emergency.

poison A substance whose chemical action could damage structures or impair function when introduced into the body.

polydipsia Excessive thirst that persists for long periods, despite reasonable fluid intake; often the result of excessive urination.

polyphagia Excessive eating; in diabetes, the inability to use glucose properly can cause a sense of hunger.

polypharmacy The use of multiple medications on a regular basis.

polyuria The passage of an unusually large volume of urine in a given period; in diabetes, this can result from the wasting of glucose in the urine.

pons An organ that lies below the midbrain and above the medulla and contains numerous important nerve fibers, including those for sleep, respiration, and the medullary respiratory center.

poor air exchange A term used to describe the degree of distress in a patient with a mild airway obstruction. With this, the patient often has a weak, ineffective cough, increased difficulty breathing, or possible cyanosis and may produce a high-pitched noise during inhalation (stridor).

portable stretcher A stretcher with a strong, rectangular, tubular metal frame and rigid fabric stretched across it.

position of function A hand position in which the wrist is slightly dorsiflexed and all finger joints are moderately flexed.

positional asphyxia Restriction of chest wall movements and/or airway obstruction; can rapidly lead to sudden death.

postconventional reasoning A type of reasoning in which a child bases decisions on his or her conscience.

posterior The back surface of the body; the side away from you in the standard anatomic position.

posterior tibial artery The artery just behind the medial malleolus; supplies blood to the foot.

postictal state The period following a seizure that lasts 5 to 30 minutes; characterized by labored respirations and some degree of altered mental status.

posttraumatic stress disorder (PTSD) A delayed stress reaction to a prior incident. Often the result of one or more unresolved issues concerning the incident and may relate to an incident that involved physical harm or the threat of physical harm.

potential energy The product of mass, gravity, and height, which is converted into kinetic energy and results in injury, such as from a fall.

power grip A technique in which the stretcher or backboard is gripped by inserting each hand under the handle with the palm facing up and the thumb extended, fully supporting the underside of the handle on the curved palm with the fingers and thumb.

power lift A lifting technique in which the EMT's back is held upright, with legs bent, and the patient is lifted when the EMT straightens the legs to raise the upper body and arms.

preconventional reasoning A type of reasoning in which a child acts almost purely to avoid punishment to get what he or she wants.

preeclampsia A pregnancy complication that is characterized by high blood pressure, headache, visual changes, and swelling of the hands and feet; also called pregnancy-induced hypertension or toxemia of pregnancy.

prefix Part of a term that appears before a word root, changing the meaning of the term.

pregnancy-induced hypertension A condition of late pregnancy that is characterized by headache, visual changes, and swelling of the hands and feet; also called preeclampsia or toxemia of pregnancy.

preload The precontraction pressure in the heart as the volume of blood builds up.

preoxygenation The process of providing oxygen, often in combination with ventilation, prior to intubation in order to raise the oxygen levels of body tissues; a critical step in advanced airway management. This extends the time during which an advanced airway can be placed in an apneic patient, because the more oxygen that is available in the alveoli, the longer the patient can maintain adequate gas exchange in the lungs during the procedure.

presbycusis An age-related condition of the ear that produces progressive bilateral hearing loss that is most noted at higher frequencies.

preschool-age Children between ages 3 to 6 years.

preschooler (preschool-age) A child age 3 to 6 years.

prescription medications Medications that are distributed to patients only by pharmacists according to a physician's order.

presentation The position in which an infant is born; defined by the part of the body that appears first.

priapism A painful, tender, persistent erection of the penis; can result from spinal cord injury, erectile dysfunction drugs, or sickle cell disease.

primary assessment A step within the patient assessment process that identifies and initiates treatment of immediate and potential life threats.

primary blast injury Injuries caused by an explosive pressure wave on the hollow organs of the body.

primary (direct) injury An injury to the brain and its associated structures that is a direct result of impact to the head.

primary prevention Efforts to prevent an injury or illness from ever occurring.

primary service area (PSA) The designated area in which the EMS agency is responsible for the provision of prehospital emergency care and transportation to the hospital.

primary triage A type of patient sorting used to rapidly categorize patients; the focus is on speed in locating all patients and determining an initial priority as their conditions warrant.

primigravida A woman who is experiencing her first pregnancy.

projectile Any object propelled by force, such as a bullet by a weapon.

prolapse of the umbilical cord A situation in which the umbilical cord comes out of the vagina before the fetus.

prone Lying face down.

prostate gland A small gland that surrounds the male urethra where it emerges from the urinary bladder; it secretes a fluid that is part of the ejaculatory fluid.

protected health information (PHI) Any information about health status, provision of health care, or payment for health care that can be linked to an individual. This is interpreted rather broadly and includes any part of a patient's medical record or payment history.

proximal Closer to the trunk.

proximate causation When a person who has a duty abuses it, and causes harm to another individual, the EMT, the agency, and/or the medical director may be sued for negligence.

psychiatric disorder An illness with psychological or behavioral symptoms and/or impairment in functioning caused by a social, psychologic, genetic, physical, chemical, or biologic disturbance.

psychiatric emergency An emergency in which abnormal behavior threatens a person's own health and safety or the health and safety of another person, for example when a person becomes suicidal, homicidal, or has a psychotic episode.

