Recall from Chapter 10, *Airway Management*, that negative-pressure ventilation—the process that occurs with normal breathing—involves contraction of the diaphragm and intercostal muscles and a decrease in intrathoracic pressure; as a result, air is pulled into the lungs. Positive-pressure ventilation involves pushing air into the lungs, as with artificial ventilation. It is critical to perform positive-pressure ventilation correctly. Deliver each breath over a period of 1 second, just enough to produce visible chest rise, at a rate that is appropriate for the patient (10 to 12 breaths/min for adults; 12 to 20 breaths/min for infants and children). If positive-pressure ventilation is delivered too fast or with too much force (hyperventilation), the resultant increase in intrathoracic pressure may compress the venae cavae and thereby impair blood return to the right atrium. If blood return is impaired, less blood is pumped from the left ventricle per contraction (stroke volume). As a result, the patient's blood pressure (and perfusion status) will deteriorate.

11. What does *exacerbation* mean?

Exacerbation means to intensify or worsen in severity. In acute exacerbation of COPD, no copathologic (secondary) condition exists that would clearly explain the patient's sudden deterioration (ie, congestive heart failure, pneumonia). Patients with COPD often experience acute exacerbation of their disease secondary to a change in environmental conditions, such as weather, humidity, or sudden activation of central heating or cooling in the home. As with diseases such as asthma, COPD can also be exacerbated by certain triggers, such as cat dander, dust, and seasonal allergens. In some cases, acute exacerbation is idiopathic (of unknown cause). As the patient's disease progresses, he or she will eventually reach a point at which the lungs simply cannot support oxygenation and ventilation (end-stage COPD). In end-stage COPD, it can be difficult to determine whether the patient is experiencing an exacerbation that can be treated effectively or if he or she has reached the end of the disease process. This will not affect your treatment, however, which involves airway management and ensuring adequate oxygenation and ventilation.

EMS Patient Care Report (PCR)

Date: 3-12-16	**Incident No.:** 130309	**Nature of Call:** Respiratory		**Location:** 109 East Lawler	
Dispatched: 0430	**En Route:** 0432	**At Scene:** 0440	**Transport:** 0449	**At Hospital:** 0510	**In Service:** 0519

Patient Information

Age: 72 **Sex:** F **Weight (in kg [lb]):** 50 kg (110 lb)	**Allergies:** Sulfa, ibuprofen, aspirin **Medications:** Oxygen, Combivent, albuterol, lisinopril **Past Medical History:** Emphysema, hypertension, gout **Chief Complaint:** Trouble breathing

Vital Signs

Time: 0443	**BP:** 116/54	**Pulse:** 110	**Respirations:** 28	**Spo_2:** 88%
Time: 0449	**BP:** 108/50	**Pulse:** 124	**Respirations:** 8	**Spo_2:** 82%
Time: 0455	**BP:** 112/70	**Pulse:** 118	**Respirations:** 12	**Spo_2:** 90%

Narrative

Dispatched to the residence of a 72-year-old woman with difficulty breathing. On arrival at the scene, found the patient sitting on the edge of her couch; she was wearing home oxygen via nasal cannula and was smoking a cigarette. Immediately asked patient to extinguish cigarette and continued with the primary assessment. Patient could only speak in two-word sentences and was experiencing marked respiratory distress. Past medical history significant for emphysema, hypertension, and gout. The patient states that she is normally short of breath; however, it suddenly worsened today. Further assessment revealed pursed lip breathing, prolonged exhalation, and scattered wheezing on auscultation. Obtained vital signs and applied high-flow oxygen via nonrebreathing mask because of signs of worsened hypoxemia. Patient takes numerous medications and states that she has been compliant with all of them. Placed patient onto stretcher, loaded her into the ambulance, and reassessed her condition. Patient's level of consciousness had markedly decreased (responsive to pain only), her respirations became slow and shallow, her oxygen saturation decreased, and she developed cyanosis around her mouth and to her nail beds. Inserted nasal airway and began assisting her ventilations with a BVM and high-flow oxygen. Began transport to hospital and continued treatment. En route, noted that patient's oxygen saturation had improved and her cyanosis had resolved; however, her LOC remained unchanged. Continued treatment and reassessment until arrival at the hospital. Transferred patient care to ED staff w/o incident. Verbal report given to staff nurse.**End of report**

Prep Kit

Ready for Review

- Dyspnea is a common complaint that may be caused by numerous medical problems, including infections of the upper or lower airways, acute pulmonary edema, COPD, spontaneous pneumothorax, asthma, allergic reactions, pleural effusion, mechanical obstruction of the airway, pulmonary embolism, and hyperventilation.
- Each of these lung disorders has the ability to interfere with the exchange of oxygen and carbon dioxide that takes place during respiration. This interference may be in the form of damage to the alveoli, separation of the alveoli from the pulmonary vessels by fluid or infection, obstruction of the air passages, or air or excess fluid in the pleural space.
- Patients with chronic lung diseases often have high levels of blood carbon dioxide; in some cases, giving too much oxygen to them may depress or stop respirations (hypoxic drive). However, never withhold oxygen from patients with dyspnea.
- Patients often develop breathing difficulty and/ or hypoxia with the following medical conditions: upper or lower airway infection, acute pulmonary edema, COPD, hay fever, asthma, anaphylaxis, spontaneous pneumothorax, and pleural effusion.
- Infectious diseases associated with dyspnea include epiglottitis, bronchitis, tuberculosis, pneumonia, and pertussis.
- Breath sounds (lung sounds) are some of the most important vital signs you should assess when treating a patient in respiratory distress.
- Signs and symptoms of breathing difficulty include adventitious breath sounds (wheezing, stridor, crackles, and rhonchi); nasal flaring; pursed lip breathing; cyanosis; inability to talk; use of accessory muscles to breathe; and sitting in the tripod position, which allows the diaphragm the most room to function.
- Interventions for respiratory problems may include the following:
  - Oxygen via a nonrebreathing mask at 15 L/min, positive-pressure ventilations using a BVM, pocket mask, or a flow-restricted oxygen-powered ventilation device
  - Airway management techniques such as use of an oropharyngeal (oral) airway, a nasopharyngeal (nasal) airway, suctioning, or airway positioning
  - Providing noninvasive ventilatory support with continuous positive airway pressure (CPAP)
  - Positioning the patient in a high-Fowler's position or a position of comfort to facilitate breathing
  - Assistance with respiratory medications found in a prescribed MDI or a small-volume nebulizer (Consult medical control to assist with its use, or follow standing orders if the orders allow for this.)
- Remember, a patient who is breathing rapidly may not be getting enough oxygen as a result of respiratory distress from a variety of problems, including pneumonia or a pulmonary embolism; trying to "blow off" more carbon dioxide to compensate for acidosis caused by a poison, a severe infection, or a high level of blood glucose; or having a stress reaction.
- In every case, prompt recognition of the problem, administration of oxygen, and prompt transport are essential.

Vital Vocabulary

acidosis The buildup of excess acid in the blood or body tissues that results from a primary illness.

adventitious breath sounds Abnormal breath sounds such as wheezing, stridor, rhonchi, and crackles.

alkalosis The buildup of excess base (lack of acids) in the body fluids.

allergen A substance that causes an allergic reaction.

anaphylaxis (anaphylactic shock) An extreme, life-threatening, systemic allergic reaction that may include shock and respiratory failure.

asthma An acute spasm of the smaller air passages, called bronchioles, associated with excessive mucus production and with swelling of the mucous lining of the respiratory passages.

atelectasis Collapse of the alveolar air spaces of the lungs.

bronchial breath sounds Normal breath sounds made by air moving through the bronchi.

bronchiolitis Inflammation of the bronchioles that usually occurs in children younger than 2 years and is often caused by the respiratory syncytial virus.

bronchitis An acute or chronic inflammation of the lung that may damage lung tissue; usually associated with cough and production of sputum and, depending on its cause, sometimes fever.

carbon dioxide retention A condition characterized by a chronically high blood level of carbon dioxide in which the respiratory center no longer responds to high blood levels of carbon dioxide.

carbon monoxide An odorless, colorless, tasteless, and highly poisonous gas that results from incomplete oxidation of carbon in combustion.

chronic bronchitis Irritation of the major lung passageways from infectious disease or irritants such as smoke.

chronic obstructive pulmonary disease (COPD) A slow process of dilation and disruption of the airways and alveoli caused by chronic bronchial obstruction.

continuous positive airway pressure (CPAP) A method of ventilation used primarily in the treatment of critically ill patients with respiratory distress; can prevent the need for endotracheal intubation.

crackles Crackling, rattling breath sounds signaling fluid in the air spaces of the lungs; formerly called rales.

croup An inflammatory disease of the upper respiratory system that may cause a partial airway obstruction and is characterized by a barking cough; usually seen in children.

diphtheria An infectious disease in which a membrane forms, lining the pharynx; this lining can severely obstruct the passage of air into the larynx.

dyspnea Shortness of breath or difficulty breathing.

embolus A blood clot or other substance in the circulatory system that travels to a blood vessel where it causes a blockage.

emphysema A disease of the lungs in which there is extreme dilation and eventual destruction of the pulmonary alveoli with poor exchange of oxygen and carbon dioxide; it is one form of chronic obstructive pulmonary disease.

epiglottitis A disease in which the epiglottis becomes inflamed and enlarged and may cause an upper airway obstruction.

hay fever An allergic response usually to outdoor airborne allergens such as pollen or sometimes indoor allergens such as dust mites or pet dander; also called allergic rhinitis.

hyperventilation Rapid or deep breathing that lowers the blood carbon dioxide level below normal.

hyperventilation syndrome (panic attack) This syndrome occurs in the absence of other physical problems. The respirations of a person who is experiencing hyperventilation syndrome may be as high as 40 shallow breaths/min or as low as only 20 very deep breaths/min.

hypoxia A condition in which the body's cells and tissues do not have enough oxygen.

hypoxic drive A condition in which chronically low levels of oxygen in the blood stimulate the respiratory drive; seen in patients with chronic lung diseases.

influenza type A Virus that has crossed the animal/ human barrier and has infected humans, recently reaching a pandemic level with the H1N1 strain.

metered-dose inhaler (MDI) A miniature spray canister used to direct medications through the mouth and into the lungs.

orthopnea Severe dyspnea experienced when lying down and relieved by sitting up.

oxygenation The process of delivering oxygen to the blood.

pandemic An outbreak that occurs on a global scale.

paroxysmal nocturnal dyspnea Severe shortness of breath, especially at night after several hours of reclining; the person is forced to sit up to breathe.

pertussis (whooping cough) An airborne bacterial infection that affects mostly children younger than 6 years. Patients will be feverish and exhibit a "whoop" sound on inspiration after a coughing attack; highly contagious through droplet infection.

pleural effusion A collection of fluid between the lung and chest wall that may compress the lung.

pleuritic chest pain Sharp, stabbing pain in the chest that is worsened by a deep breath or other chest wall movement; often caused by inflammation or irritation of the pleura.

pneumonia An infectious disease of the lung that damages lung tissue.

pneumothorax A partial or complete accumulation of air in the pleural space.

pulmonary edema A buildup of fluid in the lungs, usually as a result of congestive heart failure.

pulmonary embolism A blood clot that breaks off from a large vein and travels to the blood vessels of the lung, causing obstruction of blood flow.

respiration The exchange of oxygen and carbon dioxide.

respiratory syncytial virus (RSV) A virus that causes an infection of the lungs and breathing passages; can lead to other serious illnesses that affect the lungs or heart, such as bronchiolitis and pneumonia. RSV is highly contagious and spread through droplets.

rhonchi Coarse breath sounds heard in patients with chronic mucus in the airways.

small-volume nebulizer A respiratory device that holds liquid medicine that is turned into a fine mist. The patient inhales the medication into the airways and lungs as a treatment for conditions such as asthma.

stridor A harsh, high-pitched, barking inspiratory sound often heard in acute laryngeal (upper airway) obstruction.

tuberculosis (TB) A disease that can lay dormant in a person's lungs for decades, then reactivate; many strains are resistant to antibiotics. TB is spread by cough.

ventilation Exchange of air between the lungs and the environment, spontaneously by the patient or with assistance from another person, such as an EMT.

vesicular breath sounds Normal breath sounds made by air moving in and out of the alveoli.

wheezing A high-pitched, whistling breath sound, characteristically heard on expiration in patients with asthma or chronic obstructive pulmonary disease.

Assessment *in Action*

It is mid-February and you respond to a local movie theater for a 42-year-old man with respiratory distress. Upon arrival, you and your partner are directed to the lobby where you observe a patient who appears to be having trouble breathing. The patient is leaning forward and speaking in short bursts. You notice the patient is using accessory muscles in his neck to help with breathing. The patient informs you he was standing outside in the cold for over 20 minutes waiting for a friend. He has a remote history of asthma, but has not had an attack in several years. The patient denies any other past medical history, takes no medications, and has no allergies. Vital signs show: pulse, 106 beats/min; respirations, 26 breaths/min and labored; blood pressure, 142/88 mm Hg; and Spo_2, 91%. Your physical examination reveals obvious accessory muscle use to the chest and neck and diffuse wheezing in all lung fields.

1. Which of the following medications can be used for the treatment of an acute asthma attack?

   A. Cromolyn
   B. Albuterol
   C. Fluticasone
   D. Salmeterol

2. Which of the following statements is true regarding asthma?

   A. Asthma involves accumulation of air in the pleural space.
   B. Asthma involves a collection of fluid in the pleural space.
   C. Asthma involves excessive mucus production.
   D. Asthma involves a collection of fluid in the alveoli.

3. The patient is exhibiting signs of respiratory distress, such as accessory muscle use and difficulty speaking. Which of the following is also a sign of respiratory distress?

   A. Pursed lip breathing
   B. Respiratory rate of 16 breaths/min
   C. Warm, pink skin
   D. Clear and equal breath sounds

4. You ask your partner to administer oxygen therapy. What is the most appropriate method for oxygen delivery to this patient?

   A. Nasal cannula at 2 to 6 L/min
   B. Nonrebreathing mask at 15 L/min
   C. Venturi mask at 8 L/min
   D. BVM at 15 L/min

5. When assisting an asthmatic patient with a small-volume nebulizer attached to oxygen, what is the appropriate flow rate for the oxygen?

   A. 2 L/min
   B. 4 L/min
   C. 6 L/min
   D. 10 L/min

6. In addition to asthma, which of the following conditions is associated with wheezing?

   A. Croup
   B. Epiglottitis
   C. Pulmonary embolism
   D. Bronchitis

7. While administering a nebulizer of albuterol to your patient, you assess for possible side effects to the medication. Which of the following is typically *NOT* a side effect of nebulized albuterol?

   A. Vomiting
   B. Increased pulse rate
   C. Nervousness
   D. Muscle tremors

8. In addition to asthma, wheezing can be caused by COPD. What are the underlying causes of chronic bronchitis and emphysema?
9. What are the signs and symptoms of a pulmonary embolism?
10. Explain why carbon monoxide has been called “the silent killer.”

CHAPTER
16

Cardiovascular Emergencies

National EMS Education Standard Competencies

Pathophysiology

Applies fundamental knowledge of the pathophysiology of respiration and perfusion to patient assessment and management.

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Cardiovascular

Anatomy, signs, symptoms, and management of

› Chest pain (pp 629–665)
› Cardiac arrest (pp 629–639, 654–665)

Anatomy, physiology, pathophysiology, assessment, and management of

› Acute coronary syndrome (pp 629–639, 642–652)
  • Angina pectoris (pp 629–638, 642–652)
  • Myocardial infarction (pp 629–639, 654–665)
› Aortic aneurysm/dissection (pp 629–636, 642–652)
› Thromboembolism (pp 629–637, 642–652)
› Heart failure (pp 629–636, 640–652)
› Hypertensive emergencies (pp 629–636, 642–652)

Knowledge Objectives

1. Discuss the basic anatomy and physiology of the cardiovascular system. (pp 629–636)
2. Discuss the pathophysiology of the cardiovascular system. (pp 636–642)
3. Describe the anatomy, physiology, pathophysiology, assessment, and management of thromboembolism. (pp 636–639)

4. Describe the anatomy, physiology, pathophysiology, assessment, and management of angina pectoris. (pp 637–638)
5. Describe the anatomy, physiology, pathophysiology, assessment, and management of myocardial infarction. (pp 638–639)
6. Describe the anatomy, signs and symptoms, and management of hypertensive emergencies. (p 642)
7. Describe the anatomy, physiology, pathophysiology, assessment, and management of aortic aneurysm/ dissection. (p 642)
8. Explain the assessment for patients with cardiovascular problems. (pp 642–647)
9. Explain the relationship between airway management and the patient with cardiac compromise. (pp 643–644)
10. Give the indications and contraindications for the use of aspirin and nitroglycerin. (p 648)
11. Recognize that many patients will have had cardiac surgery and may have implanted pacemakers or defibrillators. (pp 653–654)
12. Define cardiac arrest. (p 654)
13. Compare the difference between the fully automated and the semiautomated defibrillator. (pp 654–655)
14. Describe the different types of AEDs. (p 655)
15. Explain the use of remote adhesive defibrillator pads. (p 656)
16. Recognize that not all patients in cardiac arrest require an electric shock. (p 656)
17. List the indications and contraindications for use of an automated external defibrillator (AED). (pp 656–657)
18. Discuss the reasons for early defibrillation. (pp 656–657)
19. Explain the circumstances that may result in inappropriate shocks from an AED. (p 657)
20. Explain the reason not to touch the patient, such as by delivering CPR, while the AED is analyzing the heart rhythm and delivering shocks. (p 657)
21. Describe AED maintenance procedures. (pp 657–659)
22. Explain the relationship of age to energy delivery. (p 659)
23. Explain the role of medical direction in the use of AEDs. (p 659)
24. Discuss the importance of practice and continuing education with the AED. (p 659)
25. Explain the need for a case review of each incident in which an AED is used. (p 659)
26. List quality improvement goals relating to AEDs. (p 659)
27. Discuss the procedures to follow for standard operation of the various types of AEDs. (pp 659–661)
28. Describe the emergency medical care for the patient with cardiac arrest. (pp 659–665)
29. Describe the components of patient care following AED shocks. (pp 661–663, 665)
30. Explain criteria for transport of the patient for advanced life support (ALS) following CPR and defibrillation. (pp 663–664)
31. Discuss the importance of coordinating with ALS personnel. (pp 664–665)

Skills Objectives

1. Describe the steps to take in the assessment of a patient with chest pain or discomfort. (pp 642–647)
2. Demonstrate how to provide emergency medical care for a patient with chest pain or discomfort. (pp 647–649)
3. Demonstrate the administration of nitroglycerin. (pp 648–649, Skill Drill 16-1)
4. Demonstrate how to attach a cardiac monitor to obtain an ECG. (pp 651–652, Skill Drill 16-2)
5. Demonstrate how to perform maintenance of an AED. (pp 657–659)
6. Demonstrate how to perform CPR. (pp 660–663, Skill Drill 16-3)
7. Demonstrate the use of an AED. (pp 660–663, Skill Drill 16-3)

Introduction

The American Heart Association reports that cardiovascular disease claimed 786,641 lives in the United States in 2011. This is 31.3% of all deaths, or approximately 1 of every 3 deaths. Although this is a decline from previous years, heart disease has been the leading killer of Americans since 1900.

It is important for EMS providers to understand that many deaths caused by cardiovascular disease occur because of problems that may have been avoided by people living more healthful lifestyles and by access to improved medical technology. We can help to reduce the number of deaths with better public awareness, early access to medical care, increased numbers of laypeople trained in cardiopulmonary resuscitation (CPR), increased use of evolving technology in dispatch and cardiac arrest response, public access to defibrillation devices, the recognition of the need for advanced life support (ALS) services and use of cardiac specialty centers when they are available.

This chapter begins with a brief description of the heart and how it works. It then discusses the relationship between chest pain or discomfort and ischemic heart disease. It explains how to recognize and treat acute myocardial infarction (classic heart attack) and its complications—sudden death, cardiogenic shock, and congestive heart failure (CHF). The use of nitroglycerin and aspirin are described. The last part of the chapter is devoted to the use and maintenance of the automated external defibrillator (AED).

Anatomy and Physiology

The heart is a relatively simple organ with a simple job. It has to pump blood to supply oxygen-enriched red blood cells to the tissues of the body. The heart is divided down the middle into two sides (left and right) by a wall called the septum. Each side of the heart has an **atrium**, or upper chamber, to receive incoming blood, and a **ventricle**, or lower chamber, to pump outgoing blood **Figure 16-1**. Blood leaves each of the four chambers of the heart through a one-way valve. These valves keep the blood moving through the circulatory system in the proper direction. The **aorta**, the body's main artery, receives the blood ejected from the left ventricle and delivers it to all the other arteries so they can carry blood to the tissues of the body.

The right side of the heart receives oxygen-poor (deoxygenated) blood from the veins of the body **Figure 16-2A**. Blood from the vena cava enters the right atrium, which then fills the right ventricle. After contraction of the right ventricle, blood flows into the pulmonary artery and the pulmonary circulation in the lungs, where the blood is oxygenated. As the blood reaches the lungs, it receives fresh oxygen from the alveoli and carbon dioxide waste is removed from the blood and moved into the alveoli. The blood then returns to the heart through the pulmonary veins. The left side of the heart receives oxygen-rich (oxygenated) blood from the lungs through the pulmonary veins **Figure 16-2B**. Blood enters the left atrium and then passes into the left ventricle. The left ventricle is more muscular than the right ventricle because it must pump blood into the aorta to supply all the other arteries of the body.

YOU are the Provider — PART 1

You and your partner are returning to your station after completing a call when you are dispatched to 1152 Blanco Road for a 60-year-old woman with chest pain. Dispatch advises you that the patient's son, who called 9-1-1, stated that she has a history of heart problems. You proceed to the scene, which is approximately 5 minutes away. The time is 0942 hours, traffic is light, the weather is clear, and the temperature is 80°F (27°C).

1. What is the function of the heart?
2. What does the heart require to function effectively?
3. What should you include in your primary assessment of a patient with cardiac problems?

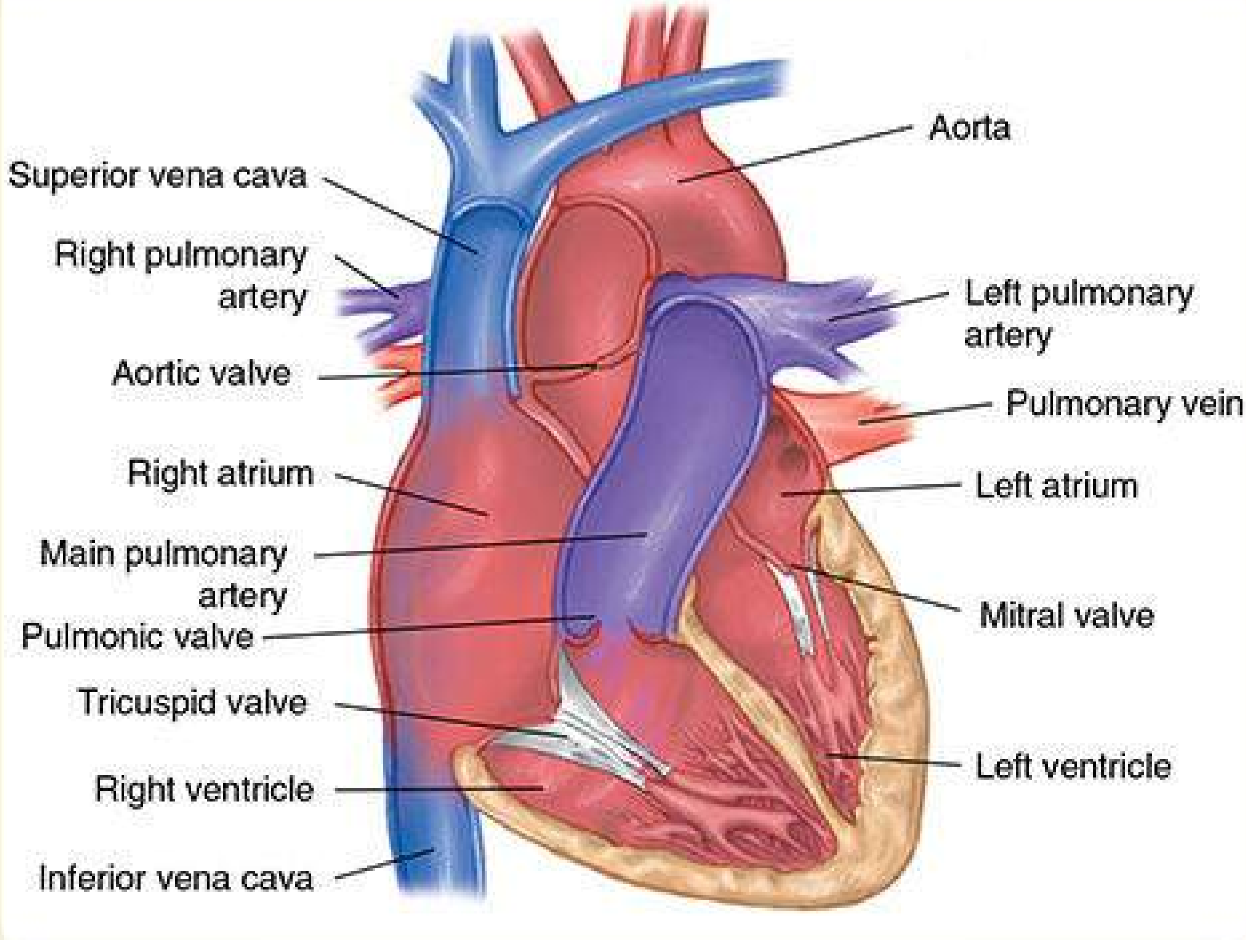

Figure 16-1 The heart is a four-chambered muscle that pumps blood to all parts of the body.

The heart contains more than muscle tissue. The heart's electrical system controls heart rate and enables the atria and ventricles to work together **Figure 16-3**. Normal electrical impulses begin in the sinus node, which is in the upper part of the right atrium and is also known as the sinoatrial (SA) node. The impulses travel across both atria, stimulating them to contract. Between the atria and the ventricles, the impulses cross a bridge of special electrical tissue called the atrioventricular (AV) node. Here, the signal is slowed for about one- to two-tenths of a second to allow blood time to pass from the atria to the ventricles. The impulses then exit the atrioventricular node and spread throughout both ventricles via the bundle of His, the right and left bundle branches, and the Purkinje fibers, causing the ventricular muscle cells to contract.

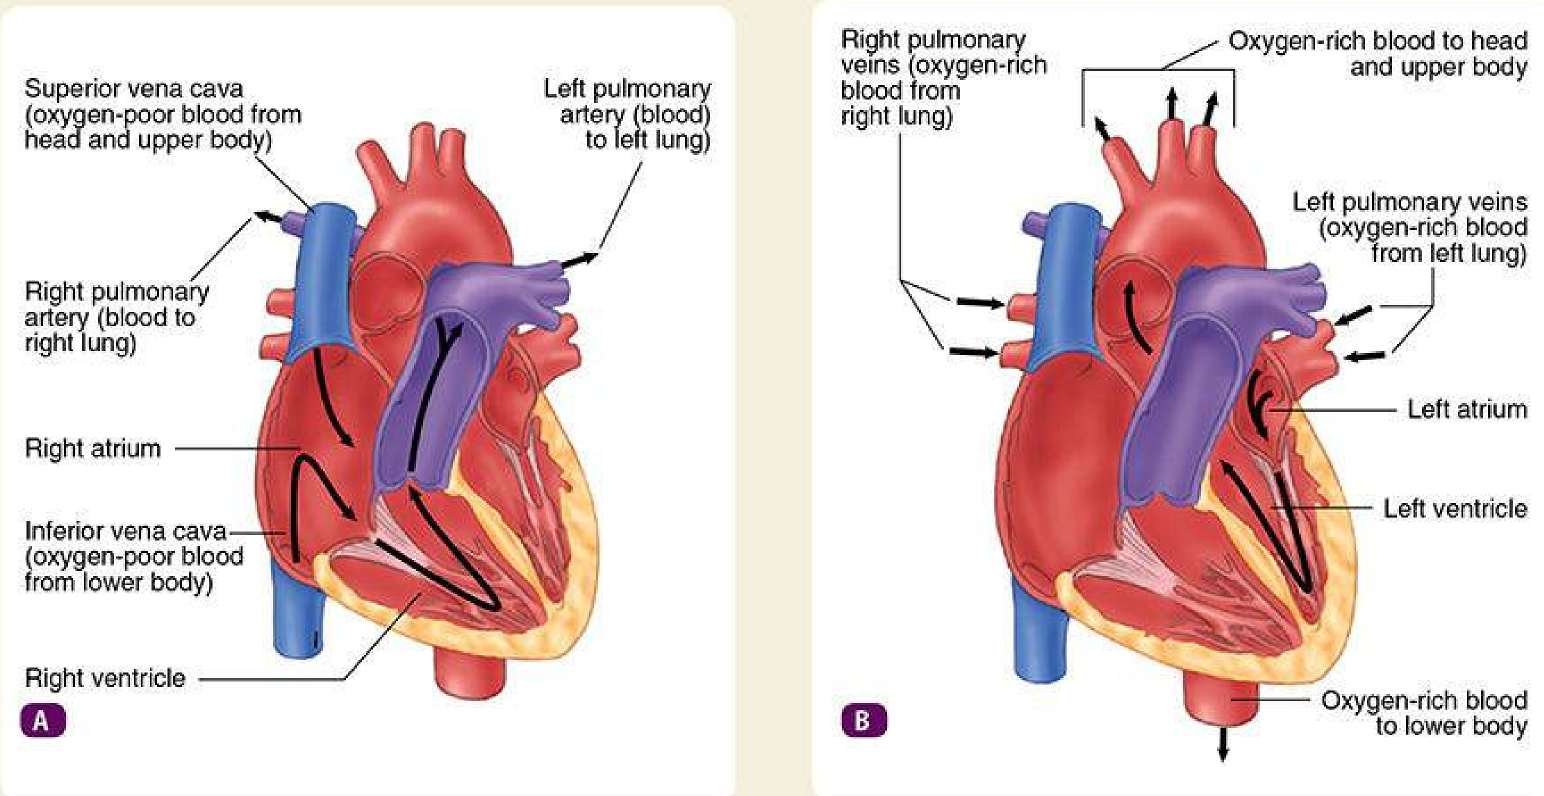

Figure 16-2 **A.** The right side of the heart receives oxygen-poor blood from the venous circulation. **B.** The left side of the heart receives oxygen-rich blood from the lungs through the pulmonary veins.

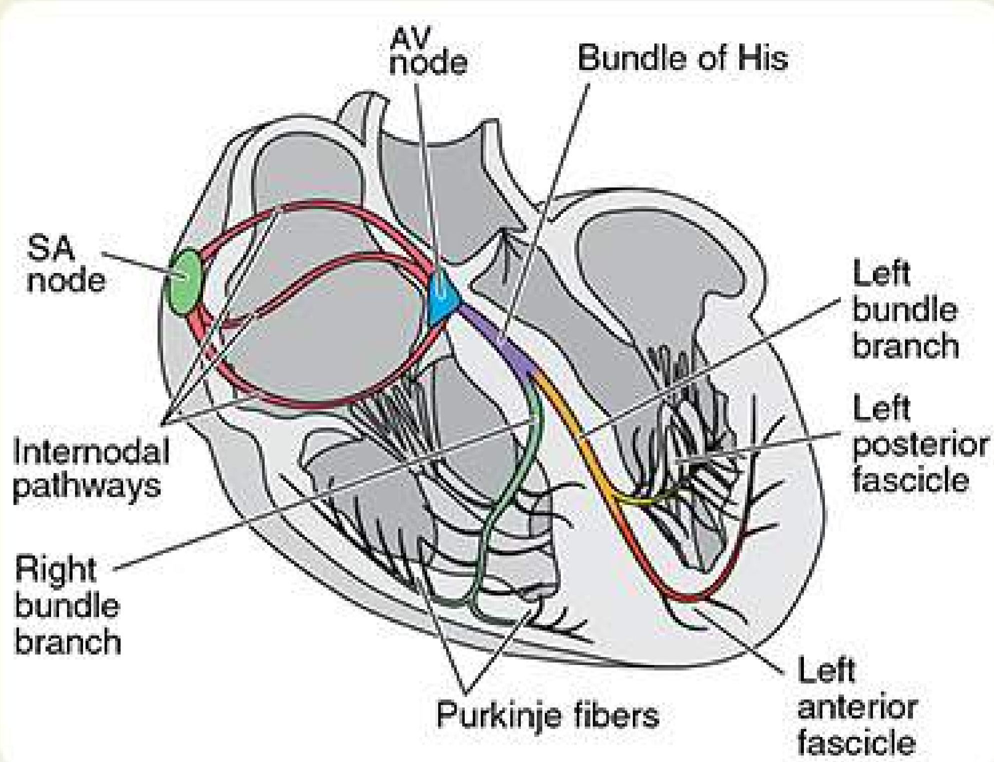

Figure 16-3 The electrical conduction system of the heart controls most aspects of heart rate and enables the four chambers to work together.

Cardiac muscle cells have a special characteristic called **automaticity** that is not found in any other type of muscle cells. Automaticity allows a cardiac muscle cell to contract spontaneously without a stimulus from a nerve source. Normal impulses in the heart start at the sinoatrial node. As long as impulses come from the sinoatrial node, the other myocardial cells will contract when the impulse reaches them. If no impulse arrives, however, the other myocardial cells are capable of creating their own impulses and stimulating a contraction of the heart, although at a generally slower rate.