psychogenic shock Shock caused by a sudden, temporary reduction in blood supply to the brain that causes fainting (syncope).

psychosis A mental disorder characterized by the loss of contact with reality.

pubic symphysis A hard, bony, and cartilaginous prominence found at the midline in the lowermost portion of the abdomen where the two halves of the pelvic ring are joined by cartilage at a joint with minimal motion.

pubis One of three bones that fuse to form the pelvic ring.

public health Focused on examining the health needs of entire populations with the goal of preventing health problems.

public information officer (PIO) In incident command, the person who keeps the public informed and relates any information to the media.

public safety access point A call center, staffed by trained personnel who are responsible for managing requests for police, fire, and ambulance services.

pulmonary artery The major artery leading from the right ventricle of the heart to the lungs; carries oxygen-poor blood.

pulmonary blast injuries Pulmonary trauma resulting from short-range exposure to the detonation of high-energy explosives.

pulmonary circulation The flow of blood from the right ventricle through the pulmonary arteries and all of their branches and capillaries in the lungs and back to the left atrium through the venules and pulmonary veins; also called the lesser circulation.

pulmonary contusion Injury or bruising of lung tissue that results in hemorrhage.

pulmonary edema A buildup of fluid in the lungs, usually as a result of congestive heart failure.

pulmonary embolism A blood clot that breaks off from a large vein and travels to the blood vessels of the lung causing obstruction of blood flow.

pulmonary veins The four veins that return oxygenated blood from the lungs to the left atrium of the heart.

pulse The pressure wave created as the heart contracts and forces blood out of the left ventricle and into the major arteries.

pulse oximetry An assessment tool that measures oxygen saturation of hemoglobin in the capillary beds.

pulse pressure The difference between the systolic and diastolic pressures.

punitive damages Damages that are sometimes awarded in a civil lawsuit when the conduct of the defendant was intentional or constituted a reckless disregard for the safety of the public.

pupil The circular opening in the middle of the iris that admits light to the back of the eye.

putrefaction Decomposition of body tissues; a definitive sign of death.

quadrants Describes the sections of the abdominal cavity, in which two imaginary lines intersect at the umbilicus, dividing the abdomen into four equal areas.

quality control The responsibility of the medical director to ensure the appropriate medical care standards are met by EMTs on each call.

quaternary blast injury A blast injury that falls into one of the following categories: burns, crush injuries, toxic inhalation, medical emergencies, or mental health disorders.

rabid Infected with rabies.

raccoon eyes Bruising under the eyes that may indicate a skull fracture.

radial artery The major artery in the forearm; it is palpable at the wrist on the thumb side.

radiation The transfer of heat to colder objects in the environment by radiant energy; for example, heat gain from a fire.

radioactive material Any material that emits radiation.

radiologic dispersal device (RDD) Any container that is designed to disperse radioactive material.

radius The bone on the thumb side of the forearm.

rape Sexual intercourse forcibly inflicted on another person, against that person's will.

rapid extrication technique A technique to move a patient from a sitting position inside a vehicle to supine on a backboard in less than 1 minute when conditions do not allow for standard immobilization.

rapport A trusting relationship that you build with your patient.

reassessment A step within the patient assessment process performed at regular intervals during the assessment process to identify and treat changes in a patient's condition. This should occur every 5 minutes for a patient in unstable condition and every 15 minutes for a patient in stable condition.

recovery position A side-lying position used to maintain a clear airway in unconscious patients who are breathing adequately and do not have suspected injuries to the spine, hips, or pelvis.

rectum The lowermost end of the colon.

red blood cells Cells that carry oxygen to the body's tissues; also called erythrocytes.

reduce To return a dislocated joint or fractured bone to its normal position; to set.

referred pain Pain felt in an area of the body other than the area where the cause of pain is located.

rehabilitation area The area that provides protection and treatment to firefighters and other responders working at an emergency. Here, workers are medically monitored and receive any needed care as they enter and leave the scene.

rehabilitation supervisor In incident command, the person who establishes an area that provides protection for responders from the elements and the situation.

renal pelvis A cone-shaped area that collects urine from the kidneys and funnels it through the ureter into the bladder.

repeater A special base station radio that receives messages and signals on one frequency and then automatically retransmits them on a second frequency.

res ipsa loquitor When the EMT or an EMS system is held liable even when the plaintiff is unable to clearly demonstrate how an injury occurred.

rescue supervisor In incident command, the person appointed to determine the type of equipment and resources needed for a situation involving extrication or special rescue; also called the extrication officer.

residual volume The air that remains in the lungs after maximal expiration.

respiration The physiologic process of exchanging oxygen and carbon dioxide, or, in the context of environmental emergencies, the loss of body heat as warm air in the lungs is exhaled into the atmosphere and cooler air is inhaled.

respiratory compromise The inability of the body to move gas effectively.

respiratory syncytial virus (RSV) A virus that causes an infection of the lungs and breathing passages; can lead to other serious illnesses that affect the lungs or heart, such as bronchiolitis and pneumonia; highly contagious and spread through droplets.

respiratory system All the structures of the body that contribute to the process of breathing, consisting of the upper and lower airways and their component parts.

responsiveness The way in which a patient responds to external stimuli, including verbal stimuli (sound), tactile stimuli (touch), and painful stimuli.

reticular activating system Located in the upper brain stem; responsible for maintenance of consciousness, specifically one's level of arousal.

retina The light-sensitive area of the eye where images are projected; a layer of cells at the back of the eye that changes the light image into electric impulses, which are carried by the optic nerve to the brain.

retinal detachment Separation of the retina from its attachments at the back of the eye.

retractions Movements in which the skin pulls in around the ribs during inspiration.

retrograde amnesia The inability to remember events leading up to a head injury.

retroperitoneal Behind the abdominal cavity.

retroperitoneal space The space between the abdominal cavity and the posterior abdominal wall, containing the kidneys, certain large vessels, and parts of the gastrointestinal tract.

return of spontaneous circulation (ROSC) The return of a pulse and effective blood flow to the body in a patient who previously was in cardiac arrest.

reverse triage A triage process used in treating multiple victims of a lightning strike, in which efforts are focused on those who are in respiratory and cardiac arrest; differs from conventional triage where such patients would be classified as deceased.

Revised Trauma Score (RTS) A scoring system used for patients with head trauma.

rhonchi Coarse, low-pitched breath sounds heard in patients with chronic mucus in the upper airways.

ricin A neurotoxin derived from mash that is left from the castor bean; causes pulmonary edema and respiratory and circulatory failure leading to death.

rigor mortis Stiffening of the body muscles; a definitive sign of death.

rooting reflex An infant reflex that occurs when something touches an infant's cheek, and the infant instinctively turns his or her head toward the touch.

route of exposure The manner by which a toxic substance enters the body.

rule of nines A system that assigns percentages to sections of the body, allowing calculation of the amount of skin surface involved in the burn area.

sacroiliac joint The connection point between the pelvis and the vertebral column.

sacrum One of three bones (sacrum and two pelvic bones) that make up the pelvic ring; consists of five fused sacral vertebrae.

safe zone An area of protection providing safety from the danger zone (hot zone).

safety officer In incident command, the person who monitors the scene for conditions or operations that may present a hazard to responders and patients; he or she may stop an operation when responder safety is an issue.

sagittal (lateral) plane An imaginary line where the body is divided into left and right parts.

saline locks (buff caps) Special types of intravenous devices filled with a small amount of normal saline to keep blood from clotting at the end of the catheter, allowing an IV site to be maintained without running fluids through the vein; also called heparin caps and heparin locks.

salivary glands The glands that produce saliva to keep the mouth and pharynx moist.

SAMPLE history A brief history of a patient’s condition to determine signs and symptoms, allergies, medications, pertinent past history, last oral intake, and events leading to the injury or illness.

sarin (GB) A nerve agent that is one of the G agents; a highly volatile colorless and odorless liquid that turns from liquid to gas within seconds to minutes at room temperature.

scald burn A burn caused by hot liquids.

scalp The thick skin covering the cranium, which usually bears hair.

scanner A radio receiver that searches or “scans” across several frequencies until the message is completed; the process is then repeated.

scapula The shoulder blade.

scene size-up A step within the patient assessment process that involves a quick assessment of the scene and the surroundings to provide information about scene safety and the mechanism of injury or nature of illness before you enter and begin patient care.

schizophrenia A complex, difficult-to-identify mental disorder whose onset typically occurs during early adulthood. Symptoms typically become more prominent over time and include delusions, hallucinations, a lack of interest in pleasure, and erratic speech.

school-age A person who is 6 to 12 years of age.

sciatic nerve The major nerve to the lower extremities; controls much of muscle function in the leg and sensation in most of the leg and foot.

sclera The tough, fibrous, white portion of the eye that protects the more delicate inner structures.

scoop stretcher A stretcher that is designed to be split into two or four sections that can be fitted around a patient who is lying on the ground or other relatively flat surface; also called an orthopedic stretcher.

scope of practice Most commonly defined by state law; outlines the care that the EMT is able to provide for the patient.

scuba gear A system that delivers air to the mouth and lungs at various atmospheric pressures, increasing with the depth of the dive; stands for self-contained underwater breathing apparatus.

sebaceous glands Glands that produce an oily substance called sebum, which discharges along the shafts of the hairs.

secondary assessment A step within the patient assessment process in which a systematic physical examination of the patient is performed. The examination may be a systematic exam or an assessment that focuses on a certain area or region of the body, often determined through the chief complaint.

secondary blast injury A penetrating or nonpenetrating injury caused by ordnance projectiles or secondary missiles.

secondary containment An engineered method to control spilled or released product if the main containment vessel fails.

secondary device A secondary explosive used by terrorists, set to explode after the initial bomb.

secondary (indirect) injury The after effects of the primary injury; includes abnormal processes such as cerebral edema, increased intracranial pressure, cerebral ischemia and hypoxia, and infection; onset is often delayed following the primary brain injury.

secondary prevention Efforts to limit the effects of an injury or illness that you cannot completely prevent.

secondary triage A type of patient sorting used in the treatment area that involves retriage of patients.

sedative A substance that decreases activity and excitement.

seizure A neurologic episode caused by a surge of electrical activity in the brain; can be a convulsion characterized by generalized, uncoordinated muscular activity, and can be associated with loss of consciousness.