The stimulus that originates in the sinoatrial node is controlled by impulses from the brain, which arrive by way of the **autonomic nervous system**. The autonomic nervous system is the part of the brain that controls the functions of the body that do not require conscious thought, such as the heartbeat, respirations, dilation and constriction of blood vessels, and digestion of food. The autonomic nervous system has two parts, the **sympathetic nervous system** and the **parasympathetic nervous system**. The sympathetic nervous system is also known as the "fight-or-flight" system and makes adjustments to the body to compensate for increased physical activity. The sympathetic nervous system speeds up the heart rate, increases respiratory rate and depth, dilates blood vessels in the muscles, and constricts blood vessels in the digestive system. The parasympathetic nervous system directly opposes the sympathetic nervous system. The parasympathetic nervous system slows the heart and respiratory rates, constricts blood vessels in the muscles, and dilates blood vessels in the digestive system. Normally, these two systems balance each other, but in times of stress, the sympathetic nervous system gains primary control, whereas in times of relaxation, the parasympathetic system takes control.

Circulation

To carry out its function of pumping blood, the **myocardium**, or heart muscle, must have a continuous supply of oxygen and nutrients. During periods of physical exertion or stress, the myocardium requires more oxygen. The heart must increase cardiac output to meet the increased metabolic requirements of the body. Cardiac output is increased by increasing the heart rate or stroke volume. The **stroke volume** is the volume of blood ejected with each ventricular contraction. In the normal heart, increased oxygen demand of the myocardium itself is supplied by **dilation**, or widening, of the coronary arteries, which increases blood flow. The **coronary arteries** are the blood vessels that supply blood to the heart muscle **Figure 16-4**. They start at the first part of the aorta, just above the **aortic valve**. The right coronary artery supplies blood to the right atrium and right ventricle and, in most people, the bottom part, or inferior wall, of the left ventricle. The left coronary artery supplies blood to the left atrium and left ventricle and divides into two major branches, just a short distance from the aorta.

Two major arteries branching from the upper aorta supply blood to the head and arms **Figure 16-5**. The right and left carotid arteries supply the head and brain with blood. The right and left subclavian arteries (under the clavicles) supply blood to the upper extremities. As the subclavian artery enters each arm, it becomes the brachial artery, the major vessel that supplies blood to each arm. Just below the elbow, the brachial artery divides into two major branches: the radial and ulnar arteries, supplying blood to the lower arms and hands.

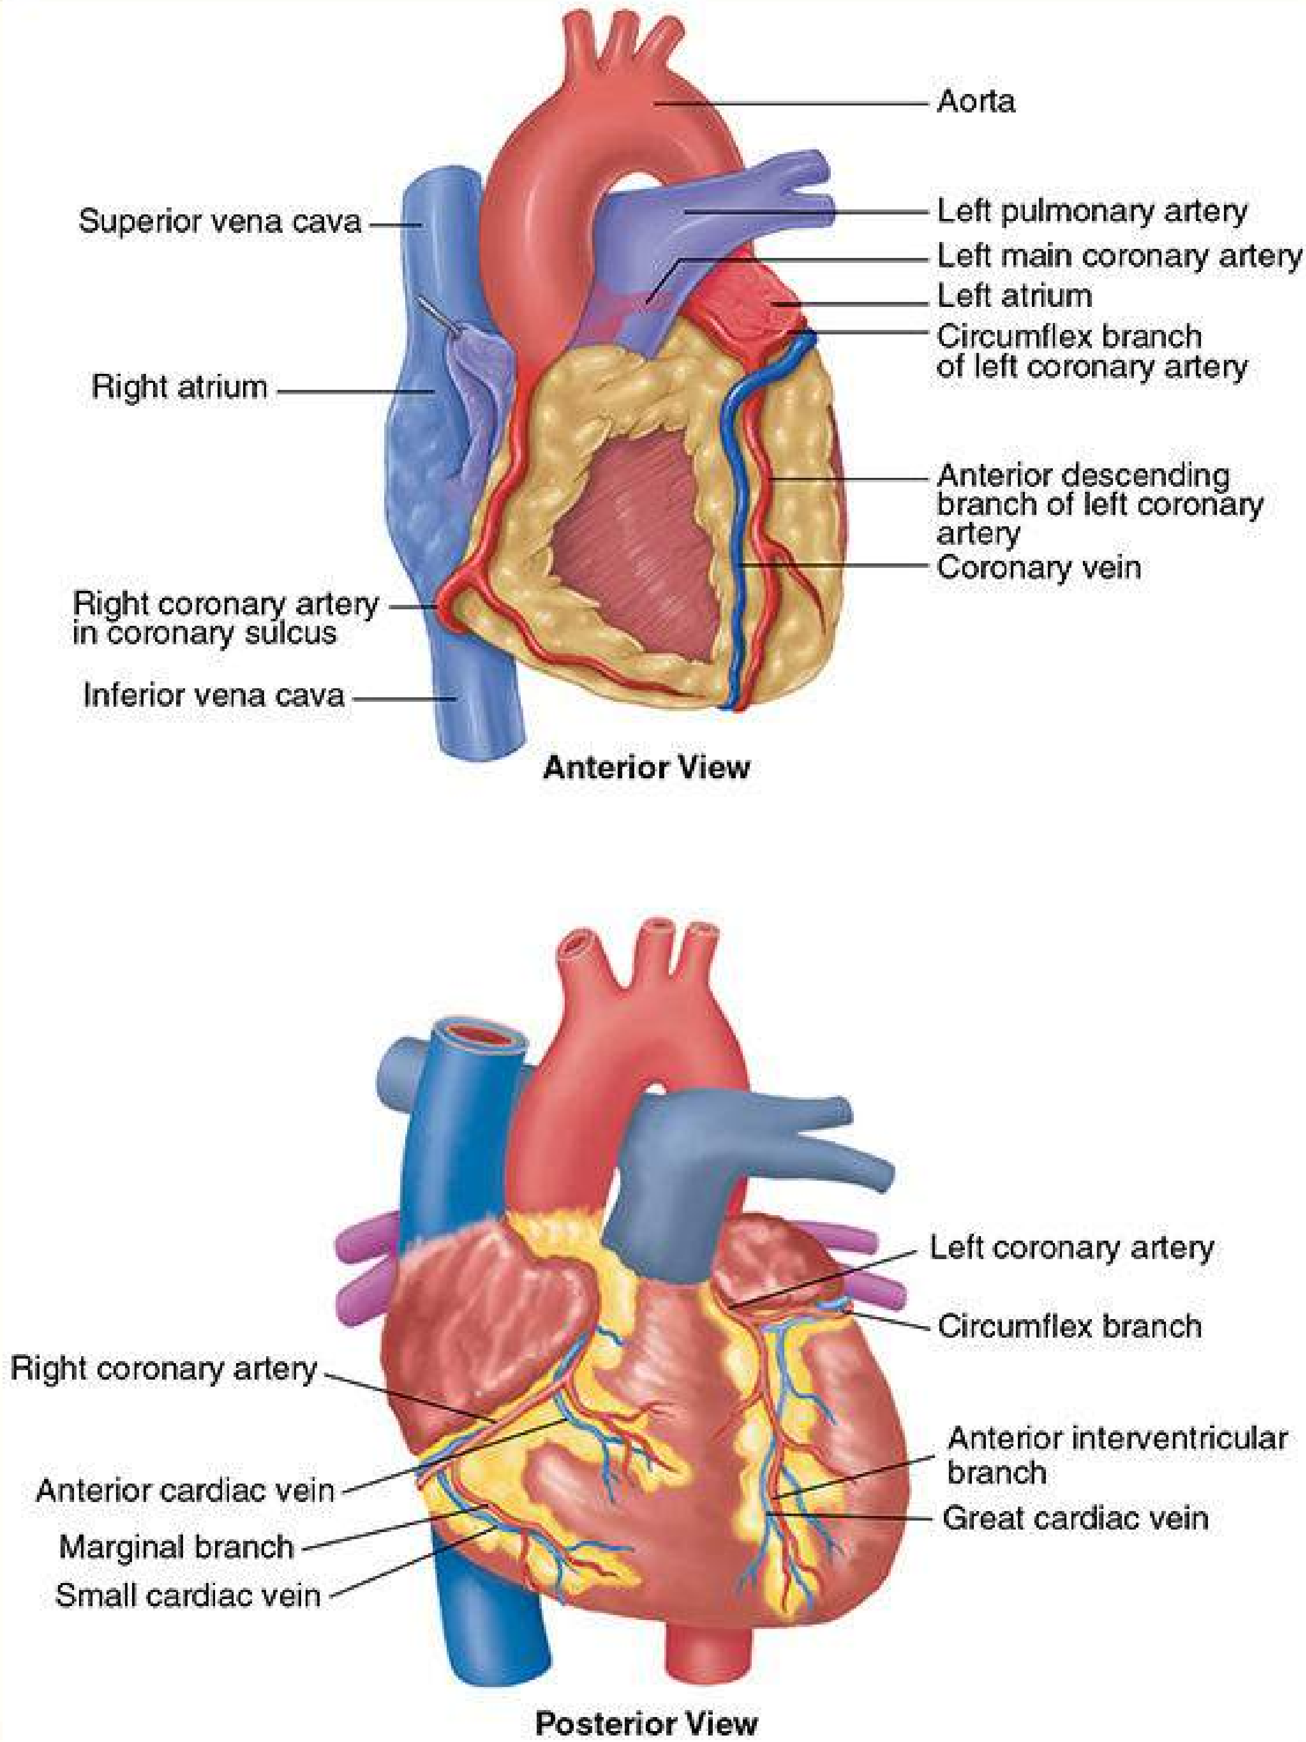

Figure 16-4 The coronary arteries carry the blood supply to the heart.

At the level of the umbilicus, the descending aorta divides into two main branches called the right and left iliac arteries, which supply blood to the groin, pelvis, and legs. As the iliac arteries enter the legs through the groin, they become the right and left femoral arteries. At the level of the knee, the femoral artery divides into the **anterior** (front) and **posterior** (back) tibial arteries and the peroneal artery, supplying blood to the lower legs and feet.

After blood travels through the arteries, it enters smaller and smaller vessels called arterioles and eventually enters the capillaries. Capillaries are tiny blood vessels about one cell thick that connect arterioles to venules. Capillaries, which are found in all parts of the body, allow the exchange of nutrients and waste at the cellular level. As the blood passes through the capillaries, it gives up oxygen to the tissues and picks up carbon dioxide and other waste products to be removed from the body.

Venules are the smallest branches of veins. After traveling through the capillaries, oxygen-poor blood enters the system of veins, starting with the venules, on its way back to the heart. The veins become larger and larger and eventually form the two large venae cavae: the superior vena cava and the inferior vena cava. The **superior** (upper) vena cava carries blood from the head and arms back to the right atrium. The **inferior** (lower) vena cava carries blood from the abdomen, kidneys, and legs back to the right atrium. The superior and inferior venae cavae join at the right atrium of the heart, where blood is eventually returned into the pulmonary circulation for oxygenation.

Blood consists of fluid and several types of cells **Figure 16-6**. Red blood cells are the most numerous and give the blood its color. Red blood cells carry oxygen to the body's tissues and remove carbon dioxide. Larger white blood cells help to fight infection. Platelets, which help the blood to clot, are much smaller than either red or white blood cells. Plasma is the fluid that the cells float in. It is a mixture of water, salts, nutrients, and proteins.

Blood pressure is the force of circulating blood against the walls of the arteries. Systolic blood pressure is the maximum pressure generated in the arms and legs during the contraction of the left ventricle, during the time period known as systole. As the left ventricle relaxes in the stage known as diastole, the arterial pressure falls. When the left ventricle relaxes, the aortic valve closes and blood flow between the left ventricle and the aorta stops. The diastolic blood pressure is the pressure exerted against the walls of the arteries while the left ventricle is at rest. Remember that the top number in a blood pressure reading is the systolic pressure, and the bottom number is the diastolic, or resting, pressure. The cardiac cycle consists of one systolic and one diastolic time period.

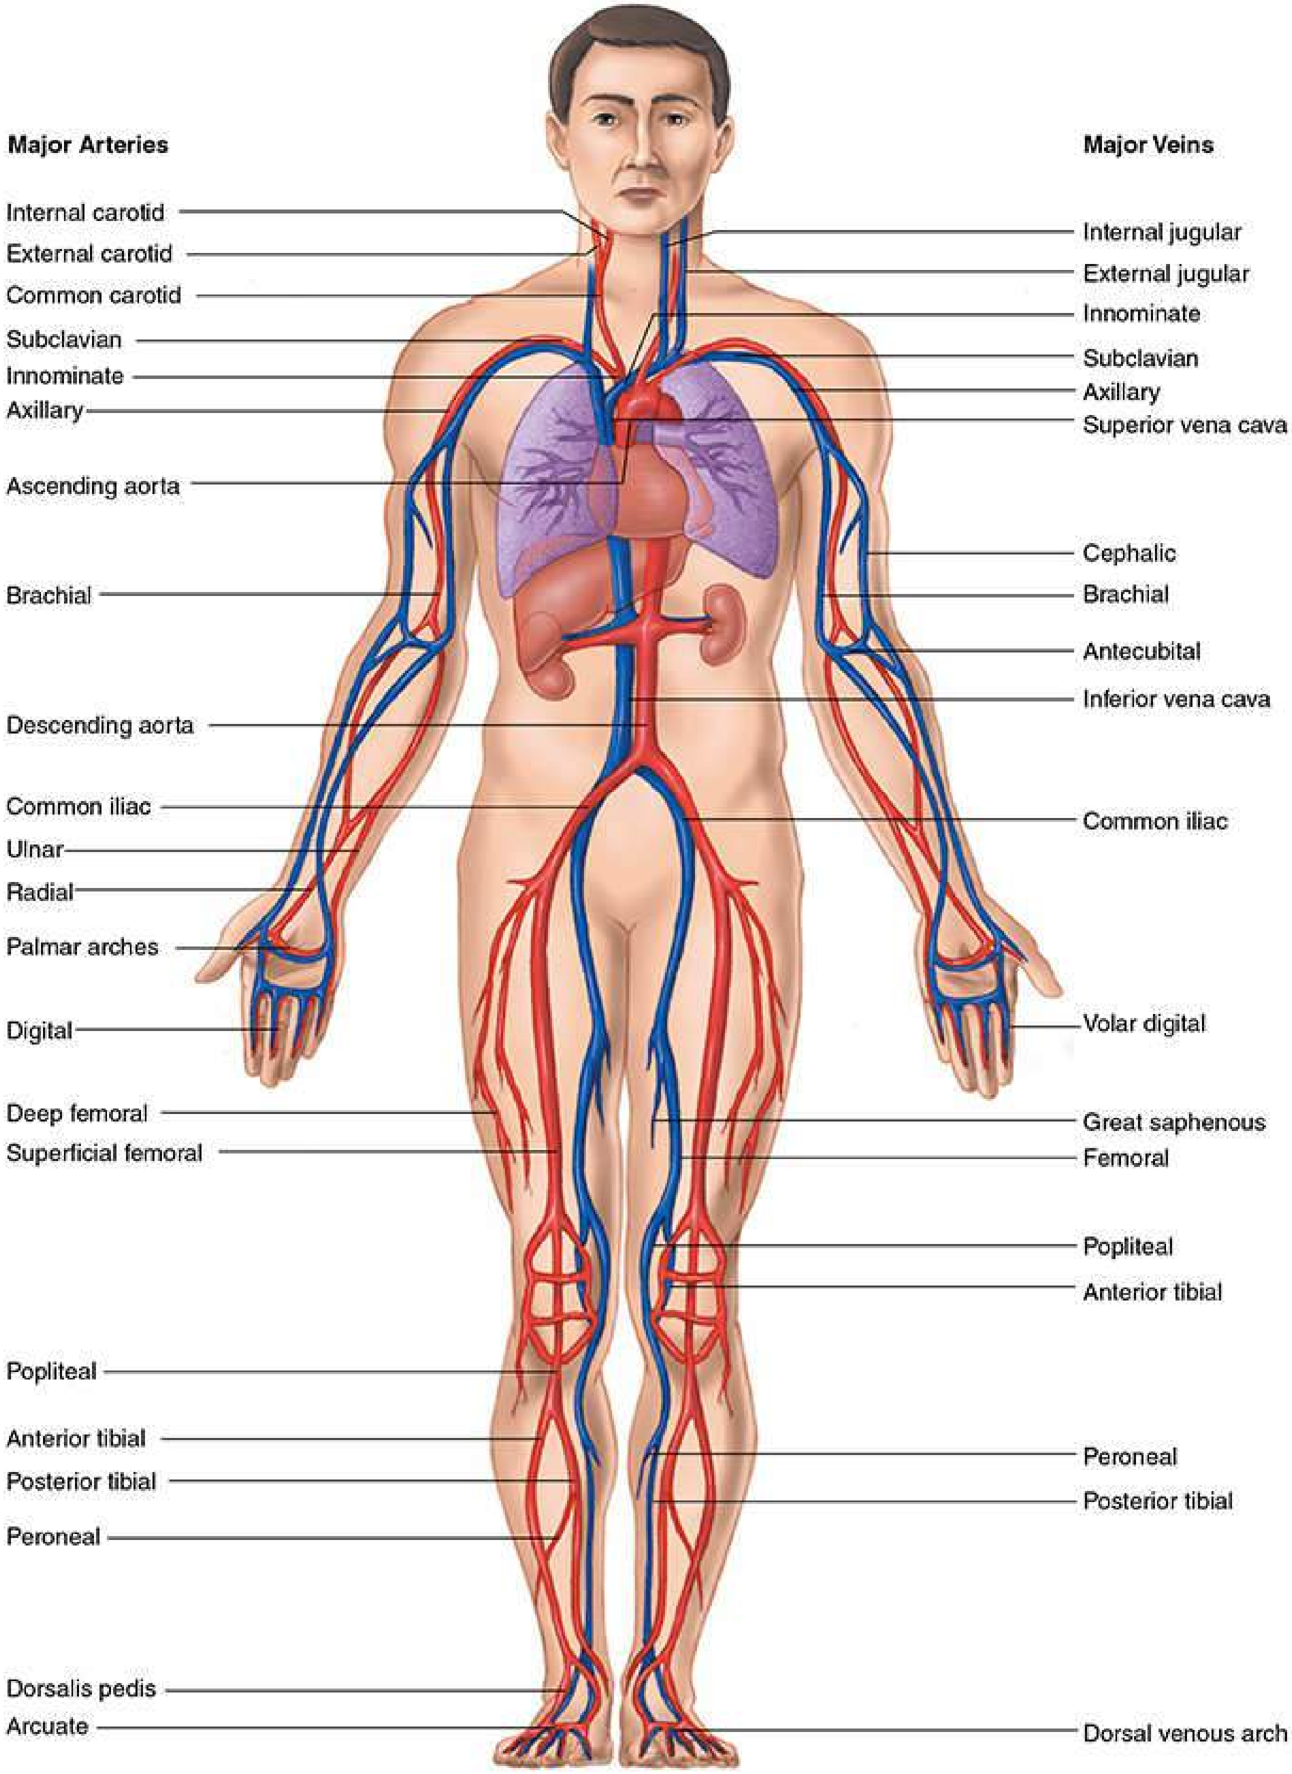

Figure 16-5 The major arteries of the body carry oxygen-rich blood to all parts of the body. The major veins of the body carry deoxygenated blood back to the heart.

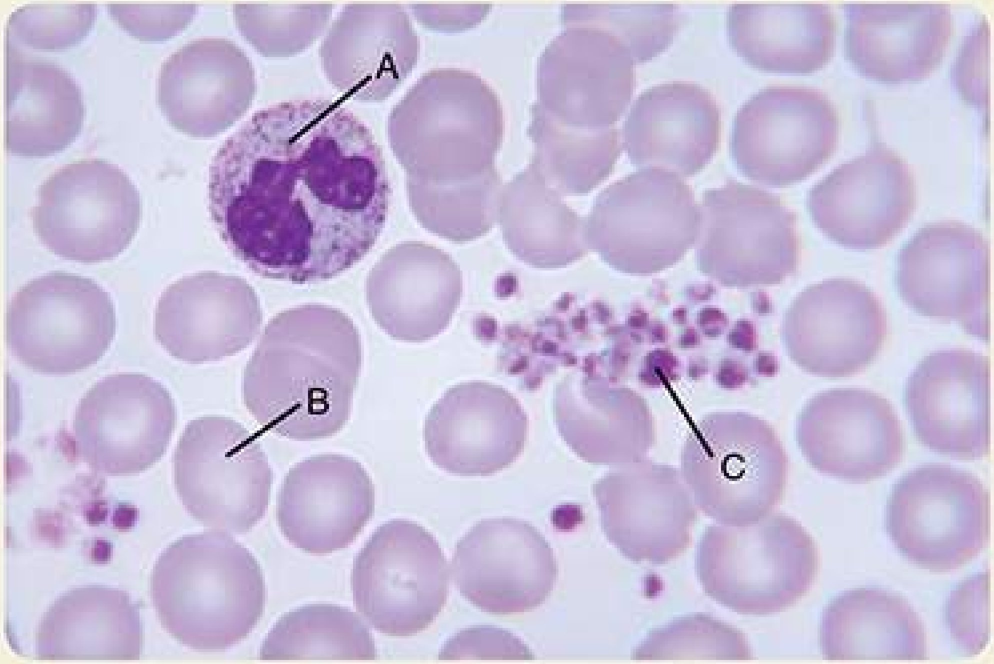

Figure 16-6 Blood consists of fluid and several types of cells, including red blood cells (B), white blood cells (A), and platelets (C).

© Carolina Biological Supply, Co/Visuals Unlimited.

As the blood passes through an artery during systole, a pulse is generated. This pulse can be felt by placing a finger on the skin over the artery at a point where the artery lies near the skin surface and gently compressing. Pulses felt in the extremities, such as the radial and the posterior tibial, are called peripheral pulses, whereas pulses near the trunk of the body, such as the femoral and carotid pulses, are known as central pulses.

The rate of cardiac contractions can be increased or decreased by the autonomic nervous system. The heart also has the ability to increase or decrease the volume of blood it pumps with each contraction based on the autonomic nervous system response. To obtain an accurate measure of the efficiency of the heart, we have to measure the volume of blood pumped and the heart rate. This is determined by calculating the cardiac output. The **cardiac output** is calculated by multiplying the heart rate by the volume of blood ejected with each contraction, or the stroke volume. This is the volume of blood that passes through the heart in 1 minute and is the best measure of the output of the heart. In the field, we have no way of directly measuring the volume of blood being pumped; therefore, we must rely on the heart rate and the strength of the pulse to estimate the cardiac output.

The constant flow of oxygenated blood to the tissues is known as **perfusion**. Good perfusion requires three primary components. The first is a well-functioning heart, or “pump.” The heart must operate at an appropriate rate because a rate that is too slow or too fast will reduce the volume of blood circulated and, thus, reduce the cardiac output. When the heart beats too rapidly, there is not enough time between contractions for the heart to refill completely, and when the heart beats too slowly, the volume of blood circulated per minute decreases due to the slow pulse rate. The second component of good perfusion is an adequate volume of “fluid,” or blood. If there is blood loss through hemorrhage, the reduced volume will limit the amount of tissue that can be perfused. Third, the blood must be carried in a properly sized “container.” This means that the blood vessels must be appropriately constricted to match the volume of blood available so that circulation can occur without problems. If the blood vessels dilate, thereby increasing the size of the container, and the volume of fluid remains the same, there will not be enough blood to fill the blood vessels and perfusion will be reduced. If there is a problem with the functioning of the heart, the functioning of the blood vessels, or the volume of blood, perfusion will fall, which will lead to cellular death and, eventually, death of the patient.

Words of Wisdom

Pulsation

As the left ventricle contracts, it ejects a forceful wave of blood through the arteries. You can feel that wave in areas where the artery lies near the surface of the skin. This wave of blood is called the pulse. The evaluation of a patient's pulse is important in the assessment and treatment of cardiovascular emergencies. EMTs should be skilled at finding multiple pulse points and should compare proximal and distal pulses bilaterally, when applicable, to determine any differences in quality or strength that could indicate the patient's condition is progressing to decompensated shock.

Common places to feel for a pulse include the following **Figure 16-7**:

- The carotid pulse can be felt in the neck by placing two fingertips in the center of the throat on the windpipe, and then sliding them towards you into the groove between the trachea and the neck muscle. Do not assess both carotid pulses at the same time as this could greatly reduce blood flow to the brain.
- The femoral pulse can be felt in the groin at the crease dividing the lower abdomen from the leg.
- The brachial pulse can be felt on the medial aspect of the elbow at the level of the crease. This is the pulse that you listen for when you take blood pressure. Pulsations also can be palpated on the medial side of the arm midway between the elbow and armpit.
- The radial pulse can be felt on the thumb side of the wrist, about one fingerbreadth above the wrist crease.
- The posterior tibial pulse can be felt on the inside of the ankle, just behind the medial malleolus. The medial malleolus is the bony bump at the bottom end of the tibia.
- The dorsalis pedis pulse can be felt at the top of the foot. This artery is not in the same place in all people. To find the pulse, place your hand across the top of the foot just below the ankle crease. Once you feel something that might be a pulse, use your fingertips to confirm that finding.

Practice feeling for these pulses on yourself and on friends and family members.

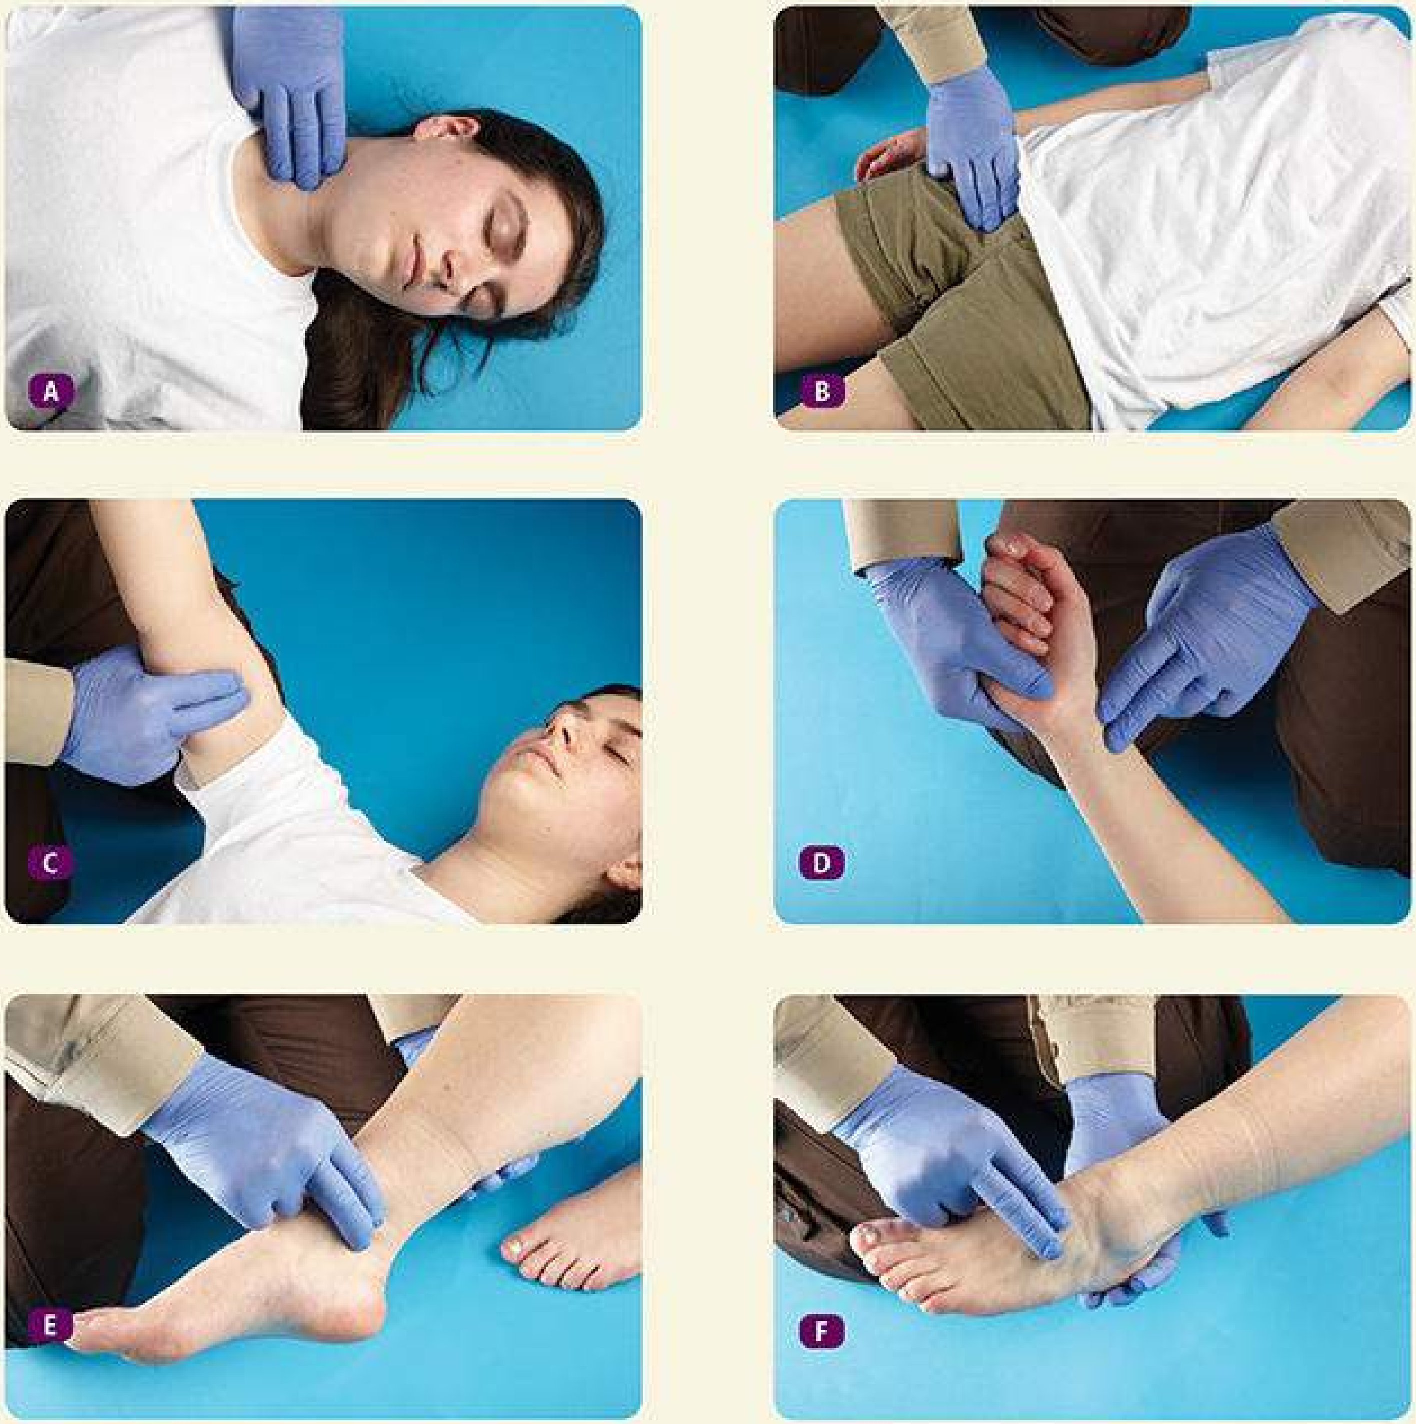

Figure 16-7 Common pulse points. **A.** The carotid pulse is felt in the neck. **B.** The femoral pulse is felt in the groin area. **C.** The brachial pulse is felt on the inside of the upper arm. **D.** The radial pulse is felt on the thumb side of the wrist. **E.** The posterior tibial pulse is felt on the inside of the ankle. **F.** The dorsalis pedis pulse is felt on the top of the foot.

Words of Wisdom

Cardiac Output = Heart Rate × Stroke Volume

Cardiac output is the amount of blood pumped out of the left ventricle in 1 minute.

Heart rate is the number of times the heart contracts in 1 minute.

Stroke volume is the volume of blood pumped out by the left ventricle in one contraction.

Stroke volume is affected by preload, afterload, and contractility. Preload is related to the venous return to the right atrium. Afterload is associated with systemic vascular resistance, which is a function of the constriction of the systemic blood vessels. As the blood vessels constrict, it is harder for the ventricle to push the blood into them. Contractility refers to how forcefully the heart contracts.

Pathophysiology

Chest pain or discomfort that is related to the heart usually stems from a condition called **ischemia**, which is decreased blood flow, in this case, to the heart. Because of a partial or complete blockage of blood flow through the coronary arteries, heart tissue fails to get enough oxygen and nutrients. The tissue soon begins to starve and, if blood flow is not restored, eventually dies. Ischemic heart disease, then, is disease involving a decrease in blood flow to one or more portions of the heart muscle.

Atherosclerosis

Most often, the low blood flow to heart tissue is caused by coronary artery atherosclerosis. **Atherosclerosis** is a disorder in which calcium and a fatty material called cholesterol build up and form a plaque inside the walls of blood vessels, obstructing flow and interfering with their ability to dilate or contract **Figure 16-8**. Eventually, atherosclerosis can even cause complete **occlusion**, or blockage, of a coronary artery. Atherosclerosis usually involves other arteries of the body as well.

The problem begins when the first trace of cholesterol is deposited on the inside of an artery. This may happen as early as the teenage years. As a person ages, more of this fatty material is deposited; the **lumen**, or the inside diameter of the artery, narrows. As the cholesterol deposits grow, calcium deposits can form as well. The inner wall of the artery, which is normally smooth and elastic, becomes rough and brittle with these atherosclerotic plaques. Damage to the coronary arteries may become so extensive that they cannot accommodate increased blood flow during times of maximum need.