self-contained breathing apparatus (SCBA) Respirator with independent air supply used by firefighters to enter toxic and otherwise dangerous atmospheres.

semen Fluid ejaculated from the penis and containing sperm.

seminal vesicles Storage sacs for sperm and seminal fluid, which empty into the urethra at the prostate.

sensitization Developing a sensitivity to a substance that initially caused no allergic reaction.

sensorineural deafness A permanent lack of hearing caused by a lesion or damage of the inner ear.

sensory nerves The nerves that carry sensations such as touch, taste, smell, heat, cold, and pain from the body to the central nervous system.

septic shock Shock caused by severe infection, usually a bacterial infection.

severe airway obstruction Occurs when a foreign body completely obstructs the patient’s airway. The patient cannot breathe, talk, or cough.

sexual assault An attack against a person that is sexual in nature, the most common of which is rape.

shaken baby syndrome A syndrome seen in abused infants and children; the patient has been subjected to violent, whiplash-type shaking injuries inflicted by the abusing individual that may cause coma, seizures, and increased intracranial pressure due to tearing of the cerebral veins with consequent bleeding into the brain.

shallow respirations Respirations characterized by little movement of the chest wall (reduced tidal volume) or poor chest excursion.

shock A condition in which the circulatory system fails to provide sufficient circulation, and therefore inadequate oxygen and nutrient delivery, to maintain normal cellular functions; also called hypoperfusion.

shoulder girdle The proximal portion of the upper extremities, made up of the clavicle, the scapula, and the humerus.

shunts Tubes that drain excess cerebrospinal fluid (CSF) from the brain to another part of the body outside of the brain, such as the abdomen; lowers pressure in the brain.

sickle cell disease A hereditary disease that causes normal, round red blood cells to become oblong, or sickle shaped.

side effects Any effects of a medication other than the desired ones.

sign Objective findings that can be seen, heard, felt, smelled, or measured.

simple access Access that is easily achieved without the use of tools or force.

simple pneumothorax Any pneumothorax that is free from significant physiologic changes and does not cause drastic changes in the vital signs of the patient.

simplex Single-frequency radio; transmissions can occur in either direction but not simultaneously in both; when one party transmits, the other can only receive, and the party that is transmitting is unable to receive.

single command system A command system in which one person is in charge, generally used with small incidents that involve only one responding agency or one jurisdiction.

situational awareness Knowledge and understanding of one’s surroundings and the ability to recognize potential risks to the safety of the patient or EMS team.

size-up The ongoing process of information gathering and scene evaluation to determine appropriate strategies and tactics to manage an emergency.

skeletal muscle Muscle that is attached to bones and usually crosses at least one joint; striated, or voluntary, muscle.

skeleton The framework that gives the body its recognizable form; also designed to allow motion of the body and protection of vital organs.

slander False and damaging information about a person that is communicated by the spoken word.

sling A bandage or material that helps to support the weight of an injured upper extremity.

small intestine The portion of the digestive tube between the stomach and the cecum, consisting of the duodenum, jejunum, and ileum.

smallpox A highly contagious disease; it is most contagious when blisters begin to form.

small-volume nebulizer A respiratory device that holds liquid medicine that is turned into a fine mist. The patient inhales the medication into the airways and lungs as a treatment for conditions such as asthma.

smooth muscle Involuntary muscle; it constitutes the bulk of the gastrointestinal tract and is present in nearly every organ to regulate automatic activity.

sniffing position An upright position in which the patient's head and chin are thrust slightly forward to keep the airway open; the optimum position for the uninjured child who requires airway management.

solid organs Solid masses of tissue where much of the chemical work of the body takes place (eg, the liver, spleen, pancreas, and kidneys).

solution A liquid mixture that cannot be separated by filtering or allowing the mixture to stand.

soman (GD) A nerve agent that is one of the G agents; twice as persistent as sarin and five times as lethal; it has a fruity odor, as a result of the type of alcohol used in the agent, and is a contact and an inhalation hazard that can enter the body through skin absorption and through the respiratory tract.

somatic nervous system The part of the nervous system that regulates activities over which there is voluntary control.

span of control In incident command, the subordinate positions under the commander's direction to which the workload is distributed; the ideal supervisor/worker ratio is one supervisor for three to seven workers.

Special Atomic Demolition Munitions (SADM) Small suitcase-sized nuclear weapons that were designed to destroy individual targets, such as important buildings, bridges, tunnels, and large ships.

special weapons and tactics team (SWAT) A specialized law enforcement tactical unit.

sphincters Circular muscles that encircle and, by contracting, constrict a duct, tube, or opening. Examples are found within the rectum, bladder, and blood vessels.

sphygmomanometer A device used to measure blood pressure.

spina bifida A developmental defect in which a portion of the spinal cord or meninges may protrude outside of the vertebrae and possibly even outside of the body, usually at the lower third of the spine in the lumbar area.

spinal cord An extension of the brain, composed of virtually all the nerves carrying messages between the brain and the rest of the body. It lies inside of and is protected by the spinal canal.

splint A flexible or rigid device used to protect and maintain the position of an injured extremity.

spontaneous pneumothorax A pneumothorax that occurs when a weak area on the lung ruptures in the absence of major injury, allowing air to leak into the pleural space.

spontaneous respirations Breathing that occurs without assistance.