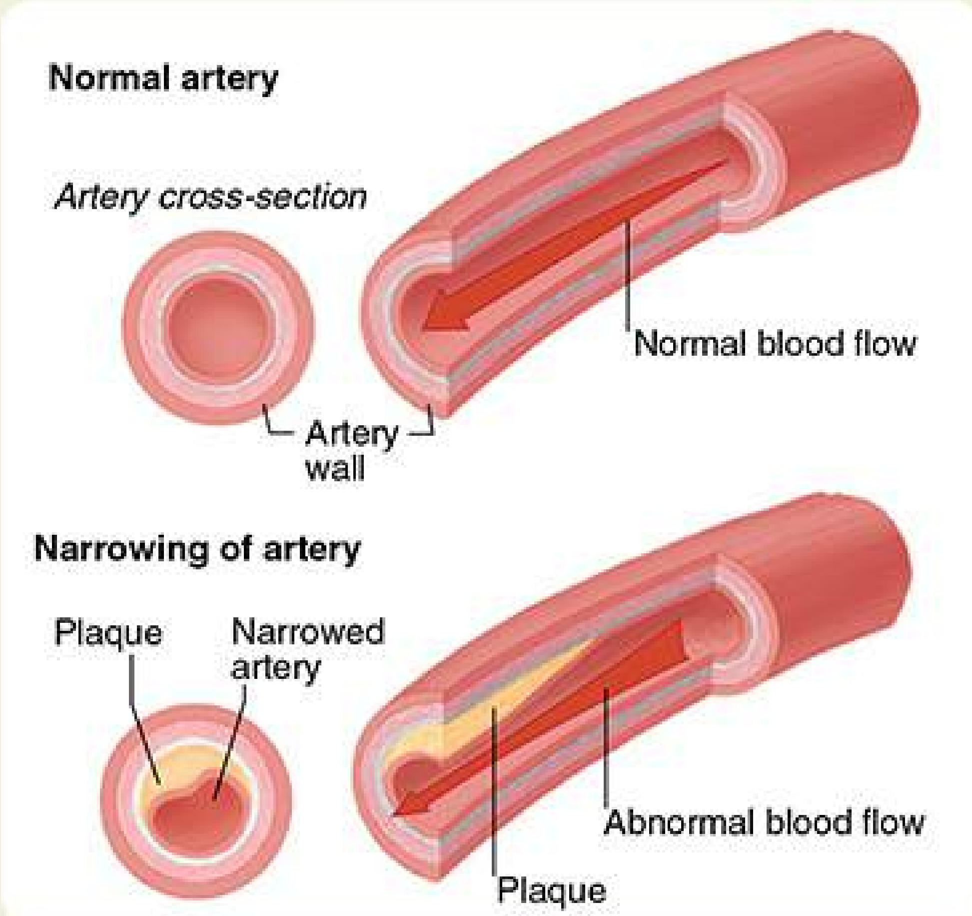

Figure 16-8 In atherosclerosis, calcium and cholesterol build up inside the walls of the coronary blood vessels, causing an obstruction in blood flow to the heart.

For reasons that are still not completely understood, a brittle plaque will sometimes develop a crack, exposing the inside of the atherosclerotic wall. Acting like a torn blood vessel, the ragged edge of the crack activates the blood-clotting system, just as when an injury has caused bleeding. In this situation, however, the resulting blood clot will partially or completely block the lumen of the artery. If it does not occlude the artery at that location, the blood clot may break loose and begin floating in the blood, becoming what is known as a thromboembolism. A **thromboembolism** is a blood clot that is floating through blood vessels until it reaches an area too narrow for it to pass, causing it to stop and block the blood flow at that point. Tissues downstream from the blood clot will have a lack of oxygen (hypoxia). If blood flow is resumed in a short time, the hypoxic tissues will recover. However, if too much time goes by before blood flow is resumed, the hypoxic tissues will die. If a blockage occurs in a coronary artery, the condition is known as an **acute myocardial infarction (AMI)**, a classic heart attack Figure 16-9. **Infarction** means the death of tissue. The same sequence may also cause the death of cells in other organs, such as the brain. The death of heart muscle can lead to severe diminishment of the heart's ability to pump or cause it to stop completely (**cardiac arrest**).

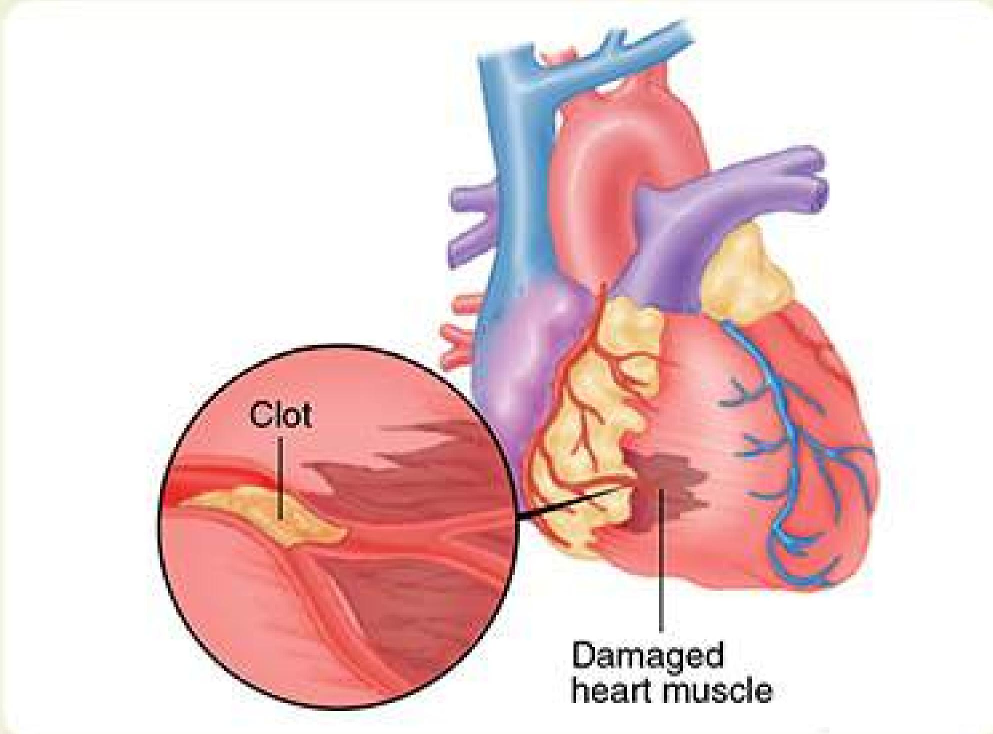

Figure 16-9 An acute myocardial infarction (heart attack) occurs when a blood clot prevents blood flow to an area of the heart muscle. If left untreated, death of heart tissue can result.

In the United States, coronary artery disease is the number one cause of death for men and women. The peak incidence of heart disease occurs between ages 45 and 64 years, but it can also strike teens and people in their 90s. You must be alert to the possibility that, although less likely, a 26-year-old with chest pain could actually be having an AMI, especially if he or she has a higher than usual risk.

Factors that place a person at higher risk for an AMI are called risk factors. The major controllable factors are cigarette smoking, high blood pressure, elevated cholesterol level, elevated blood glucose level (diabetes), lack of exercise, and obesity. The major risk factors that cannot be controlled are older age, family history of atherosclerotic coronary artery disease, race, ethnicity, and male sex. Lesser factors that play a role in heart disease are stress, excessive alcohol, and poor diet.

▶ Acute Coronary Syndrome

Many patients who call for EMS assistance because of chest pain have acute coronary syndrome. **Acute coronary syndrome**, also called ACS, is a term used to describe a group of symptoms caused by myocardial ischemia. As discussed earlier, myocardial ischemia is a decrease in blood flow to the heart, which leads to chest pain through reduction of oxygen and nutrients to the tissues of the heart. This can be a temporary situation known as angina pectoris, or a more serious condition, an AMI. Because the signs and symptoms of these two conditions are very similar, they are treated basically the same under the designation of acute coronary syndrome. To understand them better, we will look at each one separately.

Angina Pectoris

Chest pain does not always mean that a person is having an AMI. When, for a brief time, heart tissues are not getting enough oxygen, the pain is called **angina pectoris**, or angina. Although angina can result from a spasm of an artery, it is most often a symptom of atherosclerotic coronary artery disease. Angina occurs when the heart's need for oxygen exceeds its supply, usually during periods of physical or emotional stress when the heart is working hard. A large meal or sudden fear may also trigger an attack. When the increased oxygen demand goes away (eg, the person stops exercising), the pain typically goes away.

Anginal pain is commonly described as crushing, squeezing, or "like somebody standing on my chest." It is usually felt in the mid portion of the chest, under the sternum. However, it can radiate to the jaw, the arms (frequently the left arm), the midportion of the back or the epigastrium (the upper-middle region of the abdomen). The pain usually lasts from 3 to 8 minutes, rarely longer than 15 minutes. It may be associated with shortness of breath, nausea, or sweating. It usually disappears promptly with rest, supplemental oxygen, or nitroglycerin (NTG), all of which decrease the need or increase the supply of oxygen to the heart. Although angina pectoris is frightening, it does not mean that heart cells are dying, nor does it usually lead to death or permanent heart damage. It is, however, a warning that you and the patient should take seriously. Even with angina, because the oxygen supply to the heart is diminished, the electrical system can be compromised, and the person is at risk for significant cardiac rhythm problems.

Angina can be further differentiated into "stable" and "unstable" angina. Unstable angina is characterized by pain or discomfort in the chest of coronary origin that occurs in response to progressively less exercise or fewer stimuli than ordinarily required to produce angina. If untreated, it can lead to AMI. Stable angina is characterized by pain in the chest of coronary origin that is relieved by the things that normally relieve it in a given patient, such as resting or taking nitroglycerin. EMS usually becomes involved when stable angina becomes unstable, such as when a patient whose pain is normally relieved by sitting down and taking one nitroglycerin tablet has taken three tablets with no relief. Keep in mind that it can be difficult, even for physicians in hospitals, to distinguish between the pain of angina and the pain of an AMI. Patients experiencing chest pain or discomfort, therefore, should always be treated as if they are having an AMI.

Acute Myocardial Infarction

The pain of an AMI signals the actual death of cells in the area of the heart muscle where blood flow is obstructed. Once dead, the cells cannot be revived. Instead, they will eventually turn to scar tissue and become a burden to the beating heart. This is why fast action is so critical in treating a heart attack. The sooner the arterial blockage can be cleared, the fewer the cells that may die. About 30 minutes after blood flow is cut off, some heart muscle cells begin to die. After about 2 hours, as many as half of the cells in the area can be dead; in most cases, after 4 to 6 hours, more than 90% will be dead. In many cases, however, opening the coronary artery with "clot-busting" (thrombolytic) medications or angioplasty (mechanical clearing of the artery) can prevent permanent damage to the heart muscle if done within the first few hours after the onset of symptoms. Therefore, immediate prehospital treatment and transport to the emergency department (ED) are essential.

An AMI is more likely to occur in the larger, thick-walled left ventricle, which needs more blood and oxygen than the right ventricle.

Signs and Symptoms of Acute Myocardial Infarction. A patient with an AMI may show any of the following signs and symptoms:

- Sudden onset of weakness, nausea, and sweating without an obvious cause
- Chest pain, discomfort, or pressure that is often crushing or squeezing and that does not change with each breath
- Pain, discomfort, or pressure in the lower jaw, arms, back, abdomen, or neck
- Irregular heartbeat and syncope (fainting)
- Shortness of breath, or dyspnea
- Nausea/vomiting
- Pink, frothy sputum (indicating possible pulmonary edema)
- Sudden death

The Pain of Acute Myocardial Infarction. The pain of an AMI differs from the pain of angina in three ways:

- It may or may not be caused by exertion but can occur at any time, sometimes when a person is sitting quietly or even sleeping.
- It does not resolve in a few minutes; rather, it can last between 30 minutes and several hours.
- It may or may not be relieved by rest or nitroglycerin.

Note that not all patients who are having an AMI experience pain or recognize it when it occurs. In fact, about a third of patients never seek medical attention. This can be attributed, in part, to the fact that people are afraid of dying and do not want to face the possibility that their symptoms may be serious (cardiac denial). Middle-aged men, in particular, are likely to minimize their symptoms. However, some patients, particularly older people, women, and people with diabetes, do not experience any pain during an AMI but have other common complaints associated with ischemia discussed earlier. Others may feel only mild discomfort and call it indigestion. It is not uncommon for the only complaint, especially in older patients and women, to be fatigue. AMI without the classic chest pain is often referred to as a silent MI. Heart disease is the number one killer of women in the United States, and EMTs should consider AMI even when the classic symptom of chest pain is not present. This is also true for older people and people with diabetes.

Therefore, when you are called to a scene where the chief complaint is chest pain, complete a thorough assessment, no matter what the patient says. Patients with cardiac risk factors should also be carefully assessed if they have any of the associated symptoms, even if no chest pain is present. Any complaint of chest discomfort is a serious matter. In fact, the best thing you can do is to assume the worst.

Physical Findings of Acute Myocardial Infarction and Cardiac Compromise. The physical findings of AMI vary, depending on the extent and severity of heart muscle damage. The following are common:

- **General appearance.** The patient often appears frightened. There may be nausea, vomiting, and a cold sweat. The skin is often pale or ashen gray because of poor cardiac output and the loss of perfusion, or blood flow through the tissue. Occasionally, the skin will have a bluish tint, called cyanosis; this is the result of poor oxygenation of the circulating blood.
- **Pulse.** Generally, the pulse rate increases as a normal response to pain, stress, fear, or actual injury to the myocardium. Because dysrhythmias are common in an AMI, you may feel an irregularity or even a slowing of the pulse. The pulse may also be dependent on the area of the heart that has been affected by the AMI. Damage to the inferior area of the heart often presents with bradycardia.

Words of Wisdom

Documenting exactly how a patient describes chest discomfort, in the patient's own words, is a valuable source of information for hospital staff. Remember OPQRST (Onset, Provocation/Palliation, Quality, Radiation, Severity, Time of onset).

- **Blood pressure.** Blood pressure may fall as a result of diminished cardiac output and diminished capability of the left ventricle to pump. However, most patients with an AMI will have a normal or, possibly, elevated blood pressure.
- **Respiration.** The respiratory rate is usually normal unless the patient has CHF. In that case, respirations may become rapid and labored with a higher likelihood of cyanosis and possibly frothy sputum. A complaint of difficulty breathing is common with cardiac compromise, so even if the rate seems normal, look at the work of breathing, and treat the patient as if respiratory compromise were present.
- **Mental status.** Patients with AMIs often experience confusion or agitation and sometimes experience an almost overwhelming feeling of impending doom. If a patient tells you, "I think I am going to die," pay attention.

Consequences of Acute Myocardial Infarction. An AMI can have three serious consequences:

- Sudden death
- Cardiogenic shock
- Congestive heart failure

Sudden Death. Approximately 40% of all patients with an AMI do not reach the hospital alive. Sudden death is usually the result of cardiac arrest, in which the heart fails to generate effective blood flow. Although you cannot feel a pulse in someone experiencing cardiac arrest, the heart may still be twitching, though erratically. The heart is using up energy without pumping any blood. Such an abnormality of heart rhythm is a ventricular **dysrhythmia**, known as ventricular fibrillation.

A variety of other lethal and nonlethal dysrhythmias may follow an AMI, usually within the first hour. In most cases, premature ventricular contractions, or extra beats in the damaged ventricle, occur. Premature ventricular contractions by themselves may be harmless and are common among healthy people, as well as sick people. Other dysrhythmias can be much more dangerous. These include the following

- **Tachycardia**. Rapid beating of the heart, 100 beats/min or more.
- **Bradycardia**. Unusually slow beating of the heart, 60 beats/min or less.
- **Ventricular tachycardia**. Rapid heart rhythm, usually at a rate of 150 to 200 beats/min. The electrical activity starts in the ventricle instead of the atrium. This rhythm usually does not allow adequate time between beats for the left ventricle to fill with blood. Therefore, the patient's blood pressure may fall, and the pulse may be lost altogether. The patient may also feel weak or light-headed or may even become unresponsive. In some cases, existing chest pain may worsen or

chest pain that was not there before onset of the dysrhythmia may develop. Most cases of ventricular tachycardia will be sustained and may deteriorate into ventricular fibrillation.

- **Ventricular fibrillation** (V fib). Disorganized, ineffective quivering of the ventricles. No blood is pumped through the body, and the patient usually becomes unconscious within seconds. The only way to convert this dysrhythmia is to defibrillate the heart. To **defibrillate** means to shock the heart with a specialized electric current in an attempt to stop the chaotic, disorganized contraction of the myocardial cells and allow them to start again in a synchronized manner to restore a normal rhythmic beat. Defibrillation is highly successful in terms of saving a life if delivered within the first few minutes of sudden death. If a defibrillator is not immediately available, CPR must be initiated until the defibrillator arrives. Even if CPR is begun at the time of collapse, chances of survival diminish approximately 10% each minute until defibrillation is accomplished.

If uncorrected, unstable ventricular tachycardia or ventricular fibrillation will eventually lead to **asystole**, the absence of all heart electrical activity. Without CPR, asystole may occur within minutes. Asystole usually reflects a long period of ischemia, and nearly all patients you find in asystole will die.

Cardiogenic Shock

Shock is a simple concept but one that few people without medical training really understand. For that reason, Chapter 12 is devoted to a discussion of shock. The discussion of shock in this chapter is limited to that associated with cardiac problems; however, many other medical problems may cause shock as well.

Shock is a critical concept. Shock is present when body tissues do not get enough oxygen, causing body organs to malfunction. In **cardiogenic shock**, often caused by a heart attack, the problem is that the heart lacks enough power to force the proper volume of blood through the circulatory system. Cardiogenic shock is more commonly found in an AMI that affects the inferior and posterior regions of the left ventricle of the heart because this provides circulation to the majority of the body. Cardiogenic shock can occur immediately or as late as 24 hours after the onset of the AMI. The various signs and symptoms of cardiogenic shock are produced by the improper functioning of the body's organs. The challenge for you is to recognize shock in its early stages, when treatment is much more likely to be successful.

Congestive Heart Failure

Failure of the heart occurs when the ventricular heart muscle is so permanently damaged that it can no longer keep up with the return flow of blood from the atria. **Congestive heart failure (CHF)** can occur any time after a myocardial infarction, in the setting of heart valve damage, or as a consequence of long-standing high blood pressure. Any condition that weakens the pumping strength of the heart may cause CHF and this often happens between the first few hours and the first few days after a heart attack.

Just as the pumping function of the left ventricle can be damaged by coronary artery disease, it can also be damaged by diseased heart valves or chronic hypertension. In any of these cases, when the muscle can no longer contract effectively, the heart tries other ways to maintain an adequate cardiac output. Two specific changes in heart function occur: The heart rate increases, and the left ventricle enlarges in an effort to increase the amount of blood pumped each minute.

When these adaptations can no longer make up for the decreased heart function, CHF eventually develops. It is called "congestive" heart failure because the lungs become congested with fluid once the left side of the heart fails to pump the blood effectively. Blood tends to back up in the pulmonary veins, increasing the pressure in the capillaries of the lungs. When the pressure in the capillaries exceeds a certain level, fluid (mostly water) passes through the walls of the capillary vessels and into the alveoli. This condition is called pulmonary edema. It may occur suddenly, as in an AMI, or slowly over months, as in chronic CHF. Sometimes, in patients with an acute onset of CHF, severe pulmonary edema will develop, in which the patient has pink, frothy sputum and severe dyspnea.

YOU are the Provider — PART 2

You arrive at the scene and are escorted by the patient's son to her bedroom. She is sitting up in bed with her fist clutched against her chest. She is conscious and alert, but is notably anxious. Her skin is pale and diaphoretic. Your partner opens the jump kit as you assess the patient.

Recording Time: 0 Minutes	
Appearance	Anxious; notably diaphoretic
Level of consciousness	Conscious and alert

Airway	Open; clear of secretions and foreign bodies
Breathing	Increased respiratory rate; adequate depth
Circulation	Radial pulse, rapid and irregular; skin, pale and diaphoretic

After confirming that she has not taken any medication and that she is not allergic to any medications, you give the patient four 81-mg aspirins to chew and swallow according to your protocols. As you continue your assessment and further inquire about her medical history, your partner applies the pulse oximeter, which shows that the patient's oxygen saturation is 91%. Based on this he applies oxygen via nasal cannula at 4 L/ min and prepares to take her vital signs. She tells you that she had a heart attack 3 years ago; has high blood pressure; and takes enalapril (Vasotec), nitroglycerin, and one aspirin per day.

4. Why is aspirin given to patients with an acute cardiac event?
5. What type of medication is nitroglycerin? How may it help relieve chest pain, pressure, or discomfort?
6. When is nitroglycerin indicated for a patient? What is the typical dose?

Words of Wisdom

Cardiogenic Shock

Signs and Symptoms

- One of the first signs of shock is anxiety or restlessness as the brain becomes relatively starved for oxygen. The patient may report "air hunger." Think of the possibility of shock when the patient is saying that he or she cannot breathe. Obviously, the patient can breathe, because he or she can talk. However, the patient's brain is sensing that it is not getting enough oxygen.
- As the shock continues, the body tries to send blood to the most important organs, such as the brain and heart, and away from less important organs, such as the skin. Therefore, you may see pale, cool, clammy skin in patients with shock.
- As the shock gets worse, the body will attempt to compensate by increasing the amount of blood pumped through the heart. Therefore, the pulse rate will be higher than normal. In severe shock, the heart rate usually, but not always, is greater than 120 beats/min. As the shock progresses, the pulses may become irregular and weak.
- Shock can also present with rapid and shallow breathing, nausea and vomiting, and a decrease in body temperature.
- Finally, as the heart and other organs begin to malfunction, the blood pressure will fall below normal. A systolic blood pressure less than 90 mm Hg is easy to recognize, but it is a late finding that indicates decompensated shock. It is very important though not to assume that shock is not present just because the blood pressure is normal (compensated shock).

Treatment of Cardiogenic Shock

Take the following steps when treating patients with signs and symptoms of cardiogenic shock:

1. Position the patient comfortably. Some patients will be more comfortable in a semi-Fowler position (head and knees slightly elevated); however, patients with low blood pressure may not tolerate a semi-upright position but may be more comfortable and more alert in a supine position.
2. Administer high-flow oxygen.
3. Assist ventilations as necessary.
4. Cover the patient with sheets or blankets as necessary to preserve body heat. Be sure to cover the top of the patient's head in very cold weather, as this is where much heat is lost.
5. Provide prompt transport to the ED.

Congestive Heart Failure

Signs and Symptoms

- The patient finds it easier to breathe when sitting up. When the patient is lying down, more blood is returned to the right ventricle and lungs, causing further pulmonary congestion.
- Often, the patient is agitated.
- Chest pain may or may not be present.
- The patient often has distended neck veins that do not collapse even when the patient is sitting.
- The patient may have swollen ankles from dependent edema (backup of fluid).

- The patient generally will have high blood pressure, a rapid heart rate, and rapid respirations.
- The patient will usually be using accessory breathing muscles of the neck and ribs, reflecting the additional hard work of breathing.
- Skin is usually pale or cyanotic and sweaty.
- The fluid surrounding small airways may produce rales (crackles), best heard by listening to either side of the patient's chest, about midway down the back. In severe CHF, these soft sounds can be heard even at the top of the lung.

Once CHF develops, it can be treated but not cured. Regular use of medications may alleviate the symptoms. However, patients with CHF often become ill again and are frequently hospitalized. Approximately half will die within 5 years of the onset of symptoms.

Treatment of Congestive Heart Failure

Treat a patient with CHF the same way as a patient with chest pain:

1. Take the vital signs, and give oxygen by nonrebreathing mask with an oxygen flow of 10 to 15 L/min. Medical control may, either by protocol or in response to your request, order the use of continuous positive airway pressure (CPAP) to move some of the fluid out of the lungs to provide better oxygenation.
2. Allow the patient to remain sitting in an upright position with the legs down.
3. Be reassuring; many patients with CHF are quite anxious because they feel as if they cannot breathe.
4. Patients who have had problems with CHF before will usually have specific medications for its treatment. Gather these medications, and take them along to the hospital.
5. Nitroglycerin may be of value in reducing pulmonary edema if the patient's systolic blood pressure is more than 100 mm Hg. If the patient has been prescribed nitroglycerin, and medical control or standing orders advise you to do so, you can administer it sublingually.
6. Prompt transport to the ED is essential.

If the right side of the heart is damaged, fluid collects in the body, often showing up as swelling in the feet and legs. The collection of fluid in the part of the body that is closest to the ground is called **dependent edema**. The swelling causes relatively few symptoms other than discomfort. However, chronic dependent edema may indicate underlying heart disease even in the absence of pain or other symptoms. Since the right side of the heart supplies the preload for the left side of the heart, right heart failure can result in an inadequate supply of blood to the left ventricle resulting in a drop in the systemic blood pressure. It is important to realize that some patients may present with signs of both left-sided and right-sided heart failure because left-sided failure often leads to right-sided failure.

Hypertensive Emergencies

Hypertension is defined as any systolic blood pressure greater than 140 mm Hg or a diastolic blood pressure greater than 90 mm Hg. Another cardiac-related condition is a hypertensive emergency. A **hypertensive emergency** usually occurs only with a systolic pressure greater than 180 mm Hg or a rapid rise in the systolic pressure. Because patients do not feel their blood pressure, the signs and symptoms of hypertensive emergency are related to the effects of the hypertension. Some patients with chronic hypertension may not experience signs or symptoms until their systolic pressure is significantly higher than this value. One of the most common signs is a sudden severe headache. If described as "the worst headache I have ever felt," this may also be a sign of cerebral hemorrhage. Other signs and symptoms include strong bounding pulse, ringing in the ears, nausea and vomiting, dizziness, warm skin (dry or moist), nosebleed, altered mental status, and even the sudden development of pulmonary edema. Untreated hypertensive emergencies can lead to a stroke or a dissecting aortic aneurysm.

If you suspect your patient is experiencing a hypertensive emergency, attempt to make him or her comfortable and monitor the blood pressure regularly. Position the patient with the head elevated, and transport rapidly to the ED. Depending on the distance and time involved in transport, you should consider ALS assistance for the patient. Paramedics may be able to administer medications to lower the blood pressure to a safer level. If ALS personnel can be on the scene quickly, contact them early and allow them to transport the patient from the scene. If the transport distance is long, consider asking for an ALS unit to meet you along the way and take over patient care and transportation from that point. Remember that getting the patient with a hypertensive emergency to the hospital as quickly and safely as possible is the best prehospital treatment you can provide.

An **aortic aneurysm** is a weakness in the wall of the aorta. The aorta dilates at the weakened area, which makes it susceptible to rupture. A **dissecting aneurysm** occurs when the inner layers of the aorta become separated, allowing blood (at high pressures) to flow between the layers. Uncontrolled hypertension is the primary cause of dissecting aortic aneurysms. This separation of layers weakens the wall of the aorta significantly, making it more likely to be ruptured under conditions of continued high blood pressure. If the aorta ruptures, the amount of internal blood loss will be so large that the patient will die almost immediately. The signs and symptoms of a dissecting aortic aneurysm include very sudden chest pain located in the anterior part of the chest or in the back between the shoulder blades. It may be difficult to differentiate the chest pain of a dissecting aortic aneurysm from that of an AMI, but a number of distinctive features may help. The pain from an AMI is often preceded by other symptoms—nausea, indigestion, weakness, and sweating—and tends to come on gradually, getting more severe with time and often described as "pressure" rather than "stabbing." By contrast, the pain of a dissecting aortic aneurysm usually comes on full force from one minute to the next Table 16-1. A patient with a dissecting aortic aneurysm also may exhibit a difference in blood pressure between arms or diminished pulses in the lower extremities. Aortic aneurysms are almost impossible to diagnose in the prehospital setting, but you must consider them a possibility in any patient with significant hypertension. Transport the patient without delay.

Patient Assessment

While en route to the scene, consider the standard precautions that will be needed. The precautions can be as simple as gloves for a patient with chest pain or full precautions for a patient in cardiac arrest. Remember, the patient's condition can change rapidly between the time you are dispatched and your arrival.

Table 16-1 AMI Versus Dissecting Aortic Aneurysm

	AMI	Dissecting Aneurysm
Onset of pain	Gradual, with additional symptoms	Abrupt, without additional symptoms
Quality of pain	Tightness or pressure	Sharp or tearing
Severity of pain	Increases with time	Maximal from onset
Timing of pain	May wax and wane	Does not abate once it has started
Region/radiation	Substernal; back is rarely involved	Back possibly involved, between the shoulder blades
Clinical signs	Peripheral pulses equal	Blood pressure discrepancy between arms or decrease in a femoral or carotid pulse

Scene Size-up

Do not let your guard down on medical calls. Always ensure that the scene is safe for all. As you approach the scene, look for and address any hazards. Determine the necessary standard precautions and whether you will need additional resources.

Identification of the nature of illness is important to start your patient assessment in the right direction. Use the information you get from the dispatcher, clues at the scene, and comments of bystanders or family members to begin to develop an idea about the type of problem your patient might be experiencing. For patients with cardiac problems, the clues often include a report of chest pain, difficulty breathing, or sudden loss of consciousness. Once you establish a preliminary nature of illness, you will be able to guide your assessment to find the important information much more effectively. Just remember not to become fixated on a specific condition at this early point in the assessment; sometimes the situation turns out to be very different from how it initially appeared.

Primary Assessment

As you approach the patient, form a general impression of his or her condition to recognize and address life threats. You will likely begin by determining whether the patient is responsive. Perform a primary assessment of the patient. If the patient is unresponsive and is not breathing, begin CPR, starting with chest compressions, and call for an AED. Use of the AED is discussed in the section on cardiac arrest later in this chapter. Generally, an AED should be applied if the patient is pulseless, not breathing (apneic), and unresponsive. Consider calling for ALS backup if possible.

Once you have formed a general impression, the next step in the primary assessment is to assess airway and breathing. Unless the patient is unresponsive, the airway will most likely be patent. Responsive patients should be able to maintain their own airway. Some episodes of cardiac compromise may produce dizziness or even fainting spells (syncope). If dizziness or fainting has occurred, consider the possibility of a spinal injury from a fall. Assess and treat the patient as appropriate.

Assess the patient's breathing to determine if it is adequate to provide enough oxygen to an ailing heart. If the rate is too fast or too slow, the depth of respiration seems to be too shallow, or the patient is struggling to breathe, respirations are inadequate. Listen for abnormal breath sounds at this time because these can also be important indicators of respiratory distress. Some patients feel shortness of breath even though there are no obvious signs of respiratory distress. Pulse oximetry is a valuable tool in treatment of respiratory distress and should be applied at this time. If the patient is having chest pain and their oxygen saturation is less than 95%, administer oxygen at 4 L/min via a nasal cannula. If they do not improve quickly, increase the oxygen concentration. Apply a nonrebreathing mask at 15 L/min. In general, the goal is to maintain the oxygen saturation level between 95% and 99%. If the patient is not breathing or has inadequate breathing, ensure adequate ventilations with a bag-valve mask (BVM) and 100% oxygen.

Patients experiencing pulmonary edema may require positive-pressure ventilation with a BVM or CPAP. CPAP is the most effective way to assist a person with CHF to breathe effectively and prevent an invasive airway management technique. Be aware of the indications and contraindications of CPAP and be competent in utilizing this equipment.

After assessing airway and breathing, assess the patient's circulation. Determine the rate and quality of the patient's pulse. Is the pulse rhythm regular or irregular? Is the pulse too fast or too slow? If you find abnormalities in the pulse, you should be more suspicious. Assess the patient's skin condition, color, moisture, and temperature, as well as the capillary refill time. Changes in perfusion may indicate more serious cardiac compromise. Consider treatment for cardiogenic shock early to reduce the workload of the heart. Place the patient in a comfortable position, usually sitting up and well supported. Provide reassurance that appropriate treatment is being given for the condition to reduce the patient's anxiety.

Make a transport decision based on whether you were able to stabilize life threats during the primary assessment. The remainder of the assessment can be performed en route, if time allows. Generally speaking, most patients with chest pain should be transported immediately. Whether to transport using the lights and siren is determined for each specific patient and may be partially based on the estimated transport time. As a general rule, however, patients with cardiac problems should be transported in the most gentle, stress-relieving manner possible. You will save very little time using the lights and siren, but you can do a lot to calm your patient and reduce the release of heart-damaging adrenaline through your reassurance and by creating a ride to the hospital that is as pleasant as possible. Try not to allow the patient to exert himself or herself, strain, or walk. If necessary, lift the patient, using care.

Your decision of where to transport the patient will depend on your local protocol. Patients are generally transported to the closest appropriate facility. If your service is served by one hospital, the transport decision is easy. In larger urban areas, there may be several hospitals within the service areas. Some medical directors have written protocols requiring patients with suspected cardiac emergencies to be transported to cardiac specialty centers with certain capabilities, such as cardiac catheterization or targeted temperature management after resuscitation from cardiac arrest. Others require the patient to be transported to the nearest facility for stabilization before transporting to a specialty hospital. Be sure you know your local protocol.

Words of Wisdom

Athletes may have a slower (bradycardic or <60 beats/min) heart rate as a result of normal physiologic changes related to physical conditioning. Tachycardia (>100 beats/min) is a normal physiologic response to exercise to ensure adequate tissue perfusion. Pain, fear, and excitement may also cause a person to be tachycardic. It is important that you assess the patient to determine whether a bradycardic or tachycardic heart rate is appropriate for the patient.