spotter A person who assists a driver in backing up an ambulance to help adjust for blind spots at the back of the vehicle.

sprain A joint injury involving damage to supporting ligaments, and sometimes partial or temporary dislocation of bone ends.

staging supervisor In incident command, the person who locates an area to stage equipment and personnel and tracks unit arrival and deployment from the staging area.

stair chair A lightweight folding device that is used to carry a conscious, seated patient up or down stairs.

standard of care Written, accepted levels of emergency care expected by reason of training and profession; written by legal or professional organizations so that patients are not exposed to unreasonable risk or harm.

standard precautions Protective measures that have traditionally been developed by the Centers for Disease Control and Prevention for use in dealing with objects, blood, body fluids, and other potential exposure risks of communicable disease.

standing orders Written documents, signed by the EMS system's medical director, that outline specific directions, permissions, and sometimes prohibitions regarding patient care; also called protocols.

Star of Life The six-pointed star emblem that identifies vehicles that meet federal specifications as licensed or certified ambulances.

START triage A patient sorting process that stands for Simple Triage And Rapid Treatment and uses a limited assessment of the patient's ability to walk, respiratory status, hemodynamic status, and neurologic status.

state-sponsored terrorism Terrorism that is funded and/or supported by nations that hold close ties with terrorist groups.

status epilepticus A condition in which seizures recur every few minutes or last longer than 30 minutes.

statute of limitations The time within which a case must be commenced.

steam burn A burn caused by exposure to hot steam.

sterilization A process, such as heating, that removes microbial contamination.

sterile technique A technique that involves thorough decontamination, as well as the use of sterile fields around the procedure and full-scale, sterile PPE; often used during long, highly invasive surgical procedures.

sternocleidomastoid muscles The muscles on either side of the neck that allow movement of the head.

sternum The breast bone.

stimulant An agent that produces an excited state.

stoma An opening through the skin and into an organ or other structure; for example, in the neck, it connects the trachea directly to the skin.

strain Stretching or tearing of a muscle; also called a muscle pull.

strangulation Complete obstruction of blood circulation in a given organ as a result of compression or entrapment; an emergency situation causing death of tissue.

stratum corneal layer The outermost or dead layer of the skin.

stridor A harsh, high-pitched respiratory sound, generally heard during inspiration, that is caused by partial blockage or narrowing of the upper airway; may be audible without a stethoscope.

stroke An interruption of blood flow to the brain that results in the loss of brain function; also called a cerebrovascular accident (CVA).

stroke volume (SV) The volume of blood ejected with each ventricular contraction.

structure fire A fire in a house, apartment building, office, school, plant, warehouse, or other building.

subarachnoid hemorrhage Bleeding into the subarachnoid space, where the cerebrospinal fluid circulates.

subcutaneous emphysema A characteristic crackling sensation felt on palpation of the skin, caused by the presence of air in soft tissues.

subcutaneous (SC) injection Injection into the fatty tissue between the skin and muscle; a medication delivery route.

subcutaneous tissue Tissue, largely fat, that lies directly under the dermis and serves as an insulator of the body.

subdural hematoma An accumulation of blood beneath the dura mater but outside the brain.

sublingual (SL) Under the tongue; a medication delivery route.

substance abuse The misuse of any substance to produce a desired effect.

sucking chest wound An open or penetrating chest wall wound through which air passes during inspiration and expiration, creating a sucking sound. See also *open pneumothorax*.

sucking reflex An infant reflex in which the infant starts sucking when his or her lips are stroked.

suction catheter A hollow, cylindrical device used to remove fluid from the patient's airway.

sudden infant death syndrome (SIDS) Death of an infant or young child that remains unexplained after a complete autopsy.

suffix The part of a term that comes after the root word, at the end of the term.

sulfur mustard (H) A vesicant; it is a brownish, yellowish oily substance that is generally considered very persistent; has the distinct smell of garlic or mustard and, when released, is quickly absorbed into the skin and/or mucous membranes and begins an irreversible process of damaging the cells. Also called mustard gas.

superficial Closer to or on the skin.

superficial (first-degree) burns Burns that affect only the epidermis, characterized by skin that is red but not blistered or actually burned through.

superior Above a body part or nearer to the head.

superior vena cava One of the two largest veins in the body; carries blood from the upper extremities, head, neck, and chest into the heart.

supine Lying face up.

supine hypotensive syndrome Low blood pressure resulting from compression of the inferior vena cava by the weight of the pregnant uterus when the woman is supine.

surfactant A liquid protein substance that coats the alveoli in the lungs, decreases alveolar surface tension, and keeps the alveoli expanded; a low level in a premature infant contributes to respiratory distress syndrome.

suspension A mixture of ground particles that are distributed evenly throughout a liquid but do not dissolve.

swathe A bandage that passes around the chest to secure an injured arm to the chest.

sweat glands The glands that secrete sweat, located in the dermal layer of the skin.

sympathetic nervous system The part of the autonomic nervous system that controls active functions such as responding to fear (also known as the "fight-or-flight" system).

symphysis A type of joint that has grown together to form a very stable connection.

symptom Subjective findings that the patient feels but that can be identified only by the patient.