History Taking

Once you have stabilized life threats, you will want to determine and investigate the chief complaint and know more about the history of the present illness. For a conscious medical patient, begin with taking a brief past history, identifying associated signs and symptoms, and identifying pertinent negatives. Friends or family members who are present often have helpful information.

Remember that not all patients experiencing an AMI have the same signs and symptoms. A chief complaint of chest pain or discomfort, shortness of breath, or dizziness should be taken seriously. Many patients who suspect that something is wrong experience restlessness, appear anxious, and perhaps have a sense of impending doom. Act professionally; be calm. Speak to the patient in a normal voice that is neither too loud nor too soft. Let the patient know that trained responders, including you, are present to provide care and that he or she will soon be taken to the hospital. Remember, some patients may act carefree, while others may be demanding. Most patients, however, are frightened. Your professional attitude may be the single most important factor in winning the patient's cooperation and helping the patient through this event. Patients often have a good idea about what is happening, so do not lie and offer false reassurance. If asked, "Am I having a heart attack?" you can say, "I do not know for sure, but in case you are, we are taking care of you. We are going to help you now by giving oxygen, and we will be taking you to the hospital. You are in good hands."

Begin by asking questions about the current situation. Determine whether the patient is experiencing chest pain or discomfort and whether there are any other signs and symptoms. Determine whether the patient is having respiratory difficulty because this is common among patients with chest pain. If the patient is experiencing dyspnea, find out whether it is related to exertion and whether it is related to the patient's position. Often patients with chest pain experience worse difficulty breathing when they are lying down. Also determine whether the dyspnea is continuous or if it changes, especially with deep breathing. Note whether the patient has a cough and whether the cough produces sputum. Ask about other signs and symptoms that are commonly found such as nausea and vomiting, fatigue, headache, and palpitations (a feeling of the heart skipping a beat or racing). Make sure to ask about any trauma the patient might have experienced during the last few days. Be sure to record your findings, including those that are negative (known as pertinent negatives).

If the patient is responsive, obtain the SAMPLE history and ask the following questions specific to a cardiovascular emergency:

- Have you ever had a heart attack?
- Have you been told that you have heart problems?
  - Have you ever been diagnosed with angina, heart failure, or heart valve disease?
  - Have you ever had high blood pressure?
  - Have you ever been diagnosed with an aneurysm?
  - Do you have any respiratory diseases such as emphysema or chronic bronchitis?
  - Do you have diabetes or have you ever had any problems with your blood sugar?
  - Have you ever had kidney disease?
- Do you have any risk factors for coronary artery disease, such as smoking, high blood pressure, or high-stress lifestyle?
  - Is there a family history of heart disease?
  - Do you currently take any medications?

The SAMPLE history provides basic information on the patient's overall medical history. You will want to determine as many signs and symptoms as you can. For example, you may determine that the patient has chest pain at rest or absence of chest pain with respirations or movement. The more signs and symptoms a patient has, the easier it is to identify a particular problem. In addition, ask whether the patient has had the same pain before. If so, ask "Do you take any medications for the pain?" and "Do you have any of the medication with you?" If the patient has had a heart attack or angina before, ask whether the pain is similar.

Make sure to ask about allergies because the patient will very likely be given medication in the hospital. If the patient is taking medications, determine whether they are prescribed, over the counter, and/ or recreational drugs. Even when a patient may not be able to articulate his or her exact medical condition, knowing the patient's medications may give you important clues. For example, a patient may say he has "heart problems." You see that he is taking furosemide (Lasix), digoxin, and metoprolol (Toprol). Furosemide is a diuretic, digoxin increases the strength of heart contractions, and metoprolol lowers blood pressure. These medications are often prescribed together for patients with CHF and may alert you to carefully evaluate the lungs for the presence of crackles (rales), which indicate fluid in the lungs and a need to increase the amount of oxygen being delivered. When you ask about medical conditions next, be sure to ask whether the patient takes medications for any other condition he or she identifies. Also, if the patient tells you that he or she takes prescription medications, ask what condition these are taken for. Asking about the last oral intake may seem unnecessary, but this information can be very important; it is always better to have too much information rather than not enough. Also remember to ask about any home remedies the patient might have used because this information can be important too.

YOU are the Provider — PART 2

The patient took two of her prescribed nitroglycerin tablets before her son called 9-1-1; however, she is still experiencing chest pain, which she rates as a 7 on a scale of 0 to 10. Your partner takes her vital signs as you perform a more focused examination, inquire about her past medical history, and prepare for further treatment.

Recording Time: 2 Minutes	
Respirations	20 breaths/min; adequate depth
Pulse	118 beats/min; strong and irregular
Skin	Pale, cool, and diaphoretic
Blood pressure	150/90 mm Hg
Oxygen saturation (Spo_2)	98% (on oxygen)

7. What is significant about the patient's vital signs?
8. Should you give her additional nitroglycerin? Why or why not?

Be sure to include the OPQRST questions when you are obtaining the symptoms as part of the SAMPLE history. Using OPQRST helps you to understand the details of specific complaints, such as chest pain Table 16-2.

Secondary Assessment

Circumstances will dictate which aspects of the physical examination will be used. The secondary assessment of a conscious patient with chest pain or discomfort would likely focus on the patient's cardiac and respiratory systems.

The physical examination of a patient with chest pain begins with the cardiovascular system. Evaluate the patient's circulation by assessing pulses at various locations, and assess skin color, temperature, and condition. Is the skin cool or moist? How do the mucous membranes look? Are they pink, ashen, or cyanotic? Are the pulses of equal strength bilaterally? Does the patient have any edema in the extremities, especially the lower extremities? All of these physical findings can help identify poor circulation, which may be caused by a failure of the cardiovascular system.

In addition to the cardiovascular system, examine the respiratory system for signs of inadequate ventilation. These two systems are closely related, and cardiovascular issues can cause problems with the respiratory system. Are the lung sounds clear? Wetsounding lungs indicate fluid is being moved into the lungs from the circulatory system, possibly because of a problem with the heart. Are the breath sounds equal? Are the neck veins distended? Is the trachea deviated, or is it midline? The answers to these questions can help determine whether a problem exists with the lungs or with the heart. While the physical examination is not usually as important as the history in a patient with a possible cardiac problem, it may produce important clues to the patient's condition.

Measure and record the patient's vital signs, including pulse, respirations, and blood pressure. You must obtain readings for systolic and diastolic blood pressures. Take blood pressure on both arms if time allows. If available, use pulse oximetry. Pulse oximetry may not give an accurate measurement if the patient has poor circulation, has been exposed to a toxic chemical, or is in cardiac arrest, but it should be used and the readings noted for all patients with possible cardiac problems.

Table 16-2 OPQRST Mnemonic for Assessing Pain

Onset	When did the problem begin, and what does the patient think may have caused it?
Provocation/ palliation	Ask what makes the pain or discomfort better or worse. Is it positional? Does a deep breath or palpation of the chest make it worse? Did you take anything for it (including anything nonprescribed)?
Quality	Ask the patient to describe his or her pain. Let the patient use his or her own words to describe what is happening. If the patient is unable to describe the pain, try to avoid supplying only one option. Do not ask, "Does it feel like an elephant is sitting on your chest?" Instead, say, "Tell me what the pain feels like." If the patient cannot answer an open-ended question, then provide a list of alternatives: "There are lots of different kinds of pain. Is your pain more like heaviness, pressure, burning, tearing, dull ache, stabbing, or needlelike?"
Region/radiation	Ask where the pain is located and whether the pain has spread to another part of the body.
Severity	Ask the patient to rate the pain on a simple scale. Often, a scale ranging from 0 to 10 is used; a 10 represents the worst pain imaginable. Do not use the patient's answer to determine whether the pain has a serious cause. Instead, use it to check whether the pain is getting better or worse. After a few minutes of oxygen or administration of nitroglycerin, ask the patient to rate the pain again.
Timing	Find out how long the pain lasts when it is present and whether it has been intermittent or continuous.

If you have access to continuous blood pressure monitoring, be sure to use it as well, making sure you get an accurate manual blood pressure first. Repeat the vital signs at appropriate intervals, and use the settings on the automatic blood pressure monitoring machine to remind you when it is time to recheck and record the vital signs. Be sure to note the time that each set of vital signs is taken.

In patients with chest pain, it is very valuable to have a 12-lead ECG tracing from as early as possible after the onset of the pain. EMTs may assist with placing electrodes. This is discussed later in this chapter.

Reassessment

Repeat the primary assessment by checking to see whether the patient's chief complaint and condition have improved or are deteriorating. Vital signs should be reassessed at least every 5 minutes or any time significant changes in the patient's condition occur. It is essential to monitor the patient with a suspected AMI closely because sudden cardiac arrest is always a risk. If cardiac arrest occurs, you must be ready to begin automated defibrillation or chest compressions immediately. If an AED is immediately available, use it; if not, perform CPR until the AED is available, as discussed in the later section on cardiac arrest. Reassess your interventions to see whether they are helping and whether the patient's condition is improving. Reassessment will also determine whether further interventions are indicated or contraindicated.

Transport the patient. Early, prompt transport to the ED or specialty center is critical so that treatments such as clot-busting medications or angioplasty can be initiated. To be most effective, these treatments must be started as soon as possible after the onset of the attack. If the patient does not have prescribed nitroglycerin and you do not have permission from medical control to administer nitroglycerin, complete your patient assessment and prepare to transport. Be sure that this process does not consume too much time. Do not delay transport to assist with administration of nitroglycerin. The drug can be given en route.

Alert the ED staff about the status of your patient's condition and your estimated time of arrival. Follow the instructions of medical control. Describe the patient's condition to the ED staff on arrival.

It is important to document your assessment and treatment of the patient. All interventions should be initiated according to protocol. If the intervention required an order from medical control, document the intervention and/or medication requested and that prior approval was granted. It must be clear in your documentation that the patient was reassessed appropriately following any intervention. The patient's response to the intervention and the time of each intervention must also be recorded. On completing your documentation, obtain the medical control physician's signature (if required by local protocol) showing approval of medication administration.

Emergency Medical Care for Chest Pain or Discomfort

Your treatment of the patient begins with proper positioning. As mentioned before, some patients will not tolerate being positioned supine, so they should be allowed to sit up (leaning back on the stretcher). Also loosen tight clothing, trying to make the patient as comfortable as possible.

If it is indicated, you should be giving the patient oxygen by this time, but continually reassess the oxygen saturation and patient's respiratory status. For patients with mild dyspnea, a nasal cannula may be all that is needed, whereas patients with more serious respiratory difficulty may require a nonrebreathing mask. Remember to titrate the oxygen to obtain an oxygen saturation between 95% and 99%. A patient who is unconscious or in obvious respiratory distress may need assistance with breathing. Use a BVM or another positive-pressure ventilation device if available and if you have been approved to use it in your service. Alternatively, consider CPAP depending on local protocol. Be aware that ALS may be required to support the use of positive end-expiratory pressure, CPAP, bilevel positive airway pressure, and transport ventilators.

Depending on local protocol, prepare to administer low-dose (sometimes called baby or children's) aspirin and assist with prescribed nitroglycerin. Aspirin (acetylsalicylic acid) prevents clots from forming or getting bigger. Administer low-dose aspirin according to local protocol. Low-dose aspirin comes in 81-mg chewable tablets. The recommended dose is 162 mg (two tablets) to 324 mg (four tablets). Be sure you have verified that the patient is not allergic to aspirin before you give it, because many people are. Also, ask the patient if he or she has any history of internal bleeding such as stomach ulcers, and, if so, contact medical control before giving the patient aspirin.

Nitroglycerin may help to relieve the pain of angina. Nitroglycerin comes in several forms—as a small white tablet, placed sublingually (under the tongue); as a spray, also taken sublingually; and as a skin patch applied to the chest. In any form, the effect is the same. Nitroglycerin relaxes the muscle of blood vessel walls, dilates coronary arteries, increases blood flow and the supply of oxygen to the heart muscle, and decreases the workload of the heart. Nitroglycerin also dilates blood vessels in other parts of the body and can sometimes cause low blood pressure and/or a severe headache. Other side effects include changes in the patient's pulse rate, including tachycardia or bradycardia. You should therefore take the patient's blood pressure within 5 minutes after each dose. If the systolic blood pressure is less than 100 mm Hg, do not give more medication. Other contraindications include the presence of a head injury, use of erectile dysfunction drugs within the previous 24 to 48 hours, and the maximum prescribed dose of nitroglycerin has already been given (usually three doses). Drugs used for erectile dysfunction include sildenafil (Viagra), tadalafil (Cialis), avanafil (Stendra), and vardenafil (Levitra, Staxyn).

Administering Nitroglycerin

Check the condition of the medication and its expiration date, and do not administer contaminated or expired medications. Also make sure the medication is prescribed for your patient. Occasionally, patients will try to take medications prescribed for their spouse or a friend if they think it will help them. Be sure to wear gloves when handling nitroglycerin tablets or spray because it is easily absorbed through the skin. If you handle tablets with bare fingers or get the spray on your fingers, it may be absorbed into your body, causing you to experience a very painful headache. If the patient has on a nitroglycerin patch when you arrive, be sure to carefully remove it if the patient is hypotensive or in cardiac arrest (before use of AED).

After you obtain permission from medical control, if required, help the patient administer prescribed nitroglycerin. Nitroglycerin works in most patients within 5 minutes. Most patients who have been prescribed nitroglycerin carry a supply with them. Nitrostat is one trade name for nitroglycerin. Patients take one dose of nitroglycerin under the tongue whenever they have an episode of angina that does not immediately go away with rest. If the pain is still present after 5 minutes, patients are typically instructed by their physicians to take a second dose. If the second dose does not work, most patients are told to take a third dose and then call for EMS. If the patient has not taken all three doses, you can help to administer the medication, if you are allowed to do so by local protocol.

Be aware that nitroglycerin will lose its potency over time, especially if exposed to light. Patients who take it only rarely may keep a bottle in their pocket for months. It may lose its potency even before its expiration date. When the nitroglycerin tablet loses its potency, patients may not feel the fizzing sensation when the tablet is placed under their tongue, and they may not experience the normal burning sensation and headache that often accompany nitroglycerin administration. Note that the fizzing only occurs with a potent tablet, not with the spray form. To safely assist the patient with nitroglycerin, follow the steps listed in Skill Drill 16-1:

1. Obtain an order from medical control—online or through off-line protocol.

2. Take the patient's blood pressure. Administer nitroglycerin only if the systolic blood pressure is greater than 100 mm Hg **Step 1**.
3. Check that you have the right medication, the right patient, and the right delivery route. Check the expiration date. Make sure the patient has no contraindications, such as having taken medication for erectile dysfunction in the past 24 hours.
4. Ask the patient about the last dose he or she took and its effects. Make sure that the patient understands the route of administration. Be prepared to have the patient lie down to prevent fainting if the nitroglycerin substantially lowers the patient's blood pressure (the patient gets dizzy or feels faint) **Step 2**.
5. Ask the patient to lift his or her tongue. Place the tablet or spray the dose under the tongue (while wearing gloves), or have the patient do so. Have the patient lower the tongue and keep his or her mouth closed with the tablet or spray under the tongue until it is dissolved and absorbed. Caution the patient against chewing or swallowing the tablet **Step 3**.
6. Recheck the blood pressure within 5 minutes. Record the medication and the time of administration. Reevaluate the chest pain, and note the response to the medication. If the chest pain persists and the patient still has a systolic blood pressure greater than 100 mm Hg, repeat the dose every 5 minutes as authorized by medical control. In general, a maximum of three doses of nitroglycerin is given for any one episode of chest pain **Step 4**.

Skill Drill 16-1 Administration of Nitroglycerin

Step 1

Obtain an order from medical control. Take the patient's blood pressure. Administer nitroglycerin only if the systolic blood pressure is greater than 100 mm Hg.

Step 2

Check the medication and expiration date. Ask the patient about the last dose he or she took and its effects. Make sure that the patient understands the route of administration. Prepare to have the patient lie down to prevent fainting.

Step 3

Ask the patient to lift his or her tongue. Place the tablet or spray the dose under the tongue (while wearing gloves), or have the patient do so. Have the patient keep his or her mouth closed with the tablet or spray under the tongue until it is dissolved and absorbed. Caution the patient against chewing or swallowing the tablet.

Step 4

Recheck the blood pressure within 5 minutes. Record each medication and the time of administration. Reevaluate the chest pain and blood pressure, and repeat treatment if necessary.

Cardiac Monitoring

Some EMS systems will allow EMTs to place electrodes, attach the leads, and obtain an electrocardiogram (ECG) tracing prior to transport. If your service allows you to perform this skill, the following information will guide you.

For an ECG to be reliable and useful, the electrodes must be placed in consistent positions on each patient. Figure 16-10

shows placement of limb lead electrodes, which are used to obtain a 3-lead ECG. **Figure 16-11** shows placement of limb lead electrodes and 12-lead ECG electrodes, both of which are used when obtaining a 12-lead ECG. To maintain consistency in monitoring and obtaining a useful ECG, there are predetermined locations for each electrode. Electrodes used in the prehospital setting are generally adhesive and have a gel center to aid in skin contact. Whichever type is used, certain basic principles should be followed to achieve the best skin contact and minimize **artifact** in the signal. Artifact refers to an ECG tracing that is the result of interference, such as patient movement, rather than the heart's electrical activity. Guiding principles are as follows:

- To maintain the correct lead placement, it may occasionally be necessary to shave body hair from the electrode site. Do not be fooled by a hairy chest. It may initially appear that you have good skin contact, but the electrode will rise off the skin and stick to the hair. If you must shave the site, be very careful to avoid nicking the skin. If one is available, it is best to use an electric razor to remove hair, because single-blade manual razors irritate the skin and can easily cut a patient.
- To remove oils and dead tissues from the surface of the skin, rub the electrode site briskly with an alcohol swab before application. Wait for the alcohol to dry before applying electrodes or dry it with a quick wipe of a 4-inch × 4-inch gauze pad. This step may have to be repeated if the patient is very sweaty as many cardiac patients are.
- Attach the electrodes to the ECG cables before placement. Confirm that the appropriate electrode now attached to the cable is placed at the correct location on the patient's chest or limbs (each cable is marked and color coded as to the correct location for placement).
- Once all electrodes are in place, switch on the monitor, and print a sample rhythm strip.

If the strip shows any interference (artifact), verify that the electrodes are firmly applied to the skin and the monitor cable is plugged in correctly.

Artifact on the monitor can be tricky. Patient movement, including deep breathing or muscle tremor, may cause a wavy baseline or small up-and-down squiggles on the baseline. These will prevent the ECG from being usable. Make sure that the patient is supine if possible or in the semi-Fowler position if he or she is having difficulty breathing. Also make sure that the patient's arms are relaxed by his or her side and his or her feet are uncrossed.

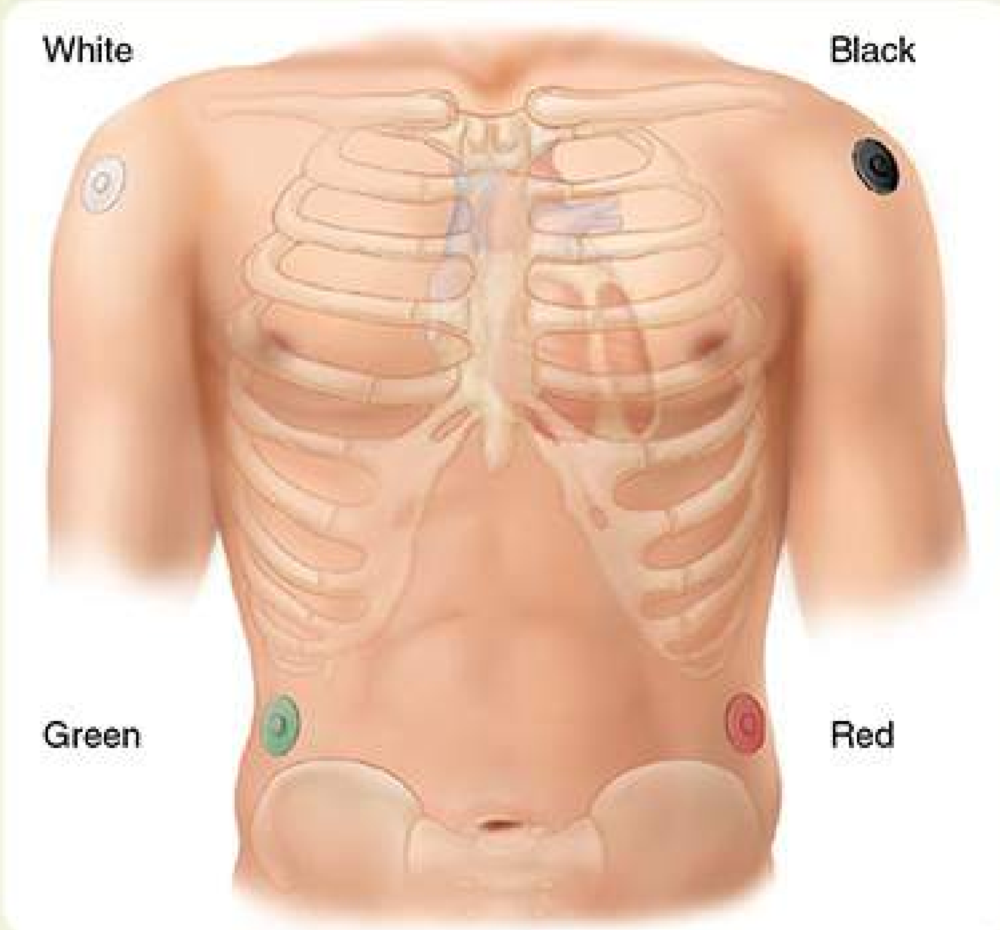

Figure 16-10 Limb electrode placement for cardiac monitoring.

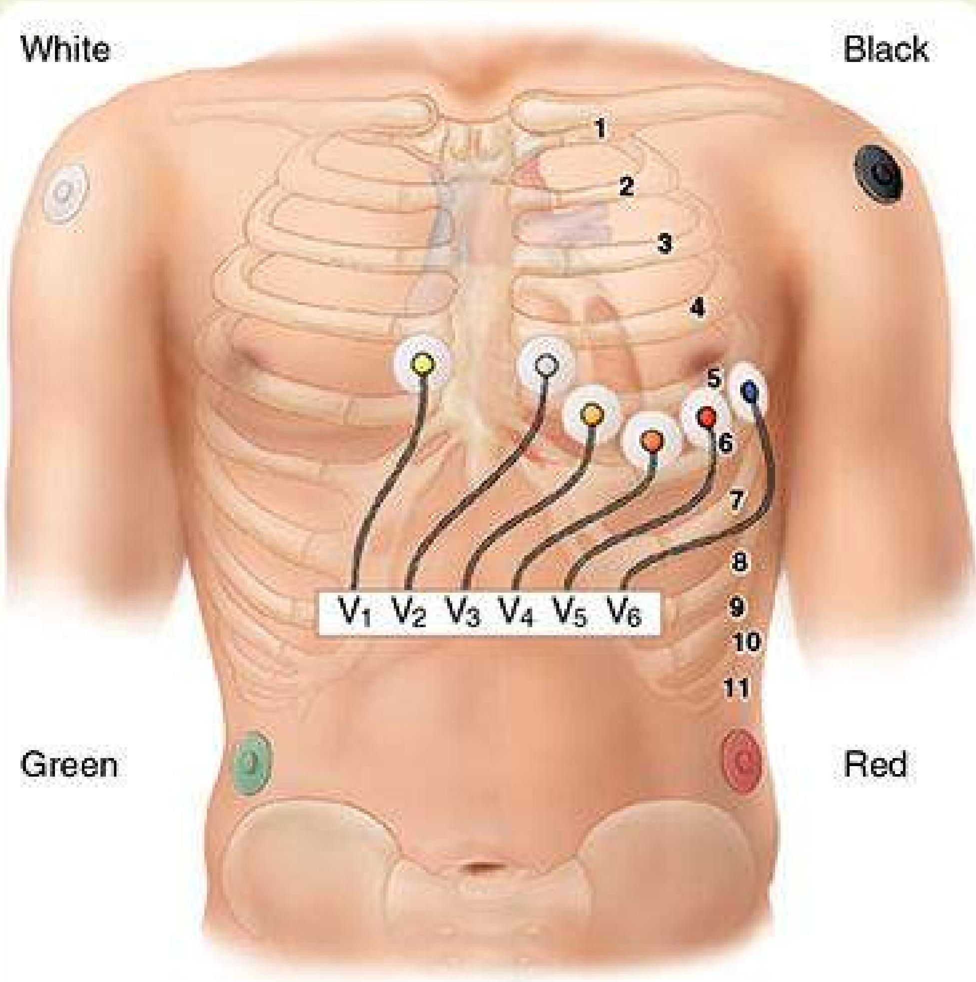


Lead	Location	View
V_1	4th intercostal space, right sternal border	Ventricular septum
V_2	4th intercostal space, left sternal border	Ventricular septum
V_3	Between V_2 and V_4	Anterior wall of left ventricle
V_4	5th intercostal space, midclavicular line	Anterior wall of left ventricle
V_5	Lateral to V_4 at the anterior axillary line	Lateral wall of left ventricle
V_6	Lateral to V_5 at the midaxillary line	Lateral wall of left ventricle

Figure 16-11 12-lead ECG electrode placement.

Skill Drill 16-2 shows the steps for performing cardiac monitoring:

1. Take standard precautions **Step 1**.
2. Explain the procedure to the patient. Prepare the skin for electrode placement **Step 2**.
3. Attach the electrodes to the leads before placing them on the patient **Step 3**.
4. Position the limb electrodes on the patient, on the torso if performing continuous monitoring, on the limbs if you will be acquiring a 12-lead ECG. The RA electrode goes on the right arm distal to the shoulder or on the wrist (avoid placing it directly over a bone). The LA electrode goes on the left arm at the same location as you placed the RA electrode on the right arm. The LL electrode is placed on the left leg on the thigh or ankle, although if you do not plan to obtain a 12-lead ECG tracing, this electrode is often placed on the lower left side of the abdomen (slightly lower

than an AED pad would be placed). Place the RL electrode at the same location on the right side of the body as the LL electrode on the left **Step 4**.

5. If you plan to obtain a 12-lead ECG tracing, place the chest leads on the chest as shown. The V_1 electrode is placed on the right side of the sternum between the fourth and fifth ribs. The V_2 electrode is placed on the left side of the sternum directly across from V_1. The V_4 is placed next, between the fifth and sixth ribs in a straight line down from the middle of the clavicle. The V_3 is then placed halfway between V_2 and V_4. The V_6 is placed next and is located horizontally even with V_4 in a straight line down from the middle of the armpit. Finally, V_5 is placed halfway between V_4 and V_6 **Step 5**.
6. Turn on the monitor **Step 6**.
7. Record tracings. As soon as a rhythm is visible on the screen, press the print button on the monitor and print a strip while counting slowly to six or seven. Then press the print button again to stop the printout. If the time is not printed correctly on the strip, write it on the edge of the strip. If you are obtaining a 12-lead ECG tracing, ask the patient to hold his or her breath or to take very shallow breaths. Press the 12-lead button and wait for the machine to acquire, analyze, and print or transmit the 12-lead ECG tracing. Gently tear off the tracing when the printer automatically stops **Step 7**.
8. Label each strip **Step 8**.

Skill Drill 16-2 Performing Cardiac Monitoring

Step 1

Take standard precautions.

Step 2

Explain the procedure to the patient. Prepare the skin for electrode placement.

Step 3

Attach the electrodes to the leads before placing them on the patient.

Step 4

Position the limb electrodes on the patient. Place the leads on the torso if performing continuous monitoring, on the limbs if you will be acquiring a 12-lead ECG.

Step 5

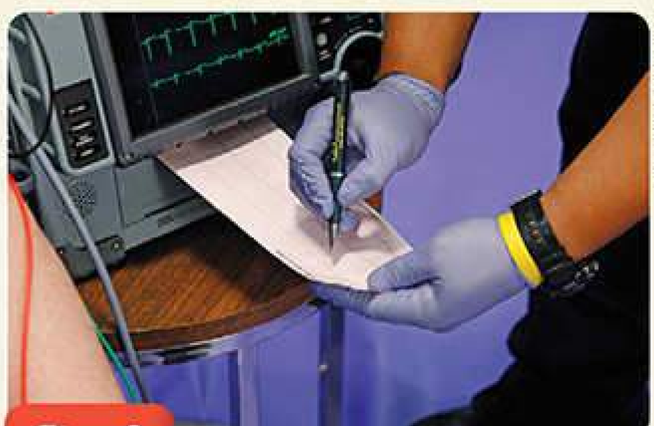
If you plan to obtain a 12-lead ECG tracing, place the chest leads on the chest.

Step 6

Turn on the monitor.

Step 7

Record tracings.



Step 8

Label each strip.

Heart Surgeries and Cardiac Assistive Devices

During the last 30 years, hundreds of thousands of open-heart surgeries have been performed to bypass damaged segments of coronary arteries in the heart. In a coronary artery bypass graft, a blood vessel from the chest or leg is sewn directly from the aorta to a coronary artery beyond the point of the obstruction. Another procedure is the percutaneous transluminal coronary angioplasty, which aims to dilate, rather than bypass, the coronary artery. In this procedure, usually called an angioplasty or balloon angioplasty, a tiny balloon is attached to the end of a long, thin tube. The tube is introduced through the skin into a large artery, usually in the groin, and then threaded into the narrowed coronary artery, with radiographs serving as a guide. Once the balloon is in position inside the coronary artery, it is inflated. The balloon is then deflated, and the tube is removed from the body. Sometimes, a metal mesh cylinder called a stent is placed inside the artery instead of or after the balloon. The stent is left in place permanently to help keep the artery from narrowing again.

A patient who has had an AMI or angina in the past will possibly have had one of these procedures. Patients who have had a bypass graft will have a long surgical scar on the chest from the operation. Patients who have had an angioplasty or a coronary artery stent usually will not. However, newer "keyhole" surgical techniques for bypass surgery may not produce a large scar. You should not assume that a patient who has a small scar has not had bypass surgery. Chest pain in a patient who has had any of these procedures should be treated in the same manner as chest pain in patients who have not had any heart surgery. Carry out all the described tasks, and transport the patient promptly to the ED of the hospital. If CPR is required, perform it in the usual way, regardless of the scar on the patient's chest. Likewise, if indicated, an AED should be used as well.

In the United States many people with heart disease have cardiac pacemakers to maintain a regular cardiac rhythm and rate. Pacemakers are inserted when the electrical control system of the heart is so damaged that it cannot function properly. These battery-powered devices deliver an electrical impulse through wires that are in direct contact with the myocardium. The generating unit is generally placed under a heavy muscle or a fold of skin. It typically resembles a small silver dollar under the skin in the left upper portion of the chest **Figure 16-12**.

Figure 16-12 A pacemaker, which is typically inserted under the skin in the left upper portion of the chest, delivers an electrical impulse to regulate the heartbeat.

Normally, you do not need to be concerned about problems with pacemakers. Thanks to modern technology, an implanted unit will not require replacement for years. Wires are well protected and rarely broken. In the past, pacemakers sometimes malfunctioned when a patient got too close to an electrical radiation source, such as a microwave oven. This is no longer the case; however, patients with pacemakers should avoid exposure to strong magnets. Every patient with a pacemaker should be aware of the precautions, if any, that must be taken to maintain its proper functioning.

If a pacemaker does not function properly, as when the battery wears out, the patient may experience syncope, dizziness, or weakness because of an excessively slow heart rate. The pulse ordinarily will be less than 60 beats/min because the heart is beating without the stimulus of the pacemaker and without the regulation of its own electrical system, which may be damaged. In these circumstances, the heart tends to assume a fixed slow rate that is not fast enough to allow the patient to function normally. A patient with a malfunctioning pacemaker should be promptly transported to the ED; repair of the problem may require surgery. When an AED is used, the patches should not be placed directly over the pacemaker. This will ensure a better flow of electricity through the patient’s body.

â–¶ Automatic Implantable Cardiac Defibrillators

More and more patients who survive cardiac arrest due to ventricular fibrillation have a small automatic implantable cardiac defibrillator implanted **Figure 16-13**. Some patients who are at particularly high risk for a cardiac arrest have them as well. These devices are attached directly to the heart and can prolong the lives of certain patients. They continuously monitor the heart rhythm, delivering shocks as needed. Regardless of whether a patient having an AMI has an automatic implantable cardiac defibrillator, he or she should be treated like all other patients having an AMI. Treatment should include performing CPR and using an AED if the patient goes into cardiac arrest. Generally, the electricity from an automatic implantable cardiac defibrillator is so low that it will not have an effect on rescuers and, therefore, should not be of concern to you.

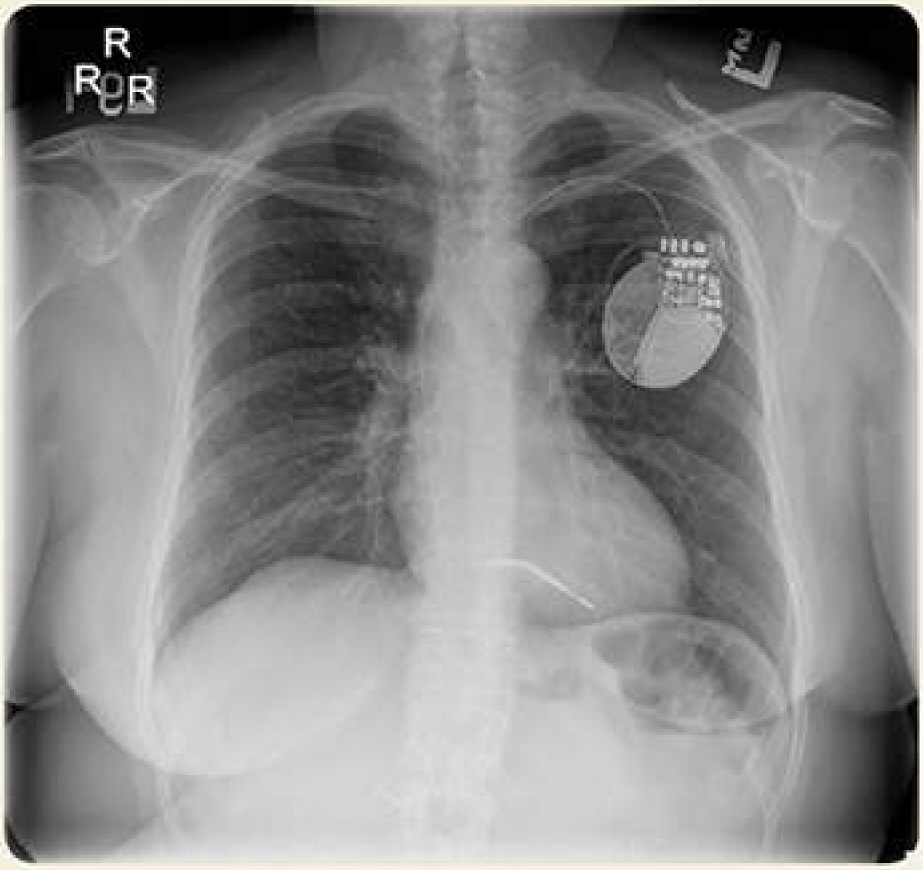


Figure 16-13 An automatic implantable cardiac defibrillator is attached directly to the heart and continuously monitors heart rhythm, delivering shocks as needed. The electricity from the defibrillator is so low that it has no effect on rescuers.

External Defibrillator Vest

An alternative to the implantable cardiac defibrillator is the external defibrillator vest. This device is a vest with built-in monitoring electrodes and defibrillation pads, which is worn by the patient under his or her clothing. The vest is attached to a monitor worn on a belt or hung from a shoulder strap. The monitor provides alerts and voice prompts when it recognizes a dangerous rhythm and before a shock is delivered. Unlike the implantable defibrillator, this device uses high-energy shocks similar to an AED, so you should avoid contact with the patient if the device warns that it is about to deliver a shock. Blue gel under the large defibrillation pads indicates that the device has already delivered at least one shock.

If the patient is in cardiac arrest, the vest should remain in place while CPR is being performed unless it interferes with compressions. If it is necessary to remove the vest, simply remove the battery from the monitor and then remove the vest. You can then use your own AED on the patient. Any patient who is wearing a device that has already delivered a shock should be transported to the hospital for further evaluation.

Left Ventricular Assist Devices

Left ventricular assist devices (LVADs) are used to enhance the pumping of the left ventricle in patients with severe heart failure or in patients who need a temporary boost due to an MI. There are several types of LVADs; the most common ones have an internal pump unit and an external battery pack. These pumps may be pulsatile, meaning they pump the blood in pulsations just like the natural heart, or they may be continuous, in which case the patient will not have any palpable pulses. If you encounter a patient with a LVAD, he or she (or his or her family members) may be able to tell you about the unit. Unless it malfunctions you should not need to deal with it. If you are unsure of what to do, contact medical control for assistance. Also, LVADs provide a number to call for assistance. Transport all LVAD supplies and battery packs to the hospital with the patient.

Cardiac Arrest

Cardiac arrest is the complete cessation of cardiac activity—electrical, mechanical, or both. It is indicated in the field by the absence of a carotid pulse. Until the advent of CPR and external defibrillation in the 1960s, cardiac arrest was virtually always a terminal event. Although it is still infrequent for a patient to survive a cardiac arrest without neurologic damage, great strides have been made in resuscitation science during the last 50 years.

When you arrive to find a patient who appears to be in cardiac arrest, you should automatically follow your CPR training. CPR is covered in Chapter 13, *BLS Resuscitation*.

Automated External Defibrillation

In the late 1970s and early 1980s, scientists developed a small computer that could analyze electrical signals from the heart and determine when ventricular fibrillation was taking place. This development, along with improved battery technology, made the automated portable defibrillator—a device that can automatically administer an electrical shock to the heart when needed—possible.

AED machines come in different models with different features **Figure 16-14**. All of them require a certain degree of operator interaction, beginning with turning on the machine and applying the pads. The operator also has to push a button to deliver an electrical shock, regardless of the model. Many AEDs use a computer voice synthesizer to advise the operator which steps to take on the basis of the AED's analysis. Some have a button that tells the computer to analyze the heart's electrical rhythm; other models start doing this as soon as they are turned on. Even though most defibrillators are now semiautomated, we still use the term automated external defibrillator (AED) to describe all of these machines. There are few fully automatic AEDs (which would deliver a shock without the operator pressing a button) left. All manufacturers are now producing only semiautomated external defibrillators.

Figure 16-14 Automated external defibrillators vary in their design, features, and operation.

A: Photographee.eu/Shutterstock; B: Jones & Bartlett Learning.

AEDs deliver electrical energy from one pad to the other (and then back to the first pad) to electrically stun the heart and allow it to resume normal function. The amount of electricity delivered by the machine varies among the manufacturers but each one has shown that the energy they deliver is adequate to defibrillate the heart. The factors involved in the defibrillation include voltage, current, and impedance. Most AEDs are set up to adjust the voltage based on the impedance (or resistance of the body to the flow of electricity) to deliver the proper amount of current, which is what actually causes the cells to defibrillate.

Special Populations

A pediatric patient with chest pain is not a common call. It is usually associated with a child who has a preexisting heart condition, usually congenital (present since birth). In pediatric situations, it is vital to see family members or caregivers as a valuable source of information.

Cardiac arrest in infants and children is usually the result of respiratory failure, not a primary cardiac event. However, the American Heart Association has determined that AEDs are safe to use in infants and children. If the patient is age 8 or less, pediatric-sized pads and a dose-attenuating system (energy reducer) are preferred. However, if these are unavailable, a regular adult AED can be used. If the child is between 1 month and 1 year of age (an infant), a manual defibrillator is preferred to an AED. If a manual defibrillator is not available, an AED equipped with a pediatric dose attenuator is preferred. If neither is available, an AED without a pediatric dose attenuator may be used.

The computer inside the AED is specially programmed to recognize rhythms that require defibrillation to correct, most commonly ventricular fibrillation. AEDs are extremely accurate. It would be rare for an AED to recommend a shock when a shock is not required, and an AED rarely fails to recommend one when it would be helpful. Therefore, if the AED recommends a shock, you can believe that it is indicated.

Automated external defibrillation offers a number of advantages. First, the machine is fast, and it delivers the most important treatment for a patient in ventricular fibrillation: an electrical shock. It can be delivered within 1 minute of your arrival at the patient's side. Second, AEDs are easy to operate. ALS providers do not have to be on the scene to provide this definitive care.

Current AEDs offer two other advantages. The shock can be given through remote, adhesive defibrillator pads, which are safe to use. Also, the pad area is larger than manual paddles, which means that the transmission of electricity is more efficient. Usually, there are pictures on the pads to remind you where they go on the patient's chest. As a safety measure, make sure the patient is not lying on wet ground or touching metal objects when he or she is being shocked.

Not all patients in cardiac arrest require an electrical shock. Although the cardiac rhythm of all patients in cardiac arrest should be analyzed with an AED, some do not have shockable rhythms (eg, pulseless electrical activity and asystole). Asystole (flatline) indicates that no electrical activity remains. Pulseless electrical activity refers to a state of cardiac arrest that exists despite an organized electrical complex. In both cases, CPR should be initiated as soon as possible beginning with chest compressions.

Rationale for Early Defibrillation

Few patients who experience sudden cardiac arrest outside a hospital survive unless a rapid sequence of events takes place. The chain of survival is a way of describing the ideal sequence of events that can take place when such an arrest occurs.

The five links in the chain of survival are as follows **Figure 16-15**:

- Recognition of early warning signs and immediate activation of EMS
- Immediate CPR with emphasis on high-quality chest compressions
- Rapid defibrillation

Figure 16-15 The five links of the chain of survival.

YOU are the Provider PART 4

After completing the remainder of your assessment and initial treatment, you place the patient onto the stretcher, load her into the ambulance, and proceed to a hospital located 20 miles away. You ask your partner to notify the hospital to alert the staff as you reassess the patient.

Recording Time: 10 Minutes	
Level of consciousness	Conscious and alert; still anxious
Respirations	18 breaths/min; adequate depth
Pulse	84 beats/min; strong and irregular
Skin	Pale and cool; less diaphoretic
Blood pressure	136/84 mm Hg
Spo_2	96% (on oxygen)

9. Why is early notification of the receiving facility so important for patients with an acute coronary event?
10. Should you apply the AED to determine if she is experiencing a cardiac dysrhythmia? Why or why not?

- Basic and advanced EMS
- ALS and postarrest care

If any one of the links in the chain is absent, the patient is more likely to die. For example, few patients benefit from defibrillation when more than 10 minutes elapse before administration of the first shock or if CPR is not performed in the first 2 to 3 minutes. If all links in the chain are strong, the patient has the best possible chance of survival. The link that is the most common determinant for survival is the third link—rapid defibrillation. This link and those for immediate high-quality CPR and basic and advanced EMS are where EMTs are most involved.

CPR helps patients in cardiac arrest because it prolongs the period during which defibrillation can be effective. Rapid defibrillation has successfully resuscitated many patients with cardiac arrest due to ventricular fibrillation. However, defibrillation works best if it takes place within 2 minutes of the onset of the cardiac arrest. To try to achieve better survival rates among cardiac arrest victims, many communities are exploring the idea that nontraditional first responders should be trained to administer rapid defibrillation. These responders would include police officers, security personnel, lifeguards, maintenance workers, and flight attendants. As an EMT, you should support these efforts to shorten the interval until defibrillation. Remember, seconds really matter when a patient is in cardiac arrest.

The final step in the chain of survival is ALS and postarrest care. This refers to continuing ventilation at less than 12 breaths/min to achieve an $ETCO_2$ of 35 to 40 mm Hg; maintaining oxygen saturation between 94% and 99%; assuring blood pressure is above 90 mm Hg; and maintaining glucose levels in the patient who is hypoglycemic. It also includes cardiopulmonary and neurologic support at the hospital as well as other advanced assessment techniques and interventions when indicated.

Integrating the Automated External Defibrillator and Cardiopulmonary Resuscitation

Because most cardiac arrests occur in the home, a bystander at the scene may already have started CPR before you arrive. For this reason, you must know how to work the AED into the CPR sequence. Remember that the AED is not very complex, but it may not be able to distinguish other movements from ventricular fibrillation. To avoid this problem, apply the AED only to pulseless, unresponsive patients and stay clear of the patient (do not touch the patient) while the AED is analyzing the heart rhythm and delivering shocks. Stop CPR, and let the AED do its job.

Automated External Defibrillator Maintenance

One of your primary missions as an EMT is to deliver an electrical shock to a patient in ventricular fibrillation. To accomplish this mission, you need to have a functioning AED. You must become familiar with the maintenance procedures required for the brand of AED your system uses. Read the operator's manual. If your defibrillator does not work on the scene, someone will want to know what went wrong. That person may be your system's administrator, your medical director, the local newspaper reporter, or the family's attorney. You will be asked to show proof that you maintained the defibrillator properly and attended any mandatory in-service sessions.

The main legal risk in using the AED is failing to deliver a shock when one was needed. The three most common errors in using certain AEDs are failure of the machine to shock fine V fib; applying the AED to a patient who is moving, squirming, or being transported; and turning off the AED before analysis or shock is complete. Operator errors include failing to apply the AED to a patient in cardiac arrest, not pushing the analyze or shock buttons when the machine advises you to do so, or pushing the power button instead of pushing the shock button when a shock is advised. Like any other manufactured item, the AED can fail, although this is rare. Ideally, you will encounter any such failure while doing routine maintenance, not while caring for a patient in cardiac arrest.

Another reason includes failure due to a battery that did not work, usually because it was not properly maintained. To avoid a battery that is not charged, many defibrillator companies have built smarter machines that will warn the operator that the battery is unlikely to work. However, some of the older models do not have this feature. Check your equipment, including your AED, daily at the beginning of each shift and exercise the battery as often as the manufacturer recommends. Ask the manufacturer for a checklist of items that should be checked daily, weekly, or less often **Figure 16-16**.

An error can also occur when the AED is applied to a responsive patient with a rapid heart rate. Most AEDs identify a regular rhythm faster than 150 or 180 beats/min as ventricular tachycardia, which should be shocked. Sometimes, however, a patient has another heart rhythm that should not be shocked but that is fast enough to confuse the computer. Again, to avoid this problem, you should apply the AED only to unresponsive patients with no pulse.

AUTOMATED EXTERNAL DEFIBRILLATOR
Inspection Checklist

Serial # ______________________ **Date** ______________________ **Time** ______________

Model # ______________________ **Inspected by** ______________________________________

Item	**Pass**	**Fail**
Exterior/Cables		
Nothing stored on top of unit		
Carry case intact and clean		
Exterior/LCD/cables connectors clean and undamaged		
Cables securely attached to unit		
Batteries		
All chargers plugged in and operational (if applicable)		
All batteries fully charged (battery in unit, spare battery)		
Valid expiration date on both batteries		
Supplies		
Two sets of electrodes in sealed packages with valid expiration dates		
Razor		
Hand towel		
Alcohol wipes		
Memory/voice recording device—module, card, microcassette		
Manual override—module, key (if applicable)		
Printer paper (if applicable)		
Operation		
Unit self-test per manufacturer's recommendation/instructions		
Display (if applicable)		
Visual indicators		
Verbal prompts		
Printer (if applicable)		
Attach AED to simulator/tester		
Recognizes shockable rhythm		
Charges to correct energy level within manufacturer's specifications		
Delivers charge		
Recognizes nonshockable rhythm		
Manual override system in working order (if applicable)

Special Populations

Like the other body systems, the cardiovascular system undergoes changes as we get older. The heart, like other major organs, will show the effects of aging. As the heart's muscle mass and tone decrease, the amount of blood pumped out of the heart per beat decreases. The residual (reserve) capacity of the heart is also reduced; therefore, when the vital organs of the body need additional blood flow, the heart cannot meet the need. When blood flow to the tissues is decreased, the organs suffer. If blood flow to the brain is inadequate, the patient may report weakness, fatigue, or dizziness and may experience syncope (fainting).

The heart muscle is stimulated by electricity and has its own electrical system. Under normal conditions, electrical impulses travel throughout the heart, resulting in the contraction of the heart muscle and the pumping of blood from the heart's chambers. With aging, the electrical system can deteriorate, causing the heart's contraction to weaken or, if blood flow to the heart muscle is affected, extra beats to form. With decreased strength of contraction, the heartbeat is weaker and blood flow to the tissues is reduced. If extra beats are produced, the patient's heart rhythm will be irregular. Although some irregular heart rhythms are not harmful, others can be lethal.

The arteries are also affected by aging. Arteriosclerosis (hardening of the arteries) can develop, affecting perfusion of the tissues. There is an increased chance of heart attack or stroke due to decreased blood flow or plaque formation (atherosclerosis) in the narrowed arteries.

Patients with diabetes can experience reduced circulation to the hands and feet, which makes peripheral pulses harder to detect. It also puts the hands and feet at particular risk for infection and ulceration.

In some older patients with angina or AMI, particularly people with diabetes, chest pain is absent, and the clinical picture can be confused with other, noncardiac conditions. These patients may present with a chief complaint of syncope (fainting), fatigue, or shortness of breath.

The cardiovascular system is affected by aging. You should be aware of the changes, seeking to determine what is normal versus what is chronic versus what is an acute condition for the individual patient. Sometimes, the weakening of the heart muscle, the deterioration of its electrical system, and the hardening of the arteries make the task of assessing and caring for older patients more difficult.

If the AED fails while you are caring for a patient, you must report the problem to the manufacturer and the US Food and Drug Administration. Be sure to follow the appropriate EMS procedures for notifying these organizations.

Medical Direction

Defibrillation of the heart is a medical procedure. Although AEDs have made the process of delivering electricity much simpler, there is still a benefit in having a physician's involvement. The medical director of your service should approve the written protocol that you will follow in caring for patients in cardiac arrest.

There should be a review of each incident in which the AED is used. After returning from the hospital or the scene, discuss with the rest of the team what happened. This discussion will help all members of the team learn from the incident. Review such events by using the written report and the device's recordings, if applicable.

There should also be a review of the incident by your service's medical director or quality improvement officer. Quality improvement involves people using AEDs and the responsible EMS system managers. This review should focus on speed of defibrillation, that is, the time from the call to the shock. Few systems will achieve the ultimate goal: shocking 100% of patients within 1 minute of the call. However, all systems continuously work on improving patient care. Mandatory continuing education with skill competency review is generally required for EMS providers.

Emergency Medical Care for Cardiac Arrest

Preparation

When dispatch reports an unresponsive patient with CPR being performed, the AED is probably one of the first pieces of equipment you will obtain from the ambulance. As the operator of the AED, you are responsible for making sure the electricity does not injure anyone, including yourself. Remote defibrillation using pads allows you to distance yourself safely from the patient. As long as you place the pads in the correct position and make sure no one is touching the patient, you should be safe. Do not defibrillate a patient who is in pooled water. Although there is some danger to you if you are also in the water, there is another problem. Electricity follows the path of least resistance; instead of traveling between the pads and through the patient's heart, it will diffuse into the water. Therefore, the heart will not receive enough electricity to cause defibrillation. You can defibrillate a soaking wet patient, but try first to dry the patient's chest. Do not defibrillate someone who is touching metal that others are touching, and carefully remove a nitroglycerin patch from a patient's chest and wipe the area with a dry towel before defibrillation to prevent ignition of the patch. It is often helpful to shave a hairy patient's chest before pad placement to increase conductivity. Be sure to consult local protocols for issues such as pad placement and preparation of the pad site.

Determine the nature of illness and/or mechanism of injury. If the incident involves trauma, consider spinal immobilization as you begin the primary assessment. Is there only one patient? If you are in a tiered system and the patient is in cardiac arrest, call for ALS assistance. If you suspect that the patient may be in cardiac arrest, discuss who will perform which resuscitation responsibilities prior to arrival on the scene. Preparation tasks should be done concurrently, so that time to defibrillation is minimized. For example, one provider begins compressions while another prepares for ventilation and another prepares the AED. Working as a well-organized team will improve the chances for a successful resuscitation.

Performing Defibrillation

If you witness a patient's cardiac arrest, begin CPR starting with chest compressions and attach the AED as soon as it is available. As soon as the AED is turned on and attached, follow the instructions to analyze and deliver shocks to the patient. Make sure to minimize the time when you are not performing chest compressions; research has shown the best survival rates for patients in whom compressions were interrupted for the least amount of time. At each defibrillation, the person performing compressions should switch places with the person providing ventilations so that neither gets overtired. Immediately after each defibrillation, resume CPR with compressions first. The steps for using the AED are listed here and shown in **Skill Drill 16-3**:

1. If bystander CPR is in progress, assess the effectiveness of chest compressions by palpating for a carotid or femoral pulse. If compressions are effective, you should be able to feel a pulse. If you do, leave your fingers in that position and stop compressions. If you lose the pulse when compressions stop, immediately resume compressions. It is important to limit the amount of time compressions are interrupted. If the patient is responsive, do not apply the AED.
2. If the patient is unresponsive and CPR has not been started yet, begin providing chest compressions and rescue breaths at a ratio of 30 compressions to 2 breaths and a rate of 100 to 120 compressions per minute, continuing until an AED arrives and is ready for use **Step 1**. It is important to start chest compressions and use the AED as soon as possible. Compressions provide vital blood flow to the heart and brain, improving the patient's chance of survival. High quality compressions (ie, performed at the appropriate rate and depth, with no leaning on the chest during recoil, and interruptions minimized) provide the best cardiac output.
3. Turn on the AED **Step 2**. Remove clothing from the patient's chest area. Apply the pads to the chest: one just to the right of the breastbone (sternum) just below the collarbone (clavicle), the other on the left lower chest area with the top of the pad 2 inches to 3 inches below the armpit. Do not place the pads on top of breast tissue in women. If necessary, move the breast out of the way with the back of your hand and place the pad underneath. Ensure that the pads are attached to the patient cables (and that they are attached to the AED in some models). Plug in the pads connector to the AED.
4. Stop CPR when the AED instructs you to.
5. State aloud, "Clear the patient," and ensure that no one is touching the patient.
6. Push the Analyze button, if there is one, and wait for the AED to determine whether a shockable rhythm is present. If a shock is advised, perform chest compressions while the AED is charging.
7. If a shock is not advised, perform five cycles (about 2 minutes) of CPR, beginning with chest compressions, and then reanalyze the cardiac rhythm. If a shock is advised, reconfirm that no one is touching the patient and push the Shock button. If at any time the AED advises to check the patient, quickly assess for a carotid or femoral pulse. This should not take longer than 5 to 10 seconds. If you feel a pulse, the patient has experienced **return of spontaneous circulation (ROSC)**. ROSC is defined as the return of a pulse and effective blood flow to the body in a patient who previously was in cardiac arrest. Continue to monitor the patient.
8. After the shock is delivered, immediately resume CPR, beginning with chest compressions. Remember to change to a different person for chest compressions each time CPR is paused to prevent rescuer fatigue **Step 3**.
9. After five cycles (about 2 minutes) of CPR, reanalyze the patient's cardiac rhythm **Step 4**. Do not interrupt chest compressions for more than 10 seconds.
10. If the AED advises a shock, clear the patient, push the Shock button, and immediately resume CPR compressions. If no shock is advised, immediately resume CPR, beginning with chest compressions and remembering to change the person providing compressions.
11. Gather additional information about the arrest event.
12. After five cycles (2 minutes) of CPR, reassess the patient.
13. Repeat the cycle of 2 minutes of CPR, one shock (if indicated), and 2 minutes of CPR.
14. Transport, and contact medical control as needed **Step 5**.

If the AED advises no shock and the patient has a pulse, check the patient's breathing. If the patient is breathing adequately, give oxygen via nonrebreathing mask, adjusting the flow as soon as pulse oximetry gives a reading, and transport. If the patient is not breathing adequately, provide artificial ventilation with a BVM or pocket mask device attached to 100% oxygen and transport. Ensure that proper airway techniques are used at all times.

If the patient has no pulse, perform five cycles (approximately 2 minutes) of CPR beginning with chest compressions. After 2 minutes of CPR, reanalyze the patient's cardiac rhythm. If the AED advises to shock, deliver one shock followed immediately by CPR, beginning with chest compressions. Repeat these steps if needed.

If the patient has no pulse and the AED advises no shock, perform five cycles (approximately 2 minutes) of CPR, beginning with chest compressions. After five cycles (2 minutes) of CPR, reanalyze the patient's cardiac rhythm. If no shock is advised, continue CPR. Transport the patient, and contact medical control as needed.

After Automated External Device Shocks

The care of the patient after the AED delivers a shock depends on your location and EMS system; therefore, you should follow your local protocols. After the AED protocol is completed, one of the following is likely:

YOU are the Provider PART 2

The patient is still conscious and alert and appears less anxious. She tells you that her chest pain has decreased in severity and is now a 3 on a 0 to 10 scale. After reassessing her, you contact the receiving facility and give the staff a patient update.

Recording Time: 17 Minutes	
Level of consciousness	Conscious and alert; less anxious
Respirations	16 breaths/min; adequate depth
Pulse	80 beats/min; strong and irregular
Skin	Pink, cool, and dry
Blood pressure	128/78 mm Hg
Spo_2	98% (on oxygen)

You deliver the patient to the emergency department (ED), where the cardiac team greets you and assumes care of the patient. The physician obtains a 12-lead electrocardiogram and determines that she is experiencing an acute myocardial infarction. Within 15 minutes, she is taken to the cardiac catheterization laboratory, where two coronary stents are successfully placed.

11. What is the difference between angina pectoris and an acute myocardial infarction?
12. As an EMT, how can you distinguish angina pectoris from an acute myocardial infarction?

Skill Drill 16-3 AED and CPR

Step 1

Take standard precautions. Determine scene safety. Question bystanders. Determine responsiveness.

Assess compression effectiveness if CPR is already in progress. If the patient is unresponsive and CPR has not been started yet, begin providing chest compressions and rescue breaths at a ratio of 30 compressions to two breaths and a rate of 100 to 120 compressions per minute, continuing until an AED arrives and is ready for use.

Step 2

Turn on the AED. Apply the AED pads to the chest and attach the pads to the AED. Stop CPR. If a shock is not advised, perform five cycles (about 2 minutes) of CPR, beginning with chest compressions, and then reanalyze the cardiac rhythm. If a shock is advised, reconfirm that no one is touching the patient and push the Shock button. If at any time the AED advises to check the patient, quickly assess for a carotid or femoral pulse. This should not take longer than 5 to 10 seconds. If you feel a pulse, the patient has experienced ROSC (return of spontaneous circulation). Continue to monitor the patient.

Step 3

Verbally and visually clear the patient. Push the Analyze button, if there is one. Wait for the AED to analyze the cardiac rhythm. If no shock is advised, perform five cycles (2 minutes) of CPR and then reanalyze the cardiac rhythm. If a shock is advised, recheck that all are clear, and push the Shock button. After the shock is delivered, immediately resume CPR beginning with chest compressions and remember to switch rescuers.

Step 4

After five cycles (2 minutes) of CPR, reanalyze the cardiac rhythm. Do not interrupt chest compressions for more than 10 seconds.

Step 5

If shock is advised, clear the patient, push the Shock button, and immediately resume CPR compressions. If no shock is advised, immediately resume CPR compressions and be sure to switch rescuers. After five cycles (2 minutes) of CPR, reanalyze the cardiac rhythm. Repeat the cycle of five cycles (2 minutes) of CPR, one shock (if indicated), and 2 minutes of CPR. Transport, and contact medical control as needed.

- Pulse is regained (ROSC).
- No pulse, and the AED indicates that no shock is advised.
- No pulse, and the AED indicates that a shock is advised.

Patients who do not regain a pulse on the scene of the cardiac arrest usually do not survive. What you do with these patients, again, depends on your EMS system. Whether you should transport the patient or wait for ALS to arrive should be in the local protocols established by medical control. If paramedics or another ALS service is responding to the scene, the best option usually is to stay where you are and continue the sequence of shocks and CPR. Administering CPR while patients are being moved or transported is usually not very effective. The best chance for patient survival occurs when the patient is resuscitated where found, unless the location is unsafe.

If an ALS service is not responding to the scene and your local protocols agree, you should begin transport when one of the following occurs:

- The patient regains a pulse.
- Six to nine shocks have been delivered (or as directed by local protocol).
- The machine gives three consecutive messages (separated by 2 minutes of CPR) that no shock is advised (or as directed by local protocol).

If you transport a patient while performing CPR, you need a plan for managing the patient in the ambulance. Ideally, you will have two EMTs in the patient compartment while a third drives. You may deliver additional shocks at the scene or en route with the approval of medical control. Keep in mind that AEDs cannot analyze the rhythm while the vehicle is in motion; nor is it as safe to defibrillate in a moving ambulance. Therefore, you should come to a complete stop if more shocks are needed. Be sure to memorize the protocol of your EMS system **Figure 16-17**.

Cardiac Arrest During Transport

If you are traveling to the hospital with an unconscious patient, check the pulse at least every 30 seconds. If a pulse is not present, take the following steps:

1. Stop the vehicle.
2. If the AED is not immediately ready, perform CPR, beginning with chest compressions, until it is available.
3. Call for help in the form of ALS support or any other available resources as appropriate based on circumstances and local protocol.

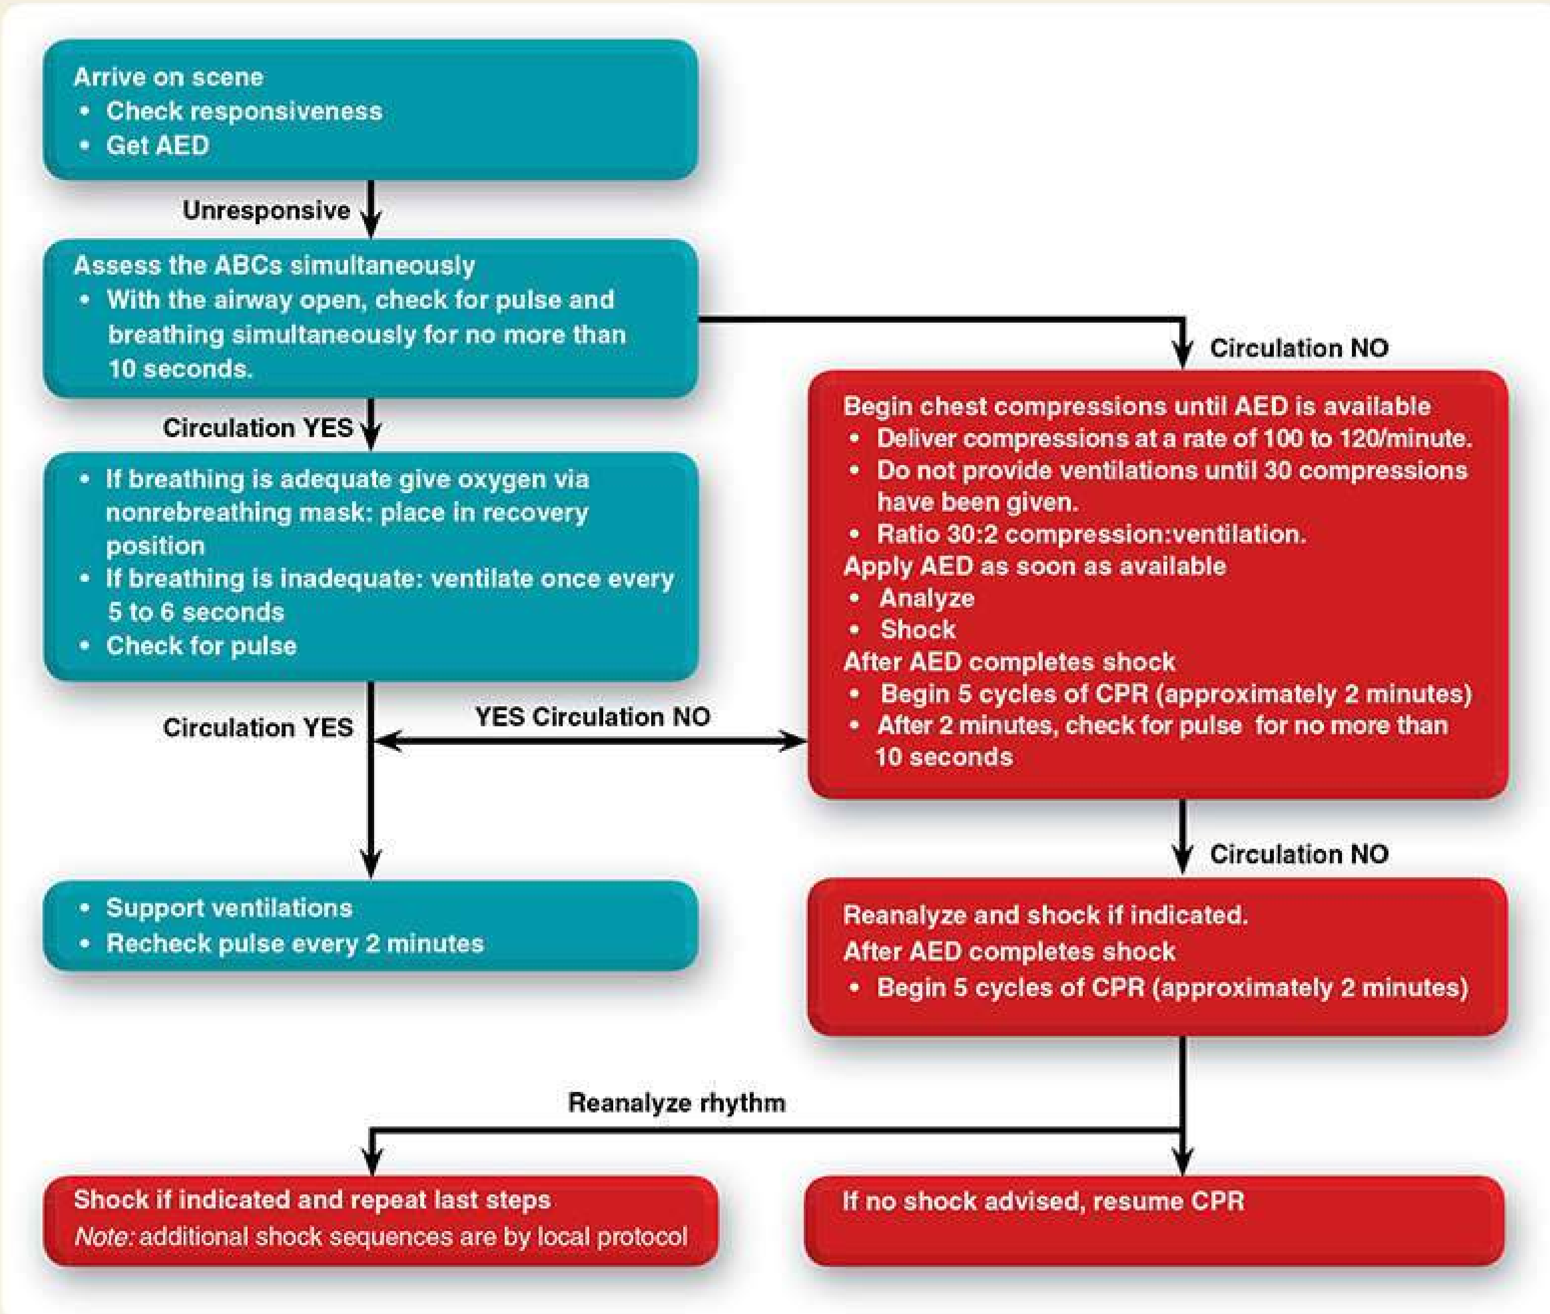

Figure 16-17 Automated external defibrillator (AED) algorithm. CPR indicates cardiopulmonary resuscitation.