symptomatic hyperglycemia A state of unconsciousness resulting from several problems, including ketoacidosis, dehydration because of excessive urination, and hyperglycemia.

symptomatic hypoglycemia Severe hypoglycemia resulting in changes in mental status.

syncope A fainting spell or transient loss of consciousness, often caused by an interruption of blood flow to the brain.

syndromic surveillance The monitoring, usually by local or state health departments, of patients presenting to emergency departments and alternative care facilities, the recording of EMS call volume, and the use of over-the-counter medications.

synovial fluid The small amount of liquid within a joint used as lubrication.

synovial membrane The lining of a joint that secretes synovial fluid into the joint space.

systemic circulation The portion of the circulatory system outside of the heart and lungs.

systemic vascular resistance (SVR) The resistance that blood must overcome to be able to move within the blood vessels; related to the amount of dilation or constriction in the blood vessel.

systole The contraction, or period of contraction, of the heart, especially that of the ventricles.

systolic pressure The increased pressure in an artery with each contraction of the ventricles (systole).

tabun (GA) A nerve agent that is one of the G agents; is 36 times more persistent than sarin and approximately half as lethal; has a fruity smell and is unique because the components used to manufacture the agent are easy to acquire and the agent is easy to manufacture.

tachycardia A rapid heart rate, more than 100 beats/min.

tachypnea Increased respiratory rate.

tactical situation A hostage, robbery, or other situation in which armed conflict is threatened or shots have been fired and the threat of violence remains.

team In the context of EMS, a collection of health care providers who have been assigned specific roles, working interdependently in a coordinated manner under a designated leader.

team leader The team member who provides a combination of role-assignment, coordination, oversight, centralized decision making, and support for the team to accomplish its goals and achieve desired results.

technical rescue group A team of emergency responders from one or more departments in a region who are trained and on call for certain types of technical rescue.

technical rescue situation A rescue that requires special technical skills and equipment in one of many specialized rescue areas, such as technical rope rescue, cave rescue, and dive rescue.

telemetry A process in which electronic signals are converted into coded, audible signals; these signals can then be transmitted by radio or telephone to a receiver with a decoder at the hospital.

temporal bones The lateral bones on each side of the cranium; the temples.

temporomandibular joint The joint formed where the mandible and cranium meet, just in front of the ear.

tendon The fibrous connective tissue that attaches muscle to bone.

tension pneumothorax An accumulation of air or gas in the pleural space that progressively increases pressure in the chest that interferes with cardiac function with potentially fatal results.

termination of command The end of the incident command structure when an incident draws to a close.

tertiary blast injury An injury from whole-body displacement and subsequent traumatic impact with environmental objects.

testicle A male genital gland that contains specialized cells that produce hormones and sperm.

therapeutic communication Verbal and nonverbal communication techniques that encourage patients to express their feelings and to achieve a positive relationship.

therapeutic effect The desired or intended effect a medication is expected to have on the body.

thermal burns Burns caused by heat.

thoracic cage The chest or rib cage.

thoracic spine The 12 vertebrae that lie between the cervical vertebrae and the lumbar vertebrae. One pair of ribs is attached to each of these vertebrae.

thorax The chest cavity that contains the heart, lungs, esophagus, and great vessels.

thromboembolism A blood clot that has formed within a blood vessel and is floating within the bloodstream.

thrombophilia A tendency toward the development of blood clots as a result of an abnormality of the system of coagulation.

thrombosis A blood clot, either in the arterial or venous system. When the clot occurs in a cerebral artery, it may result in the interruption of cerebral blood flow and subsequent stroke.

thyroid cartilage A firm prominence of cartilage that forms the upper part of the larynx; the Adam's apple.

tibia The shinbone; the larger of the two bones of the lower leg, responsible for supporting the major weight-bearing surface of the knee and the ankle.

tidal volume The amount of air (in milliliters) that is moved in or out of the lungs during one relaxed breath; about 500 mL for an adult.

toddler A child age 1 to 3 years.

tolerance The need for increasing amounts of a drug to obtain the same effect.

tonsil tips Large, semirigid suction tips recommended for suctioning the pharynx; also called Yankauer tips.

topical medications Lotions, creams, and ointments that are applied to the surface of the skin and affect only that area; a medication delivery route.

topographic anatomy The superficial landmarks of the body that serve as guides to the structures that lie beneath them.

tort A wrongful act that gives rise to a civil lawsuit.

tourniquet The bleeding control method used when a wound continues to bleed despite the use of direct pressure; useful if a patient is bleeding severely from a partial or complete amputation.

toxicity levels Indicates the risk that a hazardous material poses to the health of an individual who comes into contact with it.

toxicology The study of toxic or poisonous substances.

toxin A poison or harmful substance produced by bacteria, animals, or plants.

trachea The windpipe; the main trunk for air passing to and from the lungs.

tracheitis Inflammation of the trachea.

tracheostomy A surgical procedure to create an opening (stoma) into the trachea; a stoma in the neck connects the trachea directly to the skin.

tracheostomy tube A plastic tube placed within the tracheostomy site (stoma).

traction Longitudinal force applied to a structure.

trade name The brand name that a manufacturer gives a medication; the name is capitalized.

tragus The small, rounded, fleshy bulge that lies immediately anterior to the ear canal.

trajectory The path a projectile takes once it is propelled.