4. Analyze the rhythm.
5. Deliver one shock, if indicated, and immediately resume CPR.
6. Continue resuscitation according to your local protocol.

If you are en route with a conscious adult patient who is having chest pain and becomes unconscious, take the following steps:

1. Check for a pulse.
2. Stop the vehicle.

3. If the AED is not immediately ready, perform CPR, beginning with chest compressions, until it is ready.
4. Analyze the rhythm.
5. Deliver one shock, if indicated, and immediately resume CPR.
6. Begin compressions, and continue resuscitation according to your local protocol, including transporting the patient.

Coordination With Advanced Life Support Personnel

The time to defibrillation is critical to survival after cardiac arrest. As an EMT equipped with an AED, you have the one tool that a dying patient in ventricular fibrillation needs most. Furthermore, it is impossible to hurt someone in cardiac arrest with an AED. Therefore, if you have an AED available, do not wait for the paramedics to arrive to administer a shock to a patient in ventricular fibrillation. Waiting might seem like a good idea. It is not. It is throwing away the patient's best chance for survival.

If the patient is unresponsive and does not have a pulse, apply the AED, and push the Analyze button (if there is one) as quickly as you can. Notify the ALS personnel as soon as possible after you recognize a cardiac arrest, but do not delay defibrillation. After the paramedics arrive at the scene, inform them of your actions to that point and then interact with them according to your local protocols.

Management of Return of Spontaneous Circulation

If you are able to restore a heartbeat through the use of an AED (also known as ROSC), what is done next can be critical to the patient's survival. Monitor for spontaneous respirations, provide oxygen via BVM at 10 to 12 breaths/min, and maintain an oxygen saturation between 95% and 99%. Assess the patient's blood pressure and see if he or she can follow simple commands such as "Squeeze my fingers." If ALS is not on scene or en route, immediately begin transport to the closest appropriate hospital depending on local protocol.

Safety Tips

Always remember, when using an AED there are several safety items to review.

1. Be aware of the surface the patient is lying on. Wet and metal surfaces may conduct electricity, making defibrillation of the patient dangerous to EMTs.
2. What is the age of the patient? Use pediatric AED pads when appropriate.
3. Does the patient have a medication patch in the area the AED pads will be placed? If so, remove the medication patch, wipe the area clean, and then attach the AED pad.
4. Does the patient have an implanted pacemaker or internal defibrillator in the same area the AED pads will be placed? If so, place the AED pad below the pacemaker or defibrillator, or place the pads in anterior and posterior positions.

YOU are the Provider — SUMMARY

1. What is the function of the heart?

The heart receives deoxygenated blood from the body, sends it to the lungs to be reoxygenated, and then pumps highly oxygenated blood throughout the body. The heart must pump effectively to ensure that the body's tissues and cells receive an uninterrupted supply of oxygen and that metabolic waste (eg, carbon dioxide) is removed from the tissues and cells and returned, through the heart, for elimination from the body by the respiratory system.

2. What does the heart require to function effectively?

Like any other critical organ or muscle, the heart requires a constant supply of oxygen, which it receives from the coronary arteries. It also relies on electricity to stimulate the contraction of the muscular layer of the heart (myocardium). Adequate blood volume is also required for effective cardiac function. As blood returns to the heart, it enters the chambers, stretches their walls, and causes them to contract with greater force. If blood volume is low, the heart will stretch less, and its contractile force will decrease.

3. What should you include in your primary assessment of a patient with cardiac problems?

Your primary assessment of a patient with cardiac problems should be no different from any other patient: to find and immediately correct problems with airway, breathing, and circulation. Look for signs of impaired cardiac function, such as an irregular heartbeat, a fast or slow heart rate, a weak (thready) pulse, and poor skin condition (eg, pallor, diaphoresis).

4. Why is aspirin given to patients with an acute cardiac event?

Aspirin has clearly been shown to reduce mortality and morbidity from acute myocardial infarction (AMI). Unless the patient is allergic to aspirin, it should be given as soon as possible if an acute cardiac event is suspected. An AMI occurs when an atherosclerotic plaque ruptures and occludes a coronary artery. When this occurs, platelets rush to the area and aggregate (clump together), which further occludes the coronary artery. Aspirin makes the platelets less "sticky," which makes them less likely to aggregate. Although aspirin will not dissolve the existing clot that is occluding the coronary artery, it may help prevent it from getting larger by reducing the amount of platelet aggregation.

5. What type of medication is nitroglycerin? How may it help relieve chest pain, pressure, or discomfort?

Nitroglycerin is a vasodilator. It works by relaxing the smooth muscle that regulates the diameter of the blood vessels, causing them to dilate (open). Nitroglycerin is used by patients with coronary artery disease who are experiencing chest pain, pressure, or discomfort. It dilates the coronary arteries and increases blood flow to the heart. As a result, the myocardial oxygen supply and demand are rebalanced, and the pain subsides or resolves completely. In some cases, however, nitroglycerin does not relieve the patient's chest pain. In a patient with a cardiac history, this should make you more suspicious that he or she is experiencing an AMI.

6. When is nitroglycerin indicated for a patient? What is the typical dose?

Nitroglycerin is indicated for patients with coronary artery disease who experience chest pain, pressure, or discomfort. Many patients with coronary artery disease have prescribed nitroglycerin, which they self-administer. If the patient has not taken any of his or her prescribed nitroglycerin, you may assist the patient in doing so after ensuring that his or her systolic blood pressure is at least 100 mm Hg and that approval from medical control has been obtained. Because nitroglycerin is a vasodilator, it can cause hypotension. Therefore, it is important to reassess the patient's blood pressure within a few minutes after administering nitroglycerin to ensure that it is at least 100 mm Hg. Nitroglycerin is contraindicated in patients with a systolic blood pressure of less than 100 mm Hg and in patients who have taken drugs for erectile dysfunction (eg, sildenafil [Viagra], tadalafil [Cialis], avanafil [Stendra], and vardenafil [Levitra, Staxyn]) within the past 24 to 36 hours. Drugs for erectile dysfunction are also vasodilators; if given together with nitroglycerin, significant hypotension may occur.

7. What is significant about the patient's vital signs?

Pale, cool, clammy (diaphoretic) skin is not exclusive to a cardiac problem. However, in the context of the patient's chief complaint and history of heart problems, it is highly suggestive that her chest pain is of a cardiac origin. An irregular heartbeat indicates a disturbance in the cardiac electrical conduction system (dysrhythmia). Again, in the context of her chief complaint and cardiac history, this should further increase your index of suspicion that she is experiencing a cardiac event. An irregular heartbeat in a patient with a cardiac problem could indicate an impending life-threatening dysrhythmia. The patient's rapid heart rate (tachycardia) and relatively elevated blood pressure (150/90 mm Hg) are also clinically significant; they indicate that her heart is working harder than normal. As the heart rate and blood pressure increase, the heart consumes and requires more oxygen. If the heart is already deprived of oxygen, the patient's condition could worsen.

8. Should you give her additional nitroglycerin? Why or why not?

Despite taking two of her prescribed nitroglycerin doses before your arrival, the patient is still experiencing significant chest pain (7 on a 0 to 10 scale). Because her systolic blood pressure is well above 100 mm Hg, you should contact medical control and request permission to assist her with one more nitroglycerin dose. Remember to reassess her blood pressure within a few minutes after administering the medication.

9. Why is early notification of the receiving facility so important for patients with an acute coronary event?

The longer it takes to reestablish blood flow distal to an occluded artery, the greater the amount of cardiac muscle damage (hence the phrase, "time is muscle"). Early reperfusion—with fibrinolytic medications (clot busters) or cardiac catheterization and stent placement—has clearly been shown to minimize the amount of cardiac damage and improve the patient's outcome. The earlier you notify the receiving facility that you are transporting a patient with a possible AMI, the more time the staff will have to allocate the resources needed to facilitate rapid cardiac reperfusion. The physician determines the reperfusion strategy. Your job is to recognize that the patient may be experiencing an AMI, provide immediate lifesaving care, promptly notify the appropriate receiving facility, and transport without delay.

10. Should you apply the AED to determine if she is experiencing a cardiac dysrhythmia? Why or why not?

No. The automated external defibrillator (AED) is applied only to patients who are apneic and pulseless (eg, in cardiac arrest). At present, your patient is breathing and has a pulse. Even if you did apply the AED, it would not analyze her cardiac rhythm. An AED will not analyze the cardiac rhythm if it detects patient movement. You should have the AED readily available in case she experiences cardiac arrest, but its application is not indicated at this point.

11. What is the difference between angina pectoris and an acute myocardial infarction?

Angina pectoris occurs when the heart’s demand for oxygen exceeds its available supply (ischemia), resulting in chest pain or discomfort. Angina is typically triggered by exertion, which increases myocardial oxygen consumption and demand. When the patient ceases exertion, oxygen supply and demand are rebalanced and the pain resolves, usually in less than 15 minutes. In more severe cases, a combination of rest and nitroglycerin are required for resolution of the patient’s chest pain or discomfort.

An AMI occurs when a portion of the heart muscle is completely deprived of oxygen because of complete occlusion of one or more coronary arteries. Unlike angina, the chest pain, pressure, or discomfort associated with an AMI typically does not resolve with rest or nitroglycerin and persists for greater than 15 minutes. The patient experiencing an AMI needs prompt treatment in the hospital, which is aimed at removing the clot in the coronary artery and reestablishing distal blood flow.

12. As an EMT, how can you distinguish angina pectoris from an acute myocardial infarction?

The signs and symptoms of angina and an AMI are essentially the same and usually cannot be distinguished without advanced diagnostic procedures. In both conditions, the chest pain or discomfort may be described as a feeling of pressure or heaviness. The patient requires physician evaluation, blood analysis, and other tests to diagnose an AMI. You should assume that any patient with nontraumatic chest pain or discomfort is experiencing an AMI until ruled out by a physician.

EMS Patient Care Report (PCR)

Date: 3-10-16	**Incident No.:** 130209	**Nature of Call:** Cardiac		**Location:** 1152 Blanco Road	
Dispatched: 0942	**En Route:** 0942	**At Scene:** 0950	**Transport:** 1000	**At Hospital:** 1017	**In Service:** 1029

Patient Information

Age: 60 **Sex:** F **Weight (in kg [lb]):** 55 kg (121 lb)	**Allergies:** No known drug allergies **Medications:** Vasotec, aspirin (ASA), nitroglycerin (NTG) **Past Medical History:** Heart attack, hypertension **Chief Complaint:** Chest pain

Vital Signs

Time: 0952	**BP:** 150/90	**Pulse:** 118	**Respirations:** 20	**Spo_2:** 98%
Time: 1002	**BP:** 136/84	**Pulse:** 84	**Respirations:** 18	**Spo_2:** 96%
Time: 1012	**BP:** 128/78	**Pulse:** 80	**Respirations:** 16	**Spo_2:** 98%

EMS Treatment (circle all that apply)

Oxygen @ 4 L/min via (circle one): **NC NRM BVM**		**Assisted Ventilation**	**Airway Adjunct**	**CPR**
Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** 324 mg ASA

Narrative

Dispatched for a 60-year-old woman with chest pain. Upon arrival at the scene, found the patient sitting up in her bed with her fist clenched against her chest. She was conscious and alert, although anxious. Her airway was patent, and her breathing was adequate. She was markedly diaphoretic; had pale, cool skin; and had a rapid, irregular pulse. Patient states that she had a heart attack 3 years ago and has hypertension. She is presently taking Vasotec, NTG, and one (1) ASA per day and states that she has been compliant with her medications. Patient took two doses of her prescribed NTG before EMS arrival; however, she states that the medication had no effect; she presently describes her pain as a "7" on a scale of 0 to 10. Administered 324 mg ASA (patient stated she had no known drug allergies), applied oxygen at 4 L/min via nasal cannula to raise the oxygen saturation from 91% to just above 95%, and obtained vital signs. Contacted medical control, who authorized the administration of one more NTG dose. NTG was administered per medical control orders, the patient was placed onto the stretcher, loaded into the ambulance, and transported to the hospital. Contacted hospital shortly after departing the scene and advised that we were transporting patient with possible AMI. En route to the hospital, allowed patient to assume position of comfort and reassessed her vital signs. She was still reporting chest pain (3/10); however, her pulse rate, although still irregular, was notably slower. Reassessment of her skin revealed that it was pink, cool, and dry, and she was noted to be less anxious. Continued to monitor patient's condition throughout transport; there was no gross evidence of deterioration, and she remained conscious and alert. Delivered her to emergency department staff w/o incident. Upon arrival at the hospital, we were greeted by the cardiac team, who assumed patient care. Gave verbal report to charge nurse and returned to service.**End of report**

Prep Kit

Ready for Review

- The heart is divided down the middle into two sides, right and left, each with an upper chamber called the atrium and a lower chamber called the ventricle.
- The heart valve that keeps blood moving through the circulatory system in the proper direction is the aortic valve, which lies between the left ventricle and the aorta, the body's main artery.
- The heart's electrical system controls heart rate and helps the atria and ventricles work together to pump the blood.
- During periods of exertion or stress, the myocardium requires more oxygen. The oxygen is supplied by dilation of the coronary arteries, which increases blood flow.
- Common places to feel for a pulse include the carotid, femoral, brachial, radial, posterior tibial, and dorsalis pedis arteries.
- Low blood flow to the heart is usually caused by coronary artery atherosclerosis, a disease in which cholesterol plaques build up inside blood vessels, eventually occluding them.
- Occasionally a brittle plaque in an artery will crack, causing a blood clot to form. Heart tissue downstream suffers from a lack of oxygen and, within 30 minutes, will begin to die. This condition is called an acute myocardial infarction (AMI), or heart attack.
- Heart tissues that are not getting enough oxygen but are not yet dying can cause pain called angina. The pain of an AMI is different from the pain of angina in that it can come at any time, not just with exertion; it lasts up to several hours, rather than just a few moments; and it is not relieved by rest or nitroglycerin.
- In addition to crushing chest pain, signs of AMI include sudden onset of weakness, nausea, and sweating; sudden dysrhythmia; pulmonary edema; and even sudden death.
- Heart attacks can have three serious consequences. One is sudden death, usually the result of cardiac arrest caused by abnormal heart rhythms called dysrhythmias. These include tachycardia, bradycardia, ventricular tachycardia, and, most commonly, ventricular fibrillation.
- The second consequence is cardiogenic shock. Symptoms include restlessness; anxiety; pale, clammy skin; pulse rate higher than normal; and blood pressure lower than normal. Patients with these symptoms should receive oxygen, assisted ventilations as needed, and immediate transport.
- The third consequence of AMI is congestive heart failure, in which damaged heart muscle can no longer contract effectively enough to pump blood through the system. The lungs become congested with fluid, breathing becomes difficult, the heart rate increases, and the left ventricle enlarges.
- Signs include swollen ankles from dependent edema, high blood pressure, rapid heart rate and respirations, crackles (rales), and, sometimes, the pink sputum and dyspnea of pulmonary edema.
- Treat a patient with congestive heart failure as you would a patient with chest pain. Monitor the patient's vital signs. Give the patient oxygen via nonrebreathing face mask. Apply CPAP if it is available and you are authorized to use it. Allow the patient to remain sitting up.
- When treating patients with chest pain or discomfort, obtain a SAMPLE history, following the OPQRST mnemonic to assess the pain; measure and record vital signs; ensure the patient is in a comfortable position, usually semireclining or half sitting up; administer prescribed nitroglycerin and oxygen; and transport the patient, reporting to medical control as you do.
- If a patient is not responsive, is not breathing, and does not have a pulse, you may perform the following, depending on the patient's age and your local protocol:
  - Unresponsive adult or child older than 8 years, perform automated external defibrillation.
  - Unresponsive child younger than 8 years, perform automated external defibrillation with pediatric pads and dose attenuator; if neither is available, an adult AED may be used.
  - Unresponsive infant between the ages of 1 month and 1 year should be manually defibrillated (an ALS skill). If ALS is not available, use an AED equipped with pediatric pads and a dose attenuator. If neither is available, adult AED pads may be used.
- The AED requires the operator to apply the pads, power on the unit, follow the AED prompts, and press the shock button as indicated. The computer inside the AED recognizes rhythms that require shocking and will not mislead you.
- The three most common errors in using certain AEDs are failure of the machine to shock fine V fib, applying the AED to a patient who is moving, squirming, or being transported, and turning off the AED before analysis or shock is complete.
- Do not touch the patient while the AED is analyzing the heart rhythm or delivering shocks.
- Effective CPR and early defibrillation with an AED are critical interventions to the survival of a patient in cardiac arrest. Begin CPR starting with high-quality chest compressions and apply the AED as soon as it is available.

- If an advanced life support (ALS) service is responding to the scene, stay where you are and continue CPR and defibrillation as needed. If ALS is not responding, begin transport if the patient regains a pulse, if you have delivered six to nine shocks, or if the AED gives three consecutive messages (separated by 2 minutes of CPR) that no shock is advised. Follow your local protocols regarding when it is appropriate to transport the patient.
- If an unconscious patient has no pulse during transport, stop the vehicle, reanalyze the rhythm, and defibrillate again or begin CPR, as appropriate.
- The chain of survival, which is the sequence of events that must happen for a patient with cardiac arrest to have the best chance of survival, includes recognition of early warning signs and immediate activation of EMS, immediate high-quality CPR, rapid defibrillation, basic and advanced EMS, and ALS and postarrest care. Seconds count at every stage.

Vital Vocabulary

acute coronary syndrome A group of symptoms caused by myocardial ischemia; includes angina and myocardial infarction.

acute myocardial infarction (AMI) A heart attack; death of heart muscle following obstruction of blood flow to it. Acute in this context means "new" or "happening right now."

angina pectoris Transient (short-lived) chest discomfort caused by partial or temporary blockage of blood flow to the heart muscle; also called *angina*.

anterior The front surface of the body; the side facing you in the standard anatomic position.

aorta The main artery, which receives blood from the left ventricle and delivers it to all the other arteries that carry blood to the tissues of the body.

aortic aneurysm A weakness in the wall of the aorta that makes it susceptible to rupture.

aortic valve The one-way valve that lies between the left ventricle and the aorta and keeps blood from flowing back into the left ventricle after the left ventricle ejects its blood into the aorta; one of four heart valves.

artifact A tracing on an ECG that is the result of interference, such as patient movement, rather than the heart's electrical activity.

asystole The complete absence of all heart electrical activity.

atherosclerosis A disorder in which cholesterol and calcium build up inside the walls of blood vessels, eventually leading to partial or complete blockage of blood flow.

atrium One of two (right and left) upper chambers of the heart. The right atrium receives blood from the vena cava and delivers it to the right ventricle. The left atrium receives blood from pulmonary veins and delivers it to the left ventricle.

automaticity The ability of cardiac muscle cells to contract without stimulation from the nervous system.

autonomic nervous system The part of the nervous system that controls the involuntary activities of the body such as the heart rate, blood pressure, and digestion of food.

bradycardia A slow heart rate, less than 60 beats/ min.

cardiac arrest When the heart fails to generate effective and detectable blood flow; pulses are not palpable in cardiac arrest, even if muscular and electrical activity continues in the heart.

cardiac output A measure of the volume of blood circulated by the heart in 1 minute, calculated by multiplying the stroke volume by the heart rate.

cardiogenic shock A state in which not enough oxygen is delivered to the tissues of the body, caused by low output of blood from the heart. It can be a severe complication of a large acute myocardial infarction, as well as other conditions.

congestive heart failure (CHF) A disorder in which the heart loses part of its ability to effectively pump blood, usually as a result of damage to the heart muscle and usually resulting in a backup of fluid into the lungs.

coronary arteries The blood vessels that carry blood and nutrients to the heart muscle.

defibrillate To shock a fibrillating (chaotically beating) heart with specialized electric current in an attempt to restore a normal, rhythmic beat.

dependent edema Swelling in the part of the body closest to the ground, caused by collection of fluid in the tissues; a possible sign of congestive heart failure.

dilation Widening of a tubular structure such as a coronary artery.

dissecting aneurysm A condition in which the inner layers of an artery, such as the aorta, become separated, allowing blood (at high pressures) to flow between the layers.

dysrhythmia An irregular or abnormal heart rhythm.

hypertensive emergency An emergency situation created by excessively high blood pressure, which can lead to serious complications such as stroke or aneurysm.

infarction Death of a body tissue, usually caused by interruption of its blood supply.

inferior The part of the body or any body part nearer to the feet.

ischemia A lack of oxygen that deprives tissues of necessary nutrients, resulting from partial or complete blockage of blood flow; potentially reversible because permanent injury has not yet occurred.

lumen The inside diameter of an artery or other hollow structure.

myocardium The heart muscle.

occlusion A blockage, usually of a tubular structure such as a blood vessel.

parasympathetic nervous system The part of the autonomic nervous system that controls vegetative functions such as digestion of food and relaxation.

perfusion The flow of blood through body tissues and vessels.

posterior The back surface of the body; the side away from you in the standard anatomic position.

return of spontaneous circulation (ROSC) The return of a pulse and effective blood flow to the body in a patient who previously was in cardiac arrest.

stroke volume The volume of blood ejected with each ventricular contraction.

superior The part of the body or any body part nearer to the head.

sympathetic nervous system The part of the autonomic nervous system that controls active functions such as responding to fear (also known as the “fight-or-flight” system).

syncope A fainting spell or transient loss of consciousness.

tachycardia A rapid heart rate, more than 100 beats/min.

thromboembolism A blood clot that has formed within a blood vessel and is floating within the bloodstream.

ventricle One of two (right and left) lower chambers of the heart. The left ventricle receives blood from the left atrium (upper chamber) and delivers blood to the aorta. The right ventricle receives blood from the right atrium and pumps it into the pulmonary artery.

ventricular fibrillation Disorganized, ineffective quivering of the ventricles, resulting in no blood flow and a state of cardiac arrest.

ventricular tachycardia A rapid heart rhythm in which the electrical impulse begins in the ventricle (instead of the atrium), which may result in inadequate blood flow and eventually deteriorate into cardiac arrest.

Assessment *in Action*

© Jones & Bartlett Learning. Courtesy of MIEMSS.

You are dispatched to a person reporting chest pain and shortness of breath. You arrive at the residence to find a 56-year-old man sitting in the kitchen. His skin is ashen, and he is diaphoretic. The patient describes the pain as substernal and crushing. On a scale of 0 to 10, he states his pain is an 8. The patient had a myocardial infarction 2 years ago, and he has angina, hypertension, and high cholesterol. His medications include nitroglycerin, furosemide, and atorvastatin. His vital signs are as follows: pulse, 140 beats/min and irregular; respiratory rate, 28 breaths/min; and blood pressure, 90/50 mm Hg. You hear crackles when listening to his breath sounds.

1. The patient's difficulty breathing and crackles are due to blood backing up in which part of the body?

   A. The heart
   B. The lungs
   C. The vessels
   D. The arteries

2. On the basis of the information given, the patient is most likely experiencing which type of shock?

   A. Neurogenic
   B. Vasogenic
   C. Cardiogenic
   D. Hypovolemic

3. Treatment of this patient includes which of the following?

   A. Oxygen, furosemide, and nitroglycerin
   B. Oxygen and transport in a position of comfort
   C. Oxygen and nitroglycerin
   D. Oxygen and transport with legs raised

4. What combination of vital signs and history gives the best clue about the patient's condition?

   A. The respiratory rate of 28 breaths/min with a history of angina

B. The pulse of 140 beats/min with a history of high cholesterol
C. The pulse of 140 beats/min with a history of angina
D. The blood pressure of 90/50 mm Hg with a history of hypertension

5. What other information would be most helpful in determining the treatment of this patient?

A. A pulse oximetry measurement and a list of medication allergies
B. A description of his prior heart attack and how it was treated
C. Whether or not he has an implanted pacemaker or an internal defibrillator
D. Who is his doctor and which hospital would he prefer

6. Why would nitroglycerin be contraindicated for this patient?

A. He may have already taken it three times.
B. His blood pressure is too low.
C. He may be allergic to it.
D. He may have taken Viagra in the last 24 hours.

7. What would be your most important initial treatment of this patient?

A. Apply the AED in case he goes into cardiac arrest.
B. Give him nitroglycerin if he denies using Viagra.
C. Transport to the hospital because all other treatment is contraindicated.
D. Administer aspirin if he is not allergic to it.

8. The patient has a loss of consciousness on the way to the hospital. When you check, you cannot feel a pulse. What should you do?

A. Tell your partner to drive faster as you begin CPR on the patient.
B. Immediately apply the AED and wait for it to analyze the rhythm before taking any other action.
C. Have your partner pull over the ambulance and come back to help you with CPR and the AED.
D. Begin CPR and after 2 minutes stop to apply the AED while your partner continues driving to the hospital.

9. Describe the path of blood through the heart and lungs.

10. What is cardiogenic shock?

CHAPTER

17

Neurologic Emergencies

National EMS Education Standard Competencies

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Neurology

Anatomy, presentations, and management of

› Decreased level of responsiveness (pp 675–676, 685–686, 697)
› Seizure (pp 675–676, 681–685, 696–697)
› Stroke (pp 675–676, 678–681, 694–696)

Anatomy, physiology, pathophysiology, assessment, and management of

› Stroke/transient ischemic attack (pp 675–681, 686–696)
› Seizure (pp 675–676, 681–690, 693–697)
› Status epilepticus (pp 675–676, 682–690, 693–697)
› Headache (pp 675–678, 686–690, 693–695)

Knowledge Objectives

1. Describe the anatomy and physiology and functions of the brain and spinal cord. (pp 675–676)
2. Discuss the different types of headaches, the possible causes of each, and how to distinguish a harmless headache from a potentially life-threatening condition. (pp 676–678)
3. Explain the various ways blood flow to the brain may be interrupted and cause a cerebrovascular accident. (p 678)
4. Discuss the causes, similarities, and differences of an ischemic stroke, hemorrhagic stroke, and transient ischemic attack. (pp 678–680)
5. List the general signs and symptoms of stroke and how those symptoms manifest if the left hemisphere of the brain is affected and if the right hemisphere of the brain is affected. (pp 680–681)

6. List three conditions with symptoms that mimic stroke and the assessment techniques EMTs may use to identify them. (p 681)
7. Define a generalized seizure, partial seizure, and status epilepticus; include how they differ from each other and their effects on patients. (pp 681–682)
8. Describe how the different stages of a seizure are characterized. (p 682)
9. Discuss the importance for EMTs to recognize when a seizure is occurring or whether one has already occurred in a patient. (p 684)
10. Explain the postictal state and the specific patient care interventions that may be necessary. (pp 684–685)
11. Define altered mental status; include possible causes and the patient assessment considerations that apply to each. (pp 685–686)
12. Discuss scene safety considerations when responding to a patient with a neurologic emergency. (pp 686–687)
13. Explain the special considerations required for pediatric patients who exhibit altered mental status. (p 687)
14. Explain the primary assessment of a patient who is experiencing a neurologic emergency and the necessary interventions that may be required to address all life threats. (pp 687–689)
15. Describe the process of history taking for a patient who is experiencing a neurologic emergency and how this process varies depending on the nature of the patient's illness. (pp 689–690)
16. Explain the secondary assessment of a patient who is experiencing a neurologic emergency. (pp 690–692)
17. Explain how to use stroke assessment tools to rapidly identify a stroke patient; include two commonly used tools. (pp 690–693)
18. Explain the concept of a stroke alert and the important timeframe for the most successful treatment outcome for a patient who is suspected of having a stroke. (pp 690, 694)
19. List the key information EMTs must obtain and document for a stroke patient during assessment and reassessment. (pp 693–694)
20. Explain the care, treatment, and transport of patients who are experiencing headaches, stroke, seizure, and altered mental status. (pp 694–697)
21. Explain the special considerations required for geriatric patientsgeriatric patients who are experiencing a neurologic emergency. (p 696)

Skills Objective

1. Demonstrate how to use a stroke assessment tool such as the Cincinnati Prehospital Stroke Scale, 3-Item Stroke Severity Scale (LAG), or FAST mnemonic to test a patient for aphasia, facial weakness, and motor weakness. (pp 691–693)

Introduction

Stroke is the fifth leading cause of death and the leading cause of adult disability in the United States, according to the American Stroke Association. While stroke is common in geriatric patients, it may happen to anyone. Contributing factors for stroke include family history and race and ethnicity; African Americans, Hispanics, and Asians have an increased risk of stroke. Fortunately, treatments are available for stroke, and many hospitals are certified stroke centers. Some patients can avoid the devastating consequences of an acute stroke if they reach a hospital in time for treatment.

Seizures and altered mental status may occur in patients with brain disorders. Seizures may occur as a result of a recent or a prior head injury, a brain tumor, a metabolic disease, fever, or a genetic disposition. Your ability to recognize when a seizure has occurred or is occurring is a critical step because you can then provide the appropriate management.

Altered mental status is common in patients with a wide variety of medical conditions. However, avoid making assumptions about the cause of a patient's altered mental status. Many causes are possible, some obvious, some not: intoxication, head injury, hypoxia, stroke, metabolic disturbances, and many more. Obviously, treatment varies widely as well. Patients with altered mental status present a particular challenge in that they may be difficult to handle and frustrating to treat. This chapter will help you better understand, communicate with, and care for patients experiencing neurologic emergencies. Remember, your professionalism is paramount in these situations.

This chapter describes the structure and function of the brain and the most common causes of brain disorders, including stroke, transient ischemic attacks (TIA), seizures, headaches, and altered mental status. The signs and symptoms of each condition are explained, as well as how to approach and assess a patient with a neurologic emergency, and why prompt transport to an appropriate medical facility is so important.

Anatomy and Physiology

The brain is the body's computer. It controls breathing, speech, and all other body functions. All thoughts, memories, needs, and desires reside in the brain. Different parts of the brain perform different functions. For example, some parts of the brain receive input from the senses, including sight, hearing, taste, smell, and touch; some control the muscles and movement; and some control the formation of speech.

The brain is divided into three major parts: the brain stem, the cerebellum, and the cerebrum, which is the largest part **Figure 17-1**. The brain stem controls the most basic functions of the body, such as breathing, blood pressure, swallowing, and pupil constriction. Located just behind the brain stem is the cerebellum, which controls muscle and body coordination. The cerebellum is responsible for coordinating complex tasks that involve many muscles, such as standing on one foot without falling, walking, writing, picking up a coin, and playing the piano.

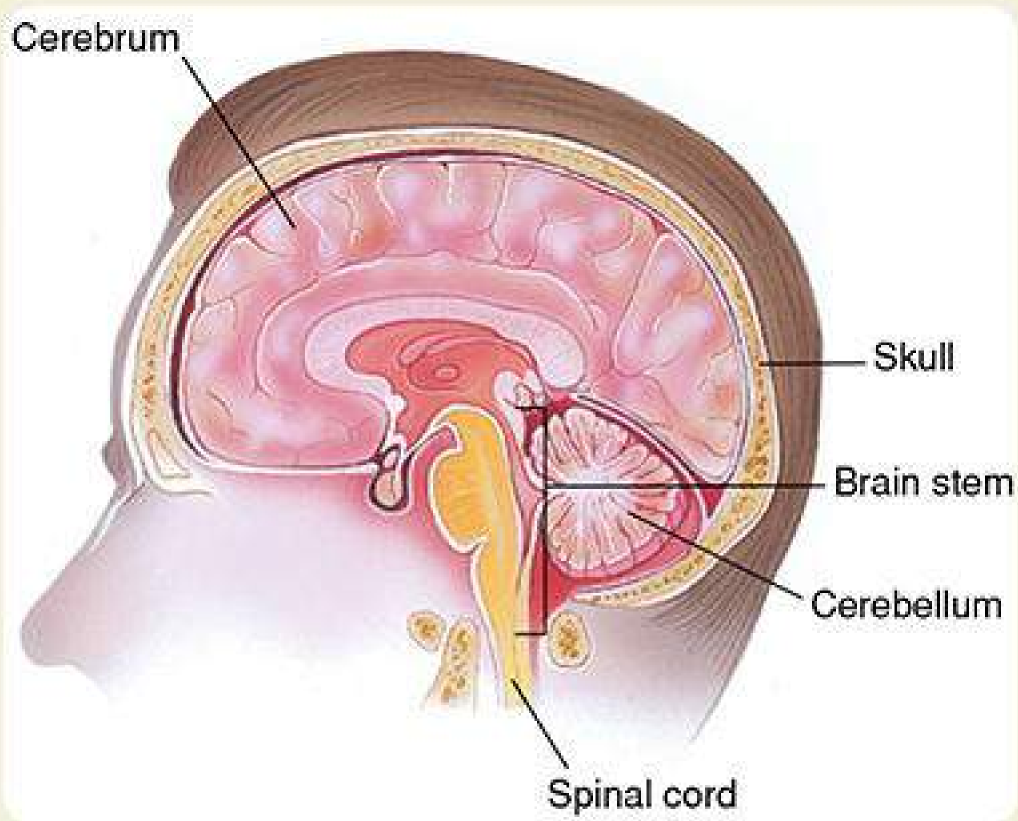

Figure 17-1 The brain is well protected within the skull. The brain's major parts are the cerebrum, the cerebellum, and the brain stem.

YOU are the Provider — PART 1

At 1823 hours, your unit is dispatched to 106 Scottie Drive. The dispatcher states that a 58-year-old woman is believed to be having a seizure. Bystanders report the patient is unresponsive, with shaking of her extremities and torso. You respond to the scene, which is located approximately 4 miles from your station. The weather is cloudy, the traffic is moderate, and the temperature is 87°F (30.6°C). While en route, you and your partner discuss the different types of seizures.

1. On the basis of the dispatch information, what type of seizure is the patient most likely experiencing?

2. What are some common causes of seizures in this patient's age group?

The cerebrum, located above the cerebellum, is divided down the middle into the right and left cerebral hemispheres. Each hemisphere controls activities on the opposite side of the body. The front part of the cerebrum controls emotion and thought, and the middle part controls sensation and movement. The back part of the cerebrum processes sight. In most people, speech is controlled on the left side of the brain, near the middle of the cerebrum.

Messages sent to and from the brain travel through nerves. Twelve cranial nerves run directly from the brain to various parts of the head, such as the eyes, ears, nose, and face. The remaining nerves join in the spinal cord and exit the brain through a large opening in the base of the skull called the foramen magnum **Figure 17-2**. At each vertebra in the neck and back, two nerves, called spinal nerves, branch out from the spinal cord and carry signals to and from the body.

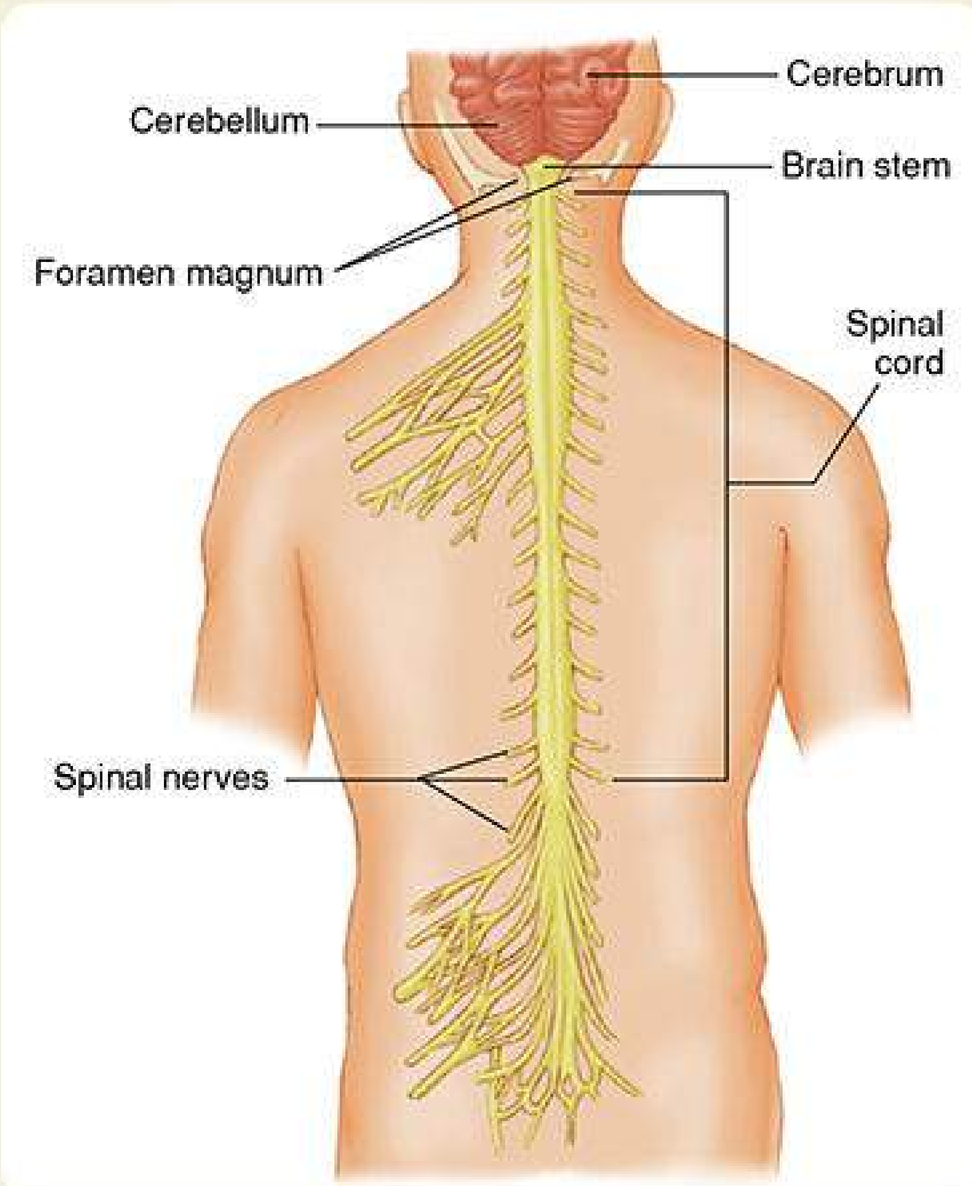

Figure 17-2 The spinal cord is the continuation of the brain stem. It exits the skull at the foramen magnum and extends down to the level of the second lumbar vertebra.

Pathophysiology

Many different disorders may cause brain dysfunction or other neurologic symptoms and may affect the patient's level of consciousness, speech, and voluntary muscle control. The brain is most sensitive to changes in oxygen, glucose, and temperature levels. A significant change in any one of these three levels will result in a neurologic change. As a general rule, if the problem is caused primarily by disorders in the heart and lungs, the entire brain will be affected. For example, when blood flow is stopped (cardiac arrest), the patient will go into a **coma**, a state of profound unconsciousness, and permanent brain damage can result within minutes. However, if the primary problem is in the brain, such as a poor blood supply to one side of the brain, the patient may have signs and symptoms affecting only one side of the body. A low oxygen level in the bloodstream will affect the entire brain, often causing anxiety, restlessness, and confusion. Very low blood glucose levels (hypoglycemia) can cause a wide spectrum of symptoms ranging from mild confusion to symptoms that mimic stroke.

Headache

One of the most common complaints of pain you will hear from your patients is headache. Because a headache is subjective, it may be a symptom of another condition or it may be considered a neurologic condition on its own. Millions of people experience a headache every year, but only a small percentage of these are caused by a serious medical condition. The brain and skull do not actually sense pain because neither contains pain receptors. The pain associated with a headache is felt from the surrounding areas of the face; scalp, meninges (membranes that cover the brain and spinal cord); larger blood vessels; and the muscles of the head, neck, and face.

Tension headaches, migraines, and sinus headaches are the most common types of headaches. These types of headaches are not considered life threatening, although they may be debilitating for the patient. Tension headaches are caused by muscle contractions in the head and neck and are attributed to stress. Patients usually describe the pain as squeezing, dull, or an ache. This type of headache typically does not have any associated symptoms and usually does not require medical attention.

Migraine headaches are thought to be caused by changes in blood vessel size in the base of the brain. Both adults and children can experience migraine headaches. Women are three times as likely as men to experience migraines. Frequently, the patient will have a history of migraines and will tell you that this episode is similar to one in the past. Pain from a migraine headache is usually described as pounding, throbbing, or pulsating. Migraines are often associated with nausea and vomiting and may be preceded by visual warning signs such as flashing lights or partial vision loss. These headaches can last for several hours to days.

Sinus headaches are caused by pressure that is the result of fluid accumulation in the sinus cavities. Patients may also have cold-like signs and symptoms of nasal congestion, cough, and fever if they have a sinus infection. Patients may report increased pain when they bend over or when their heads are moved forward. This type of headache is usually self-limiting, and prehospital emergency care is not required.

Although most headaches are not life threatening, some patients with a chief complaint of headache will require medical attention. Hemorrhagic stroke (bleeding in the brain), brain tumor, and meningitis are serious neurologic conditions that include headache as a symptom. Be concerned if the patient reports a sudden-onset, severe headache or a sudden-onset headache that has associated symptoms. Headaches accompanied by fever, stiff neck, seizures, or altered mental status or following a head trauma are potentially life threatening and require a complete assessment and transport to the hospital **Table 17-1**. An incident with multiple patients reporting a headache may indicate carbon monoxide poisoning.

A sudden, severe headache, often described as the worst pain the patient has ever had, could be a sign of a hemorrhagic stroke. The blood from a ruptured blood vessel irritates the tissues of the brain and can cause increased intracranial pressure, resulting in severe headache pain. This type of pain may initially be localized and then become more diffuse as the irritation in the meninges spreads. You should suspect a hemorrhagic stroke in patients with a severe headache, seizures, and altered mental status. Early signs of increased intracranial pressure include headache, vomiting, altered mental status, and seizures. Increasing intracranial pressure may also be caused by a hemorrhagic stroke (a blood vessel swells and ruptures), a tumor, or head trauma that may have occurred hours or days before this event. During your patient assessment ask if the patient has experienced any recent head trauma.

Table 17-1 Headache Red Flags

A patient who has a headache associated with any of the following should be evaluated for a potentially life-threatening condition:

- Sudden onset of symptoms
- Explosive/thunderclap pain
- Altered mental status
- Age >50
- Depressed immune system (known to be at higher risk for infection)
- Neurologic deficits
- Neck stiffness/pain
- Fever
- Changes in vision
- One-sided paralysis or weakness

YOU are the Provider PART 2

You arrive at the scene, and you are greeted by the patient's sister. She tells you they were having a conversation when the patient suddenly grabbed both sides of her head and then began "shaking all over." The patient is lying on the floor in her living room with a pillow under her head. She is conscious but confused and reports a severe headache. You perform an assessment as your partner opens the jump bag.

Recording Time: 0 Minutes	
Appearance	Slightly pale; skin is dry
Level of consciousness	Conscious, but confused
Airway	Open; clear of secretions and foreign bodies
Breathing	Rapid rate; adequate depth
Circulation	Radial pulse, rapid and bounding

Your partner administers oxygen and prepares to take the patient's vital signs. The patient's sister tells you her sister has never had seizures before. The patient is wearing a medical alert bracelet, which identifies her medical history of high blood pressure, heart disease, and type 2 diabetes.

3. What additional questions should you ask the patient's sister?
4. What prehospital assessments can you perform to determine the possible cause of the patient's seizure?
5. Other than oxygen, what additional treatment is indicated at this point?

Bacterial meningitis, an inflammation of the meninges caused by a bacterial infection, is a central nervous system infection in which the patient may complain of a headache, stiff neck, fever, and sensitivity to light. This is a serious condition requiring prompt medical attention. Use standard precautions, and provide supportive care of the ABCs. Provide a quiet, darkened environment when possible and consider not using lights and siren.

Stroke

A **cerebrovascular accident (CVA)**, or **stroke**, is an interruption of blood flow to an area within the brain that results in the loss of brain function. In the context of a total lack of oxygen, brain cells stop functioning and begin to die within minutes. Medical science currently has little to offer in the way of treatment once brain cells are dead. However, when oxygen levels are decreased, but not absent, because an insufficient amount of blood is getting through, brain cells may be damaged more slowly. It may take several hours or more for brain cells to die in this situation. When brain cells die or are injured, severe disability may result. For example, if cells that are responsible for controlling the left arm are starved for oxygen, the patient will not be able to move that arm. The brain cells will develop **ischemia**, a reduction in blood supply that results in inadequate oxygen being supplied to the brain cells. This causes those cells to stop functioning properly. If normal blood flow is restored to that area of the brain in time, the cells will not die and the patient may regain full use and control of the arm.

Unfortunately, many patients having a stroke deny or ignore their symptoms and delay seeking medical attention. The delay in seeking care can result in devastating consequences, because "time is brain."

> **Words of Wisdom**
>
> Stroke patients who receive treatment within the first few hours of the onset of stroke symptoms have a much greater chance of surviving and avoiding long-term brain damage. Patients with ischemic strokes, the most common type of stroke, may be candidates for treatment with tissue plasminogen activator (tPA), but this drug must be given within the first few hours after a stroke; ideally within the first hour of arrival in the ED to have the best chance of reversing the symptoms. Note the time of symptom onset and transport to a stroke center.

Types of Stroke

The two main types of stroke are ischemic and hemorrhagic. An ischemic stroke occurs when blood flow through the cerebral arteries is blocked. In hemorrhagic stroke, a blood vessel ruptures and the accumulated blood causes increased pressure in the brain.

Ischemic Stroke

According to the American Stroke Association, **ischemic stroke** is the most common type of stroke, accounting for more than 80% of all strokes. When blood flow to a particular part of the brain is stopped by a blockage (blood clot) inside a blood vessel, the result is an ischemic stroke. This blockage may be due to **thrombosis**, where a clot forms at the site of blockage, or an **embolus**, where the blood clot forms in a remote area (such as a diseased heart) and then travels to the site of the blockage. As with coronary artery disease, atherosclerosis in the blood vessels is often the cause of ischemic stroke. Patients who experience an ischemic stroke may have dramatic symptoms, including loss of movement on the side of the body opposite the side where the occlusion has occurred.

Atherosclerosis is a disorder in which calcium and cholesterol build up, forming plaque inside the walls of the blood vessels. This plaque may obstruct blood flow and interfere with the vessels' ability to dilate. Eventually, atherosclerosis may cause complete occlusion of an artery **Figure 17-3**. In other cases, an atherosclerotic plaque in the carotid artery in the neck ruptures. A blood clot forms over the crack in the plaque. Sometimes, it grows large enough to completely block all blood flow through that artery. The parts of the brain supplied by the artery are deprived of oxygen and stop functioning.

Even if the blockage in the carotid artery is not complete, smaller pieces of the blood clot may embolize (break off and be carried by the normal flow of blood) deep into the brain, where they may become lodged in a smaller branch of a blood vessel. This cerebral embolism then blocks blood flow **Figure 17-4**. Depending on the location of the lodged blood clot, the patient's symptoms can vary widely, from nothing at all to complete paralysis.

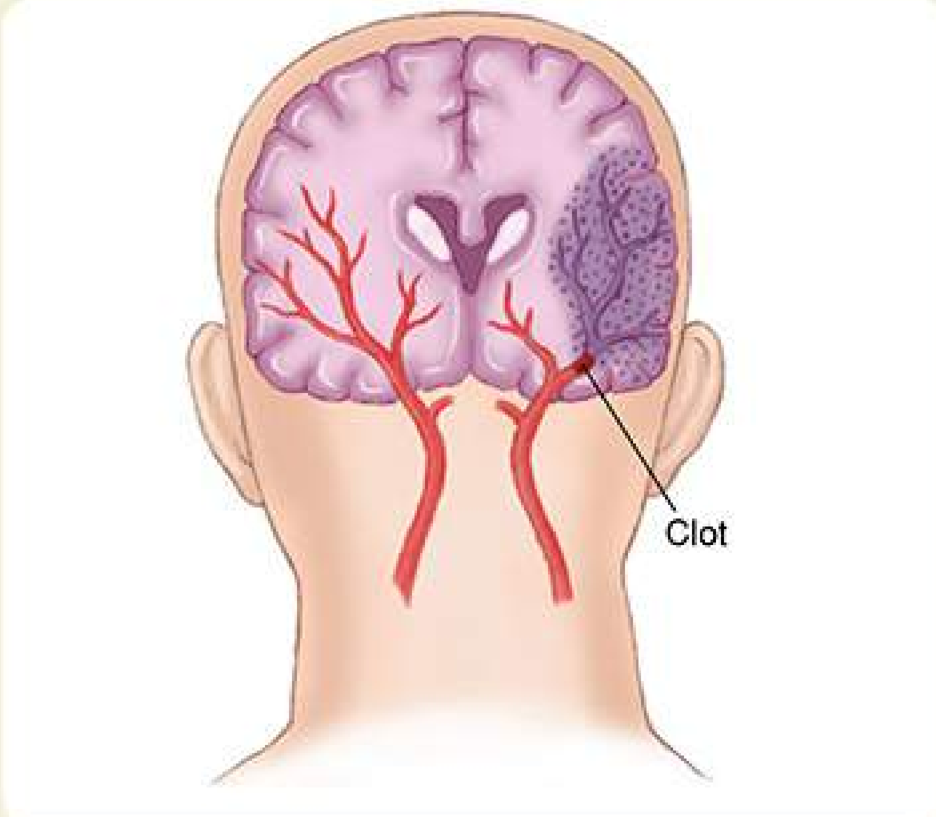

Figure 17-3 Atherosclerosis can damage the wall of a cerebral artery, producing narrowing and/or a blood clot. When a vessel is narrowed or completely blocked, blood flow to part of the brain may be blocked, causing brain cells to die because of the lack of adequate oxygenation.

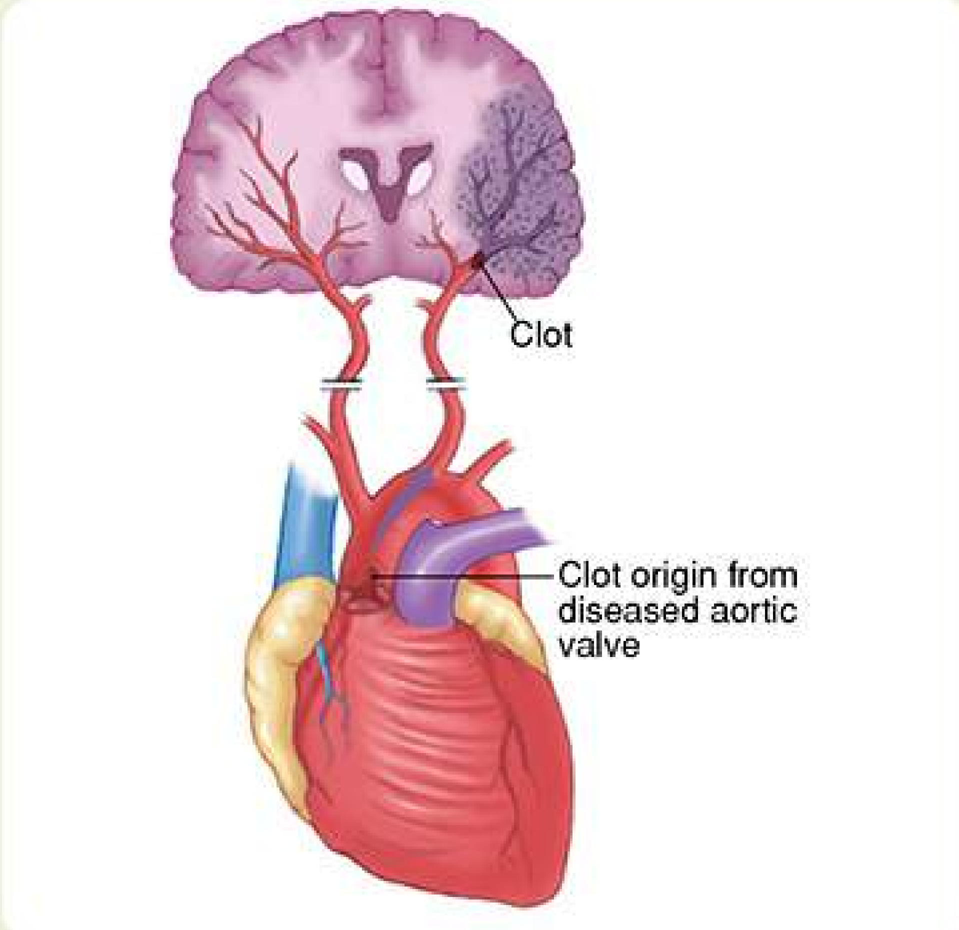

Figure 17-4 An embolus, a blood clot formed elsewhere in the body (for example, on a diseased heart valve), can travel through the body's vascular system, lodge in a cerebral artery, and cause a stroke.

Hemorrhagic Stroke

Hemorrhagic stroke occurs as a result of bleeding inside the brain. According to the American Stroke Association, hemorrhagic strokes account for 13% of all strokes. In hemorrhagic stroke, a blood vessel ruptures and the accumulated blood then forms a blood clot, which compresses the brain tissue next to it. The compression prevents oxygenated blood from getting into the area, and the brain cells begin to die. Cerebral hemorrhages are often fatal.

Hemorrhagic stroke commonly occurs in people experiencing stress or exertion. The people at highest risk for hemorrhagic stroke are those with very high blood pressure or long-term untreated elevated blood pressure. Many years of high blood pressure weaken the blood vessels in the brain. If a vessel ruptures, the bleeding in the brain will increase the pressure inside the cranium. Proper treatment of high blood pressure can help prevent this long-term damage to the blood vessels, decreasing the risk of this devastating complication.

Some people are born with a weakness in the walls of an artery. An **aneurysm**, a swelling or enlargement of the wall of an artery resulting from a defect or weakening of the arterial wall, may then develop. Figure 17-5 is an angiogram showing a cerebral aneurysm. The most notable symptom of a ruptured aneurysm is often a sudden onset, severe headache, typically described by the patient as the worst headache he or she has ever had. The headache is caused by the irritation of blood on the brain tissue after the artery swells and ruptures. A hemorrhagic stroke in an otherwise healthy young person is often caused by a weakness in a blood vessel called a *berry aneurysm*. This type of aneurysm resembles a tiny balloon (or berry) that juts out from the artery. When the aneurysm is overstretched and ruptures, blood spurts into an area between two of the coverings of the brain called the subarachnoid space. These types of strokes are called subarachnoid hemorrhages. If the patient gets to the hospital quickly, surgical repair of the aneurysm may be possible. However, like other brain bleeding and cerebral hemorrhage, this condition is often fatal.

Figure 17-5 An angiogram showing a cerebral aneurysm.

Transient Ischemic Attack

In a patient with coronary artery disease, blood flow to the heart muscle may be obstructed, causing chest pain (angina), which is considered a warning sign of a potential myocardial infarction. Similarly, when blood flow to the brain is obstructed due to atherosclerosis or a small blood clot, the patient may exhibit signs of a stroke. When these stroke-like symptoms resolve on their own in less than 24 hours, the event is called a **transient ischemic attack (TIA)**. Some people call these *mini strokes*. As with angina, no actual death of tissue (infarction) occurs with a TIA. However, since symptoms of a TIA can last up to 24 hours, you may not be able to differentiate between a stroke and a TIA.

Although most patients with TIAs do well, every TIA is an emergency. It may be a warning sign that a more significant stroke may occur in the future. Approximately one-third of patients who have a TIA will experience a stroke soon after the TIA. For this reason, all patients with a TIA should be evaluated by a physician to determine whether preventive action should be taken.

Signs and Symptoms of Stroke

The general signs and symptoms of stroke include the following:

- Facial drooping
- Sudden weakness or numbness in the face, arm, leg, or one side of the body

- Decreased or absent movement and sensation on one side of the body
- Lack of muscle coordination (ataxia) or loss of balance
- Sudden vision loss in one eye; blurred or double vision
- Difficulty swallowing (a primary reason for good airway management in a patient with a stroke)
- Decreased level of responsiveness
- Speech disorders
- Aphasia; difficulty expressing thoughts or inability to use the right words (expressive aphasia) or difficulty understanding spoken words (receptive aphasia)
- Slurred speech (**dysarthria**)
- Sudden and severe headache
- Confusion
- Dizziness
- Weakness
- Combativeness
- Restlessness
- Tongue deviation
- Coma

Left Hemisphere

If the left cerebral hemisphere has been affected by a stroke, the patient may exhibit a speech disorder called **aphasia**, the inability to produce or understand speech. Speech problems can vary widely. Some patients will have trouble understanding speech but will be able speak clearly. You can detect this problem by asking the patient a question such as "What day is today?" The patient may respond with an inappropriate answer such as, "Green." The speech is clear, but it does not make sense. Other patients will be able to understand the question but cannot produce the right sounds to provide an answer. Strokes that affect the left side of the brain can also cause paralysis of the right side of the body.

Right Hemisphere

If the right cerebral hemisphere of the brain is not getting enough blood, the patient will have trouble moving the muscles on the left side of the body. Usually, the patient will understand language and be able to speak, but the words may be slurred and hard to understand.

Interestingly, patients with right hemisphere strokes may be completely oblivious to their problems. If you ask these patients to lift their left arms and they cannot, they will lift their right arms instead. Patients will seem to have forgotten that their left arms even exist. This symptom is called neglect. Patients with conditions affecting the back part of the cerebrum may neglect certain parts of their vision. Generally, this is hard to detect in the field because patients compensate without conscious effort. Nevertheless, be aware of the possibility. Sit or stand on the patient's "good" side because he or she may be unable to see things on the "bad" side.

Neglect and lack of pain causes many patients who have had strokes to delay seeking help. A patient may be unaware that he or she has a problem until someone points out that some part of the patient's body is not functioning properly.

Bleeding in the Brain

Patients with bleeding in the brain (cerebral hemorrhage) may have very high blood pressure. High blood pressure can either cause the bleeding or be a compensatory response to the bleeding. Blood pressure increases as the body attempts to force more oxygen to the area of the brain where the damage is occurring. Remember, the brain is located inside a box (skull) with only a few openings. When bleeding occurs inside the brain, the pressure inside the skull increases. The body must increase the blood pressure to get blood to the brain's tissues, increasing the pressure even further. A trend of increasing blood pressure is an important sign. Blood pressure may then taper off and return to normal. Significant drops in blood pressure may also occur as the patient's condition worsens. Therefore, it is important to monitor the blood pressure for changes in these patients.

Conditions That May Mimic Stroke

The following conditions may appear to be a stroke:

- Hypoglycemia
- A **postictal state** (period following a seizure that lasts between 5 and 30 minutes, characterized by labored respirations and some degree of altered mental status)
- Subdural or epidural bleeding (a collection of blood near the skull that presses on the brain)

Because oxygen and glucose are needed for brain metabolism, a patient with hypoglycemia may present like a patient who is having a stroke. Good patient assessment includes finding out whether the patient's medical history includes diabetes. Always check the blood glucose level in patients with altered mental status if allowed by your local protocol.

A patient in a postictal state may look like a patient who is having a stroke. However, in most cases, a patient who has had a seizure will recover rapidly, within several minutes.

Subdural and epidural bleeding usually occur as a result of trauma. The dura is the leathery covering of the brain that lies next to the skull. A fracture near the temples may cause an artery to bleed on top of the dura, resulting in pressure on the brain **Figure 17-6A**. The onset of epidural bleeding is usually very rapid after injury. When the veins just below the dura bleed, this is referred to as subdural bleeding **Figure 17-6B**. Subdural bleeding is slower than epidural bleeding, sometimes occurring over a period of several days.

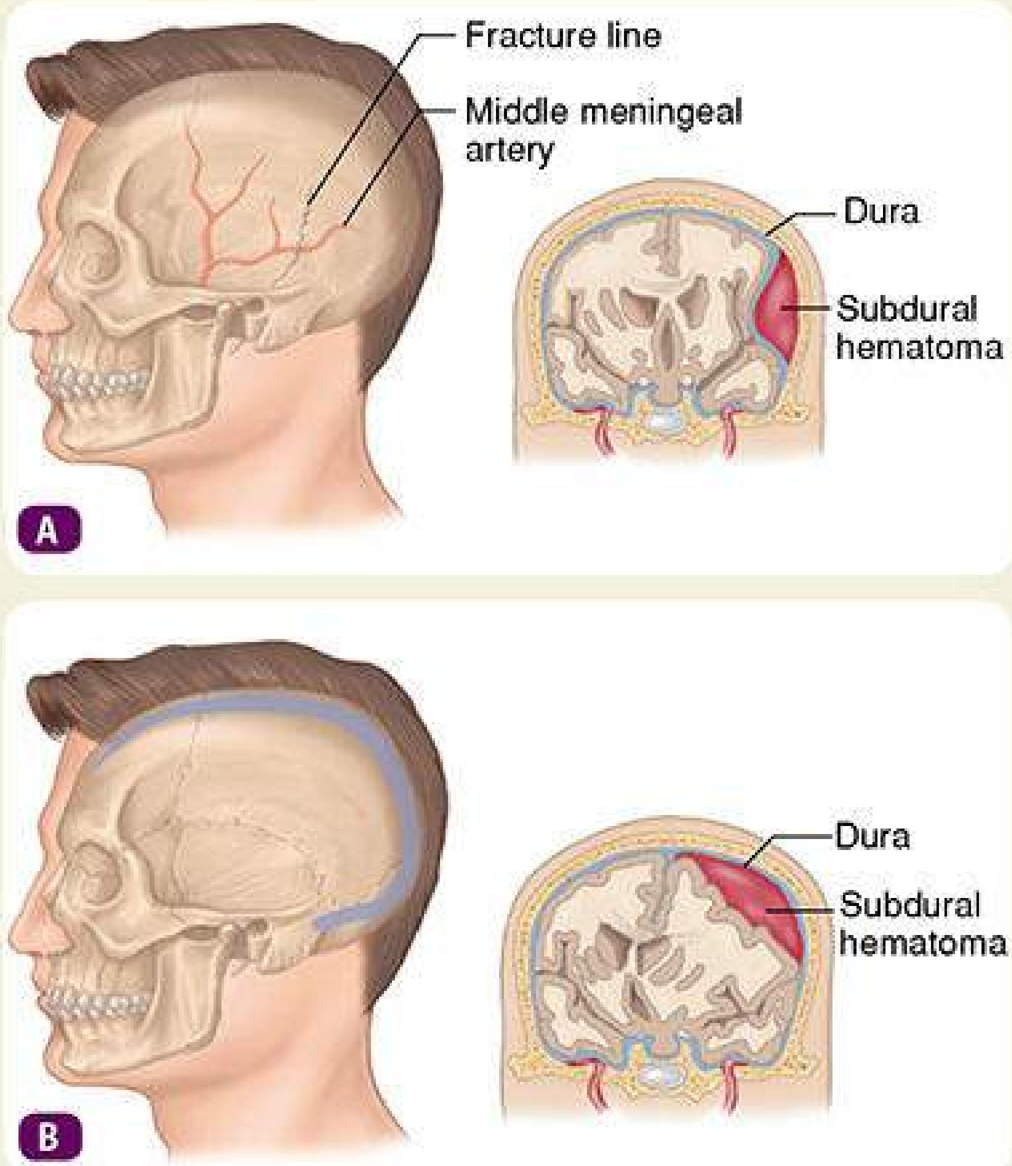

Figure 17-6 Trauma to the head may result in intracranial bleeding. **A.** Bleeding outside the dura and under the skull is called epidural bleeding. **B.** Bleeding beneath the dura but outside the brain is called subdural bleeding.

With subdural and epidural bleeding, the onset of stroke-like signs and symptoms may be subtle. The patient or family may not even remember the original injury that is causing the bleeding.

Words of Wisdom

With epidural hemorrhage after a head injury, the patient may have normal mental status for a period of time (usually minutes to hours), only to deteriorate markedly. This period between injury and deterioration is called a lucid interval.

Seizures

EMS calls frequently involve seizures. A **seizure** is a neurologic episode caused by a surge of electrical activity in the brain. It can take the form of a convulsion, characterized by generalized, uncoordinated muscle activity, and/or can be associated with a temporary alteration in consciousness. An estimated 2 to 3 million people in the United States have **epilepsy**, which is a common cause of seizures. Seizures are classified into two basic groups, generalized and partial (focal).

A **generalized (tonic-clonic) seizure** results from abnormal electrical discharges from large areas of the brain, usually involving both hemispheres. It is typically characterized by unconsciousness and a generalized severe twitching of the body's muscles that lasts several minutes or longer. In other cases, the seizure may simply be characterized by a brief lapse of consciousness in which the patient seems to stare and not to respond to anyone. This type of seizure does not involve any changes in motor activity and is called a petit mal or absence seizure.

A **partial (focal) seizure** begins in one part of the brain. Partial seizures are classified as simple or complex.

In a simple partial seizure, no change occurs in the patient's level of consciousness. Patients may report numbness, weakness, or dizziness. The senses may also be involved; the patient may report visual changes and unusual smells or tastes. A simple partial seizure may also cause twitching of the muscles and the extremities that spreads slowly from one part of the body to another, but it is not characterized by the dramatic severe twitching and muscle movements seen in a generalized seizure. The patient may also experience brief paralysis.

In a complex partial seizure, the patient has an altered mental status and does not interact normally with his or her environment. This type of seizure results from abnormal discharges from the temporal lobe of the brain. Other signs may include lip smacking, eye blinking, and isolated convulsions or jerking of the body or one part of the body such as an arm. The patient may experience unpleasant smells and visual hallucinations, exhibit uncontrollable fear, or exhibit repetitive physical behavior such as constant sitting and standing.

Some seizures occur on only one side of the body. Others begin on one side and gradually progress to a generalized seizure that affects the entire body. Depending on the type of seizure, the patient may have no loss of consciousness but still experience body shaking or muscle tremors. Most people with lifelong or chronic seizures tolerate these events reasonably well without complications, but in some patients, seizures may signal life-threatening conditions.

Often, a patient may experience a warning sign prior to the event. This is referred to as an **aura**. An aura can include visual changes (flashing lights or blind spots in the field of vision) or hallucinations (seeing, hearing, or smelling things that are not actually present). People with a history of seizures recognize their auras and usually take steps to minimize injury, such as sitting or lying down, knowing what is about to happen. However, be aware that auras do not occur prior to every seizure, and not all patients with a seizure disorder experience an aura.

A generalized seizure is characterized by sudden loss of consciousness followed by chaotic muscle movement and tone, and apnea. The patient may experience a tonic phase, usually lasting only seconds, in which there is a period of constant muscle contraction and trembling, tongue biting, bladder incontinence, or bowel incontinence. During a generalized seizure, the patient may exhibit bilateral movement characterized by a cycle of muscle rigidity and relaxation usually lasting 1 to 3 minutes. Throughout a generalized seizure, the patient exhibits tachycardia, hyperventilation, sweating, and intense salivation.

Generalized seizures last 3 to 5 minutes and are followed by a lengthy period (5 to 30 minutes or more) called a postictal state, in which a patient is unresponsive at first and gradually regains consciousness. The postictal state is over when the patient regains a complete return of his or her normal level of consciousness. In most cases, the patient will gradually begin to recover and awaken but appear dazed, confused, and fatigued. In contrast, an absence (formerly called petit mal) seizure may last for just seconds, after which the patient fully recovers with only a brief lapse of memory of the event.