transcutaneous (transdermal) Through the skin; a medication delivery route.

transient ischemic attack (TIA) A disorder of the brain in which brain cells temporarily stop functioning because of insufficient oxygen, causing stroke-like symptoms that resolve completely within 24 hours of onset.

transmission The way in which an infectious disease is spread: contact, airborne, by vehicles, or by vectors.

transportation area The area in a mass-casualty incident where ambulances and crews are organized to transport patients from the treatment area to receiving hospitals.

transportation supervisor In incident command, the person in charge of the transportation sector in a mass-casualty incident who assigns patients from the treatment area to awaiting ambulances in the transportation area.

transverse (axial) plane An imaginary line where the body is divided into top and bottom parts.

trauma emergencies Emergencies that are the result of physical forces applied to the body; injuries.

trauma score A score calculated from 1 to 16, with 16 being the best possible score. It relates to the likelihood of patient survival with the exception of a severe head injury. It takes into account the Glasgow Coma Scale (GCS) score, respiratory rate, respiratory expansion, systolic blood pressure, and capillary refill.

traumatic asphyxia A pattern of injuries seen after a severe force is applied to the chest, forcing blood from the great vessels back into the head and neck.

traumatic brain injury (TBI) A traumatic insult to the brain capable of producing physical, intellectual, emotional, social, and vocational changes.

treatment area The location in a mass-casualty incident where patients are brought after being triaged and assigned a priority, where they are reassessed, treated, and monitored until transport to the hospital.

treatment supervisor In incident command, the person, usually a physician, who is in charge of and directs EMS providers at the treatment area in a mass-casualty incident.

triage The process of sorting patients based on the severity of injury and medical need to establish treatment and transportation priorities.

triage supervisor In incident command, the person in charge of the incident command triage sector who directs the sorting of patients into triage categories in a mass-casualty incident.

triceps The muscle in the back of the upper arm.

tripod position An upright position in which the patient leans forward onto outstretched arms with the head and chin thrust slightly forward.

trunking Telecommunication systems that allow a computer to maximize utilization of a group of frequencies.

trust and mistrust Refers to a stage of development from birth to approximately 18 months of age, during which infants gain trust of their parents or caregivers if their world is planned, organized, and routine.

tuberculosis (TB) A chronic bacterial disease, caused by *Mycobacterium tuberculosis*, that usually affects the lungs but can also affect other organs such as the brain and kidneys; it is spread by cough and can lie dormant in a person's lungs for decades and then reactivate.

tunica media The middle and thickest layer of tissue of a blood vessel wall, composed of elastic tissue and smooth muscle cells that allow the vessel to expand or contract in response to changes in blood pressure and tissue demand.

turbinates Layers of bone within the nasal cavity.

turgor The ability of the skin to resist deformation; tested by gently pinching skin on the forehead or back of the hand.

two- to three-word dyspnea A severe breathing problem in which a patient can speak only two to three words at a time without pausing to take a breath.

tympanic membrane The eardrum; a thin, semitransparent membrane in the middle ear that transmits sound vibrations to the internal ear by means of auditory ossicles.

type 1 diabetes An autoimmune disorder in which the individual's immune system produces antibodies to the pancreatic beta cells, and therefore the pancreas cannot produce insulin; onset in early childhood is common.

type 2 diabetes A condition in which insulin resistance develops in response to increased blood glucose levels; can be managed by exercise and diet modification, but is often managed by medications.

UHF (*ultra high frequency*) Radio frequencies between 300 and 3,000 MHz.

ulna The inner bone of the forearm, on the side opposite the thumb.

umbilical cord The structure that connects the pregnant woman to the fetus via the placenta; contains two arteries and one vein.

unified command system A command system used in larger incidents in which there is a multiagency response or multiple jurisdictions are involved.

unintended effects Actions that are undesirable but pose little risk to the patient.

untoward effects Actions that can be harmful to the patient.

uremia Severe kidney failure resulting in the buildup of waste products within the blood. Eventually brain functions will be impaired.

ureter A small, hollow tube that carries urine from the kidneys to the bladder.

urethra The canal that conveys urine from the bladder to outside the body.

urinary bladder A sac behind the pubic symphysis made of smooth muscle that collects and stores urine.

urinary system The organs that control the discharge of certain waste materials filtered from the blood and excreted as urine.

urinary tract infection (UTI) A bacterial infection, usually of the lower urinary tract (urethra and bladder) that occurs when normal flora bacteria enter the urethra and grow.

urostomy A surgical procedure to create an opening (stoma) that connects the urinary system to the surface of the skin and allows urine to drain through the abdominal wall.

urticaria Small areas of generalized itching and/or burning that appear as multiple raised areas on the skin; hives.

uterus The muscular organ where the fetus grows, also called the womb; responsible for contractions during labor.

V agent (VX) One of the G agents; it is a clear, oily agent that has no odor and looks like baby oil; more than 100 times more lethal than sarin and is extremely persistent.

vagina The outermost cavity of a woman’s reproductive tract that connects the uterus with the vulva (the external female genitalia); the lower part of the birth canal.

vancomycin-resistant *enterococci* (VRE) A bacterium that is normally present in the human intestines and the female reproductive tract, but which can cause infection and which is resistant to the antibiotic vancomycin.

vapor hazard The term used to describe danger posed by an agent that enters the body through the respiratory tract.

vasa deferentia The spermatic duct of the testicles; also called vas deferens.

vascular access A procedure that gains access to a patient’s circulatory system in order to inject or remove fluids, medicines, or blood products, usually obtained through an intravenous catheter placed in a vein, but sometimes through a needle or catheter placed in an artery or a needle placed into bone.

vasoconstriction The narrowing of a blood vessel, such as with hypoperfusion or cold extremities.

vasoocclusive crisis Ischemia and pain caused by sickleshaped red blood cells that obstruct blood flow to a portion of the body.

vector-borne transmission The use of an animal to spread an organism from one person or place to another.

veins The blood vessels that carry blood from the tissues to the heart.

ventilation Exchange of air between the lungs and the environment, spontaneously by the patient or with assistance from another person, such as an EMT.

ventral The anterior surface of the body.

ventricle One of two (right and left) lower chambers of the heart. The left chamber receives blood from the left atrium (upper chamber) and delivers blood to the aorta. The right chamber receives blood from the right atrium and pumps it into the pulmonary artery.

ventricular fibrillation Disorganized, ineffective quivering of the ventricles, resulting in no blood flow and a state of cardiac arrest.

ventricular tachycardia A rapid heart rhythm in which the electrical impulse begins in the ventricle (instead of the atrium), which may result in inadequate blood flow and eventually deteriorate into cardiac arrest.

venules Very small, thin-walled blood vessels.

vernix caseosa A white, cheesy substance that covers the body of the fetus.

vertebrae The 33 bones that make up the spinal column.

vertex presentation A delivery in which the head of the newborn comes out first.

vesicants Blister agents; the primary route of entry for this agent is through the skin.

vesicular breath sounds Normal breath sounds made by air moving in and out of the alveoli.

VHF (very high frequency) Radio frequencies between 30 and 300 MHz; the VHF spectrum is further divided into "high" and "low" bands.

video laryngoscopy Visualization of the vocal cords, and thereby placement of the endotracheal tube, that is facilitated by use of a video camera and monitor.

viral hemorrhagic fevers (VHF) A group of diseases caused by viruses that include the Ebola, Rift Valley, and yellow fevers, among others. This group of viruses causes the blood in the body to seep out from the tissues and blood vessels.

virulence The strength or ability of a pathogen to produce disease.

viruses Germs that require a living host to multiply and survive.

visceral pleura Thin membrane that covers the lungs.

vital capacity The amount of air that can be forcibly expelled from the lungs after breathing in as deeply as possible.

vital signs The key signs that are used to evaluate the patient's overall condition, including respirations, pulse, blood pressure, level of consciousness, and skin characteristics.

vocal cords Thin white bands of tough muscular tissue that are lateral borders of the glottis and serve as the primary center for speech production.

volatility How long a chemical agent will stay on a surface before it evaporates.

voluntary activities Actions that we consciously perform, in which sensory input or conscious thought determines a specific muscular activity.

voluntary muscle Muscle that is under direct voluntary control of the brain and can be contracted or relaxed at will; skeletal, or striated, muscle.

$\dot{V}/\dot{Q}$ ratio A measurement that examines how much gas is being moved effectively and how much blood is flowing around the alveoli where gas exchange (perfusion) occurs.

warm zone The area located between the hot zone and the cold zone at a hazardous materials incident. The decontamination corridor is located in this zone.

weapon of mass casualty (WMC) Any agent designed to bring about mass death, casualties, and/or massive damage to property and infrastructure (bridges, tunnels, airports, and seaports); also known as a weapon of mass destruction (WMD).

weapon of mass destruction (WMD) Any agent designed to bring about mass death, casualties, and/or massive damage to property and infrastructure (bridges, tunnels, airports, and seaports); also known as a weapon of mass casualty (WMC).

weaponization The creation of a weapon from a biologic agent generally found in nature and that causes disease; the agent is cultivated, synthesized, and/or mutated to maximize the target population's exposure to the germ.

wheal A raised, swollen, well-defined area on the skin resulting from an insect bite or allergic reaction.

wheeled ambulance stretcher A specially designed stretcher that can be rolled along the ground. A collapsible undercarriage allows it to be loaded into the ambulance; also called an ambulance stretcher.

wheezing A high-pitched, whistling breath sound that is most prominent on expiration, and which suggests an obstruction or narrowing of the lower airways; occurs in asthma, bronchiolitis, and chronic obstructive pulmonary disease.

white blood cells Blood cells that have a role in the body's immune defense mechanisms against infection; also called leukocytes.

word root The main part of a term that contains the primary meaning.

work The measure of force over distance.

work of breathing An indicator of oxygenation and ventilation; reflects the patient's attempt to compensate for hypoxia.

xiphoid process The narrow, cartilaginous lower tip of the sternum.

zone of injury The area of potentially damaged soft tissue, adjacent nerves, and blood vessels surrounding an injury to a bone or a joint.

zygomas The quadrangular bones of the cheek, articulating with the frontal bone, the maxillae, the zygomatic processes of the temporal bone, and the great wings of the sphenoid bone.

Index

Note: Page numbers followed by f or t indicate material in figures or tables, respectively.