Seizures lasting more than 5 minutes are likely to progress to **status epilepticus**, which describes seizures that continue every few minutes without the person regaining consciousness or last longer than 30 minutes.

Recurring or prolonged seizures should be considered potentially life-threatening situations in which patients need emergency medical care. If the patient does not regain consciousness or the seizure continues, protect the patient from self-harm, and call for advanced life support (ALS) backup. These patients need advanced airway management and medication to stop the seizure.

Causes of Seizures

Some seizure disorders, such as epilepsy, are congenital. Other types of seizures may be caused by high fevers, structural problems in the brain, or metabolic or chemical problems in the body Table 17-2. In addition, a percentage of the population will experience a seizure for which the cause cannot be determined (idiopathic). Epileptic seizures can usually be controlled with medications. Medications used most often to treat seizures include the following:

- Levetiracetam (Keppra)
- Phenytoin (Dilantin)
- Phenobarbital
- Carbamazepine (Tegretol)
- Valproate (Depakote)
- Topiramate (Topamax)
- Clonazepam (Klonopin)

Patients with epilepsy will often have seizures if they stop taking their medications or if they do not take the prescribed dose on a regular basis.

Seizures may also be caused by abnormalities in the brain, such as a benign or cancerous tumor, an infection (brain abscess, meningitis), or scar tissue from some type of injury. These seizures are said to have a structural cause. Seizures from a metabolic cause may result from abnormal levels of certain blood chemicals (eg, extremely low sodium level), **hypoglycemia** (low blood glucose level), poisons, drug overdoses, or sudden withdrawal from routine heavy alcohol or sedative drug use or even from prescribed medications. Phenytoin, a drug that is used to control seizures, may itself cause seizures if the person takes too much.

Table 17-2 Common Causes of Seizures

Type	Cause
Epileptic	Congenital origin
Structural	Tumor (benign or cancerous) Infection (brain abscess) Scar tissue from injury Head trauma Stroke
Metabolic	Hypoxia Abnormal blood chemical values Hypoglycemia Poisoning Drug overdose Sudden withdrawal from alcohol or medications
Febrile	Sudden high fever

YOU are the Provider — PART 3

Your partner reports the patient's vital signs. The patient tells you she is nauseated and her headache, which is still severe, is located on both sides of her head. She further tells you the last thing she remembers was the sudden, severe headache. When she woke up, she was lying on the floor with a pillow under her head. Her sister tells you she caught the patient before she struck the ground.

Recording Time: 4 Minutes	
Respirations	14 breaths/min; adequate depth
Pulse	100 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	200/112 mm Hg
Oxygen saturation (Spo_2)	96% (on oxygen)

The patient's blood glucose level is assessed and noted to be 97 mg/dL. Her sister hands you the patient's medication list, which includes benazepril, clopidogrel (Plavix), and metformin. The patient says she is noncompliant with her medication regimen.

6. What is your field impression of this patient? Why?
7. On the basis of your last assessment, what is the patient's Glasgow Coma Scale score?

Seizures may also result from sudden high fevers, particularly in children. These **febrile seizures** are frightening for parents but are generally well tolerated by the child. Nevertheless, you must transport a child who has had a febrile seizure because this condition needs to be evaluated in the hospital. It is possible a second seizure may occur. If it does, the patient requires rapid transport to the hospital so possible causes can be identified.

The Importance of Recognizing Seizures

Regardless of the type or the cause of a seizure, it is important for you to recognize when a seizure is occurring or whether one has already occurred. You must also determine whether this episode differs from any previous ones. For example, if the previous seizure occurred on only one side of the body and this seizure occurs over the entire body, an additional or new problem may be involved. In addition to recognizing that seizure activity has occurred and/or that something different may now be occurring, you must also recognize the postictal state and the complications of seizures.

Because most seizures involve a vigorous twitching of the muscles, the muscles use a lot of oxygen. This excessive demand consumes oxygen that is needed for the vital functions of the body. As a result, there is a buildup of acids in the bloodstream, and the patient may turn cyanotic (bluish lips, tongue, and skin) from the lack of oxygen. Often, the seizures themselves prevent the patient from breathing normally, making the problem worse. In a patient with diabetes, the blood glucose level may decrease because of the excessive muscular contraction of a seizure. If your local protocol allows, closely monitor the blood glucose level after a patient with diabetes has a seizure.

Safety Tips

Be aware that a patient may behave violently during the postictal state. Although most patients who have had a seizure pose no threat to EMS personnel, signs of alcohol or other drug abuse should heighten your awareness of the potential for dangerous behavior.

Recognizing seizure activity also means looking at other problems associated with the seizure. For example, the patient may have fallen during the seizure episode and been injured; head injury is the most serious possibility. Some patients may experience **incontinence** during a generalized seizure, meaning that they may have a loss of bowel or bladder control. Therefore, one clue that unresponsive or confused patients may have had a seizure is to find that they were incontinent. Although incontinence can occur with other medical conditions, sudden incontinence is very likely a sign of a seizure. When the patient regains consciousness, he or she is likely to be embarrassed by this temporary loss of control. Minimize the patient's discomfort by covering the patient and assuring him or her that incontinence is part of the loss of control that accompanies a seizure.

Words of Wisdom

The physician's examination of a patient who has had a seizure will be aided greatly by information you provide about the seizure pattern and changes in that pattern. Record all pertinent information about the seizure in terms of duration, areas of body movement, and possible triggering factors. This requires effective interviewing of available witnesses, family members, and/or caregivers.

The Postictal State

Once a seizure has stopped, the patient's muscles relax, becoming almost flaccid, or floppy, and the breathing becomes labored (fast and deep) in an attempt to compensate for the buildup of acids in the bloodstream. By breathing faster and more deeply, the body can balance the acidity in the bloodstream. With normal circulation and liver function, the acids clear away within minutes, and the patient will begin to breathe more normally. The longer and more intense the seizures, the longer it will take for this imbalance to correct itself. Likewise, longer and more severe seizures will result in longer postictal unresponsiveness and confusion. Once the patient regains a normal level of consciousness, the postictal state is over.

Words of Wisdom

Interventions during the postictal state are very important. Patients may be unable to maintain an open airway because of their relaxed and exhausted state; therefore, patient positioning, clearing the airway of secretions, and preventing aspiration are critical steps for achieving the best patient outcomes.

In some situations, the postictal state may be characterized by **hemiparesis**, or weakness on one side of the body, resembling a stroke. Unlike a stroke, however, hypoxic hemiparesis soon resolves. Most commonly, the postictal state is characterized by lethargy and confusion to the point that the patient may be combative. Be prepared for these circumstances in your approach to scene control and in your treatment of the patient's symptoms. If the patient's condition does not improve, consider other possible underlying conditions such as hypoglycemia or infection.

Special Populations

Status epilepticus is harmful at any age, but because of physical changes caused by the normal aging process, geriatric patients are at greater risk of hypoxia, hypotension, and/or cardiac dysrhythmias.

Syncope

Seizures are often mistaken for **syncope** (fainting); however, fainting typically occurs while the patient is standing, whereas seizures may occur in any position. Fainting is not associated with a postictal state.

Altered Mental Status

Aside from stroke and seizures, the most common type of neurologic emergency you will encounter is a patient with altered mental status. Simply put, **altered mental status** means the patient is not thinking clearly or is incapable of being aroused. In some cases, the patient will be unconscious; other times, the patient may be alert but confused **Figure 17-7**. The range of problems is wide and the causes are many, including hypoglycemia, hypoxemia, intoxication, delirium, drug overdose, unrecognized head injury, brain infection, body temperature abnormalities, brain tumors, and overdoses and/or poisonings.

Causes of Altered Mental Status

Hypoglycemia

The clinical picture of patients with altered mental status caused by hypoglycemia is very complex. Because oxygen and glucose are needed for brain function, hypoglycemia can mimic conditions in the brain associated with stroke. In these cases, the patient may have hemiparesis similar to that seen with a stroke. The principal difference is that a patient who has had a stroke may be alert and attempting to communicate normally, whereas a patient with hypoglycemia almost always has an altered or decreased level of consciousness **Figure 17-8**.

Patients with hypoglycemia commonly, but not always, take medications that lower their blood glucose level. Thus, if the patient appears to have signs and symptoms of stroke and altered mental status, report your findings to medical control and treat the patient accordingly. Remember, patients with a decreased level of consciousness should not be given anything by mouth.

Figure 17-7 Some patients with altered mental status may be unconscious; others may be alert but confused.

Figure 17-8 During your assessment of a patient with an altered or decreased level of consciousness, consider the possibility of hypoglycemia.

Patients with hypoglycemia may also experience seizures, and you may arrive at the scene to find a patient in a postictal state: confused and disoriented or unresponsive. The mental status of a patient who has had a typical seizure is likely to improve soon after the seizure stops. In a patient with hypoglycemia, on the other hand, mental status is not likely to improve, even after several minutes. Consider the possibility of hypoglycemia in a patient who has had a seizure, especially if the patient has a history of diabetes.

Likewise, consider hypoglycemia in a patient who has altered mental status after an injury such as a motor vehicle crash, even when there is the possibility of an accompanying head injury. As with any other patient, look for medical identification jewelry or medications that might confirm your suspicions.

Words of Wisdom

Always remember that altered mental status is a symptom, not a disease.

Words of Wisdom

A helpful mnemonic to use when reviewing the possible causes of altered mental status is AEIOU TIPS:

A Alcohol

E Epilepsy, endocrine, electrolytes

I Insulin

O Opiates and other drugs

U Uremia (kidney failure)

T Trauma, temperature

I Infection

P Poisoning, psychogenic causes

S Shock, stroke, seizure, syncope, space-occupying lesion, subarachnoid hemorrhage

Delirium

Delirium is a symptom, not a disease. It presents as a new complaint, rather than a long-standing alteration in behavior. It is a temporary state that often has a physical or mental cause (eg, infection, changes in medications, hypoxia) and may be reversed with proper treatment.

Signs and symptoms include confusion and disorientation, disorganized thoughts, inattention, memory loss, striking changes in personality and affect, hallucinations, delusions, or a decreased level of consciousness. The patient may experience a rapid alteration between mental states such as lethargy and agitation. Symptoms of delirium may mimic intoxication, drug abuse, or severe psychological disorders such as schizophrenia. Delirium is discussed in detail in Chapter 35, *Geriatric Emergencies*.

Other Causes of Altered Mental Status

Other causes of altered mental status include unrecognized head injury and severe alcohol intoxication. Considering other possibilities is important because a patient with altered mental status may be combative and may refuse treatment and transport. Be prepared for difficult patient encounters and follow local protocols for dealing with these situations.

In most cases, a patient who appears intoxicated is just that; however, you must consider other causes as well. A person with chronic alcoholism may have decreased liver function, blood clotting, and immune system abnormalities, causing a predisposition to intracranial bleeding, brain and bloodstream infections, and hypoglycemia.

Psychological disorders and medication complications are also possible causes of altered mental status. A person who appears to have a psychological disorder may also have an underlying medical condition.

Infections, particularly those involving the brain or bloodstream, are another possible cause of altered mental status. Infections in the brain and bloodstream are life threatening and require immediate medical attention. Patients may not demonstrate the typical signs of infection, such as fever, particularly if they are very young or very old or have an impaired immune system. Altered mental status may also be caused by a drug overdose or poisoning.

Patient Assessment

Scene Size-up

Your dispatcher may obtain a lot of information about your patient or very little. In some calls, the description of the patient's signs and symptoms will give you a fairly good idea of what the problem may be (the patient has slurred speech or one-sided paralysis). In other calls, the description may be vague (the patient has a headache). Dispatchers are frequently given information regarding a seizure by the caller. Even if the caller has never seen a seizure before, on the basis of the caller's description of the convulsions, the dispatcher will be able to convey this information to the responding crew.

Special Populations

Children can have altered mental status caused by strokes, seizures, high or low blood glucose levels, infection (eg, meningitis), poisoning, or tumors. Hemorrhagic strokes are usually caused by congenital defects in blood vessels, such as berry aneurysms. Ischemic strokes can be caused by disorders such as sickle cell anemia. Children who have sickle cell anemia are at a particularly high risk for ischemic stroke. Treat stroke and altered mental status in children the same way you do in adults.

Remember, seizures can result from sudden high fevers, particularly in children. Also remember that although febrile seizures are generally well tolerated by children, you must provide rapid transport to the hospital. The possibility of a second seizure makes transport mandatory so that if other problems develop, the child is in the hospital and can receive immediate definitive care.

If you suspect that a patient with altered mental status has hypoglycemia and you are trained and approved to do so, use your glucometer to test the blood glucose level and treat the patient according to local protocols. The patient will require close monitoring, particularly of the airway, en route to the hospital.

Patients with altered mental status may exhibit a wide range of signs and symptoms and behaviors. The most significant difference between a patient with altered mental status and other emergencies is that a patient with altered mental status cannot reliably tell you what is wrong, and there may be more than one cause. Make an early determination whether the call is medical or trauma related because this will help determine the approach of care for the patient.

Do not be distracted by the seriousness of the situation or by frightened family members who want you to rush. Look first for threats to your safety, and follow standard precautions.

Consider the need for spinal immobilization based on dispatch information and your assessment of the scene as you approach the patient. Many calls involving a neurologic emergency require ALS assistance if it is available. Call for additional resources early.

Look for clues to help you determine the nature of the illness. Special considerations for a patient with a suspected neurologic emergency include an evaluation of the patient's environment, assessing for any signs of potential trauma (mechanism of injury), indications of a medical condition, such as diabetic supplies, medical alert tags, and evidence of a seizure. Answers to the following questions may help you determine the nature of the illness: Did anyone witness what happened? When was the last time the patient appeared normal? Is the patient's bed or furniture in disarray? Most patients with a neurologic emergency display a change in their level of consciousness and their ability to interact with their environment and others.

Primary Assessment

Your first priority is to look for and treat any life-threatening conditions. Perform a rapid exam. Patients become unresponsive or have an altered level of consciousness, especially from a neurologic cause, for many reasons. Use a sound approach to assessing the airway, breathing, and circulation to have significant impact on how well these systems respond to your care and treatment.

As you approach the patient, gather information from the scene (is this medical or trauma related?) and note the patient's body position and level of consciousness. This initial impression will help you determine the severity of the situation and help set the pace of your call. A patient lying on the ground in an unnatural position is more likely to have a potentially life-threatening condition than one sitting up in bed. In a call that indicates that a seizure is taking place, you should be able to tell whether the patient is still having a seizure. Unless your arrival time is one minute or less, most seizures will be over by the time you arrive. If the seizure is still occurring, the potentially life-threatening condition of status epilepticus may be present. If the patient is in a postictal state, he or she may be unresponsive or starting to regain awareness of the surroundings. When you treat any patient with altered mental status, first determine the patient's level of consciousness. To assess the patient's level of consciousness, use the AVPU scale.

As with any other situation, focus on the patient's airway and breathing on arrival. Stroke affects how the body functions in many ways. Patients may have difficulty swallowing and are at risk for choking on their own saliva. Evaluate the airway of an unresponsive patient to make sure it is patent and will remain so **Figure 17-9**. If the patient requires assistance maintaining an airway, consider an oropharyngeal or nasopharyngeal airway. Be prepared to provide suction, and position the patient to prevent aspiration. If you determine that the patient cannot protect his or her airway, place the patient in the recovery position to help prevent secretions from entering the airway.

A patient who has had or is having a seizure may have been eating or chewing gum at the time of the seizure, so check for foreign body obstruction. Bystanders may have tried to put objects in the patient's mouth to keep the person from "swallowing the tongue," even though this practice is not advised.

Figure 17-9 Securing and maintaining the airway in a patient who is unconscious is extremely important. Have suction readily available in case the patient vomits.

Assess the patient's breathing. All patients with altered mental status, regardless of the cause, should receive high-flow oxygen. Seizures cause patients to use oxygen quickly, resulting in hypoxia. Again, in the immediate postictal state following a seizure, you should anticipate rapid, deep respirations and an accompanying fast heart rate as a result of the stress of the severe convulsions. However, the respirations and the heart rate should begin to slow to normal rates after several minutes.

It is important to ventilate the patient at the appropriate rate with the proper volume. Deliver each breath during a period of 1 second (just enough to produce visible chest rise) at a rate of 10 to 12 breaths/ min. Do not hyperventilate the patient; doing so may have several negative consequences. Hyperventilation overinflates the lungs, which can impair blood return to the right atrium and cause a decrease in cardiac output. Hyperventilation also increases the risks of regurgitation and aspiration. In addition to the risks already discussed, hyperventilation may cause severe injury in patients with intracerebral bleeding and increased intracranial pressure; it causes cerebral vasoconstriction, which shunts blood (and oxygen) away from the brain. This decrease in cerebral perfusion may cause further injury to the brain.

Circulation should be confirmed as normal or treated as necessary. Your assessment of the patient's circulation should begin with checking the pulse if the patient is unresponsive. If no pulse is found, immediately begin cardiopulmonary resuscitation, and attach an automated external defibrillator. If the patient is responsive, determine whether the pulse is fast or slow, weak or strong. Oxygen administration is helpful for limiting the effects of hypoperfusion of the brain. Evaluate the patient quickly for external bleeding. A patient with a stroke is unlikely to have sustained trauma; it is more likely in a patient who has had a seizure. Consider this possibility and assess appropriately.

YOU are the Provider — PART 4

An engine crew arrives shortly before you load the patient onto the stretcher. Shortly after loading her into the ambulance, you reassess her and note that her condition has deteriorated. One of the engine crew EMTs accompanies you in the back of the ambulance, and you proceed to the hospital.

Recording Time: 10 Minutes	
Level of consciousness	Unconscious and unresponsive
Respirations	6 breaths/min; snoring, irregular, and shallow
Pulse	60 beats/min; bounding
Skin	Pink, warm, and dry
Blood pressure	198/110 mm Hg
Spo_2	94% (on oxygen)

8. What should be your most immediate action?
9. What additional treatment does this patient require?

Establish your priorities of care based on your assessment of the patient's level of consciousness and the ABCs. How the patient is presenting will guide you as to whether you stay at the scene for further assessment or proceed to immediate transport. If you suspect the patient is experiencing a stroke, provide rapid transport to an appropriate facility. Prompt treatment is a critical action to minimize the disability caused by an ischemic stroke.

History Taking

If the patient is unresponsive, you will need to gather any history of the present illness from family or bystanders. If no one is around, quickly look for explanations for the altered mental status (eg, signs of trauma, medical alert tags, track marks resulting from intravenous drug injections, environmental clues such as empty alcohol or medication containers).

To determine the chief complaint in a responsive patient, begin by asking the patient what happened. Look for signs and symptoms that may indicate a cause for the patient's altered mental status, such as a stroke (eg, hemiparalysis or one-sided weakness), or if there is any evidence of a seizure (eg, incontinence, bitten tongue). Evaluate the patient's speech. Is the patient making sense? Is his or her speech slurred?

If you know that the patient has had a seizure and is now in a postictal state, you will not be able to obtain a history from the patient. Look for any obvious trauma or explanations as to why the patient may have had a seizure.

If the patient is responsive and breathing, obtain a SAMPLE history. Also speak with family or friends who may be able to explain the events leading up to the altered mental status **Figure 17-10**, remembering that time is critically important in a neurologic emergency. Make a special effort to determine the exact time that the patient last appeared to be healthy. In the case of a patient having a stroke, this information will help physicians decide whether it is safe to begin certain treatments that must be given within the first hours after the onset of stroke symptoms. You may be the only person with the opportunity to speak with bystanders to obtain this critical information. Many times, you will be able to find out only that the patient was healthy when he or she went to sleep the night before. In those cases, the time the patient was last seen to be healthy was at bedtime, not when the patient awoke with symptoms. Collect or list all medications the patient has taken. When possible, determine allergies and the patient's last oral intake.

Figure 17-10 Speak with family members or bystanders who may know what happened. They may be able to tell you when the patient last appeared healthy.

Although a patient who has had a stroke may appear to be unconscious and unable to speak, the patient may still be able to hear and understand what is taking place. Therefore, avoid making unnecessary or inappropriate remarks. Communicate with the patient by looking for indications that the patient may understand you, such as a glance, gaze, motion or pressure of the hand, effort to speak, or head nod. Reassure your patient that you understand that communication between the two of you may be difficult at this point but that you will provide him or her with continuous information as to what you and the other team members are doing. Establish effective communication to help you calm the patient and lessen the fear that accompanies an inability to communicate **Figure 17-11**. Keep in mind that the patient has just experienced a potentially life-threatening event and that anxiety, frustration, and embarrassment may inhibit communication with you.

With patients who have had a seizure, your SAMPLE history should reveal if the patient has a history of seizures. If so, it is important to find out how the patient's seizures typically occur and whether this episode differs in some way from previous episodes. Also, ask what medications the patient has been taking, and note medications used to treat a seizure disorder. You might find that the patient ran out of medication or stopped taking the medication for a time. A patient who has a history of seizures *and* diabetes may use up all the glucose in the body to fuel the seizure.

Figure 17-11 Make a special effort to establish communication with a patient who may have had a stroke, seizure, or other neurologic emergency that impairs the patient's ability to communicate. Look for indications that the patient understands you, such as a glance, gaze, squeeze of the hand, efforts to speak, or nodding of the head.

If a patient with no history of seizures suddenly has a seizure, a serious condition should be suspected, such as a brain tumor, intracranial bleeding, or serious infection. This part of the patient assessment process is the time to determine whether the patient takes medications that lower blood glucose, such as insulin or oral hypoglycemic agents. In other situations, you may want to inquire about illicit drug use or exposure to poisons.

Words of Wisdom

When assessing a patient who might have had a stroke, it is important to pinpoint when the symptoms first started. Typically, there is a 3-hour window in which outcomes are greatly improved if the patient receives treatment. During transport, notify the receiving hospital of when the patient's symptoms first began. When appropriate, this will allow hospitals to activate stroke alerts and be ready to immediately start treating these patients as soon as they enter the ED. If the receiving hospital's CT scanner is not available, it may be better to divert to another facility with a functional CT scanner. Follow your local protocols.

Safety Tips

Be aware of the potential for a patient to become violent during a neurologic emergency. When alcohol or drugs are part of a patient's SAMPLE history, the potential for this type of behavior increases.

Secondary Assessment

Your assessment of the patient should continue with a secondary assessment of the entire body, paying particular attention to the system involved. If you suspect your patient is having a stroke, then you should direct particular attention to the neurologic assessment. As always, your secondary assessment should include a complete set of vital signs using the monitoring devices you have available.

Patients with significant intracranial bleeding (hemorrhagic stroke) may have a great deal of pressure in the skull that is compressing the brain, thus slowing the pulse and causing respirations to be erratic. Blood pressure is usually high to compensate for poor perfusion in the brain. Unequal pupil size and reactivity indicate significant bleeding and pressure on the brain. If the patient has altered mental status (regardless of the cause), check the blood glucose level if your local protocol allows. Most commonly, this is done using a portable blood glucose monitor (glucometer), similar to the one your patient may use at home. The portable blood glucose monitor measures the glucose level in whole blood, using capillary or venous samples. Chapter 9, *Patient Assessment,* discusses the use of a glucometer in more detail.

Evaluating vital signs is impossible during most active seizures, and this should not be your priority. In most cases, the vital signs of a patient in a postictal state will be close to normal limits. Obtain pulse rate, rhythm, and quality; respiratory rate, rhythm, and quality; blood pressure; skin color, temperature, and condition; and pupil size and reactivity.

It is recommended that the first blood pressure reading be taken manually, with a sphygmomanometer (blood pressure cuff) and a stethoscope. You may also use noninvasive methods to monitor blood pressure.

Stroke Assessment

A stroke assessment tool should be part of your secondary assessment. Many EMS units use stroke scales to rapidly identify stroke in the field. Stroke scales evaluate the face, arms, and speech. If the patient does not have a normal response to these evaluations, you should strongly suspect a stroke. Rapid transport to a designated stroke center is indicated.

The Cincinnati Prehospital Stroke Scale **Table 17-3** and the Los Angeles Prehospital Stroke Screen **Table 17-4** are commonly used.

To test speech, ask the patient to repeat a simple sentence such as "The sky is blue in Cincinnati." If the patient does this correctly, you know the patient understands and can produce speech. If the patient cannot repeat the phrase, the problem may be with either understanding speech or producing it.

To test facial movement, ask the patient to smile, showing his or her teeth (or gums if the patient does not have teeth). Watch whether both sides of the face around the mouth move equally. If only one side is moving well, you know something is wrong with the control of the muscles on the other side.

Table 17-3 Cincinnati Prehospital Stroke Scale

Test	Normal Response	Abnormal Response
Facial droop (Ask patient to show teeth or smile.)	Both sides of face move equally well.	One side of face does not move as well as other.
Arm drift (Ask patient to close eyes and hold both arms out with palms up.)	Both arms move the same, or neither arm moves. (The latter response requires a retest because it may indicate the patient did not understand the instructions.)	One arm does not move, or one arm drifts down compared with the other side.
Speech (Ask patient to say, "The sky is blue in Cincinnati.")	Patient uses correct words with no slurring.	Patient slurs words, uses inappropriate words, or is unable to speak.

YOU are the Provider PART 5

You continue treatment en route to the hospital. You reassess the patient and note that her condition has deteriorated further. Her pupils are unequal, and she exhibits decorticate posturing (flexion posturing to painful stimulus). You call in your report to the receiving facility, with an estimated time of arrival of 6 minutes.

Recording Time: 17 Minutes	
Level of consciousness	Unconscious and unresponsive
Respirations	6 breaths/min; irregular and shallow
Pulse	64 beats/min; bounding
Skin	Pink, warm, and dry
Blood pressure	194/104 mm Hg
Spo_2	98% (on oxygen)

You arrive at the hospital and transfer patient care to the emergency department (ED) staff. After further treatment in the ED, a computed tomographic scan of the patient's brain was performed and revealed massive intracerebral hemorrhage. Despite aggressive treatment in the intensive care unit, the patient died the next day.

10. What do unequal pupils indicate?

11. On the basis of your last assessment, what is the patient's Glasgow Coma Scale score?

Table 17-4 Los Angeles Prehospital Stroke Screen

Criterion	Yes	Unknown	No
1. Age >45 y	☐	☐	☐
2. History of seizures or epilepsy absent	☐	☐	☐
3. Symptoms <24 h	☐	☐	☐
4. At baseline, patient is not wheelchair-bound or bedridden	☐	☐	☐
5. Blood glucose between 60 and 400 mg/dL	☐	☐	☐
6. Obvious asymmetry (right versus left) in any of the following three exam categories (must be unilateral):			
	Equal	**Right Weak**	**Left Weak**
Facial smile/grimace	☐	☐ Droop	☐ Droop
Grip	☐	☐ Weak grip ☐ No grip	☐ Weak grip ☐ No grip
Arm strength	☐	☐ Drifts down ☐ Falls rapidly	☐ Drifts down ☐ Falls rapidly

Interpretation: If all criteria 1–6 are marked yes, the probability of a stroke is 97%.

To test arm movement, ask the patient to hold both arms in front of his or her body, palms up toward the sky, with eyes closed and without moving. During the next 10 seconds, watch the patient's hands. If you see one side drift down toward the ground, you know that side is affected. If both arms stay up and do not move, you know both sides of the brain are functioning. If both arms fall to the ground, you have not really learned anything. Perhaps the patient did not understand your instructions. Perform the arm test again, but this time you move the patient's arms into position yourself.

In addition, a newer scoring system called the 3-Item Stroke Severity Scale, sometimes called the LAG scale, looks specifically at three items—***l***evel of consciousness, ***a***rm drift (motor function), and *g*aze. This system may be used to assess the likelihood your patient is having a stroke. Each item is scored from 0 to 2, with zero (0) being "normal" and two (2) being a severe abnormality Table 17-5. Data show that a score of 5 or 6 indicates a high probability the patient is having a stroke. Become familiar with what is used in your local protocol.

The FAST mnemonic can also be used in assessing for a stroke:

- **F**acial droop (ask the patient to smile; look for a droop on either side of the patient's face)
- **A**rm drift (ask the patient to close his or her eyes and hold arms out with palms up, then watch for one to drift down)
- **S**peech (ask the patient to repeat a simple phrase, then listen for slurred speech)
- **T**ime (note the time the patient was last seen acting normally)

Calculate the GCS score Table 17-6 for all patients with altered mental status (stroke, TIA, seizure, of unknown cause).

Table 17-5 3-Item Stroke Severity Scale (LAG)

Item	Criteria	Score
Level of consciousness	Normal Mild dysfunction Severe dysfunction (unconscious)	0 1 2
Arm drift (hemiparesis)	Normal function Mild dysfunction Severe dysfunction (flaccid)	0 1 2
Gaze	Normal gaze (follows pen/finger to left and right sides) Mild dysfunction Severe dysfunction (fixed gaze)	0 1 2
Score (total)		**>4 indicates stroke is likely**

Table 17-6 Glasgow Coma Scale (GCS)

Eye Opening		Best Verbal Response		Best Motor Response	
Spontaneous	4	Oriented conversation	5	Obeys commands	6
In response to speech	3	Confused conversation	4	Localizes pain	5
In response to pain	2	Inappropriate words	3	Withdraws to pain	4
None	1	Incomprehensible sounds	2	Abnormal flexion	3
		None	1	Abnormal extension	2
				None	1

Score: 13–15 may indicate mild dysfunction, although 15 is the score a person without neurologic disabilities would receive.
Score: 9–12 may indicate moderate dysfunction.
Score: 8 or less is indicative of severe dysfunction.

Reassessment

The reassessment should focus on reassessing the ABCs, vital signs, and interventions provided so far. Patients who have had a stroke may have airway loss or stop breathing without warning. Multiple interventions may be necessary. The effectiveness of airway adjuncts, positive-pressure ventilations, and other treatments can be determined only with immediate and continuous observation after providing the intervention. If an intervention is not working, try something else.

You have already established baseline vital signs during your assessment, as well as a GCS score. Now is the time to compare that baseline information with updated information. Any changes may indicate if treatments are effective. Watch carefully for changes in pulse, blood pressure, respirations, and GCS scores.

Words of Wisdom

The following is key information to document for a patient who may have had a stroke:

- Time of onset of the signs and symptoms
- Score on the Glasgow Coma Scale
- Results of a stroke assessment tool (Cincinnati, Los Angeles, LAG, or FAST)
- Changes noted on reassessment

Establishing the time of onset is critical information because it helps determine whether the patient is a candidate for treatment with blood clot-dissolving drugs.

Notify the receiving facility of your patient's chief complaint and your assessment findings. Your local protocol will tell you if the designated stroke centers in your call area want you to call in a "stroke alert" for patients you have assessed and found to be having a stroke. This will alert the stroke team members at the hospital and give them time to assemble their resources to be ready to treat the patient without delay. Report the time the patient last appeared to be healthy, the findings of your neurologic examination, and the time you anticipate arriving at the hospital.

A key piece of information to document is the time of onset of the patient's signs and symptoms. If the diagnosis is an ischemic stroke, time of onset of the signs and symptoms is critical information in determining whether the patient is a candidate for treatment with blood clot-dissolving drugs. It is also important to document your findings from your stroke scale and the score of the GCS, along with any changes you found in your reassessment. Document airway management and interventions performed, including the position in which the patient was placed.

For patients who have had a seizure, give a description of the seizure activity if known. Include bystanders' comments if they witnessed the seizure. Document the onset and duration of the seizure. Did the patient mention noticing an aura? Record any evidence of trauma and interventions performed. Document whether this is the patient's first seizure or whether the patient has a history of seizures. If the patient has a history of seizure activity, determine how often the seizures occur, and if there is any history of status epilepticus. Document your interventions and record the time the intervention was performed, the patient's response to the intervention, and the findings of continued reassessments.

Emergency Medical Care

A patient with stroke, seizure, hypoglycemia, or hypoxia typically shows relatively easily identifiable signs or symptoms, and treatment options are readily available. With other neurologic emergencies, the cause of the patient's symptoms will not always be obvious, and more time and diagnostic testing may be needed at the hospital to determine the cause. This may make it difficult for you to provide definitive treatment in the field. Most of your interventions will be based on your assessment findings. For example, if the blood glucose level is low, you may give oral glucose according to your local protocol; if a patient is unresponsive, you may need to position him or her in the recovery position to protect the airway. Remember, never give anything orally to a patient with altered mental status or to a patient who is unable to swallow normally, as this may result in aspiration. Your best treatment in these situations is to perform a thorough assessment and maintain the ABCs.

In most patients with a suspected stroke, the physicians in the emergency department (ED) will need to determine whether there is bleeding in the brain. If there is no bleeding, the patient may be a candidate for blood clot-dissolving medication that may help brain cells survive. However, if bleeding is present this medication will increase the bleeding, with disastrous consequences. The only reliable way to tell whether there is bleeding in the brain is with a special type of imaging test called a computed tomography (CT) scan of the head. Blood is usually easy to see on the CT scan.

Some EMS systems designate specific hospitals, typically accredited stroke centers, to receive patients who may be having a stroke. These institutions have CT technicians, radiologists, and neurosurgeons on duty 24 hours a day. Most hospitals that are not accredited stroke centers have only one CT scanner and may not have CT technicians available 24 hours a day. It is important that you recognize the signs and symptoms of a stroke and notify the hospital staff as early as possible if you have a "stroke alert" patient. If the ED staff knows you are transporting a possible stroke patient, they can call in the technician if needed or may be able to free up the CT scanner so it is immediately available. Keep in mind that most treatments for stroke must be started as soon as possible after the onset of the event **Table 17-7**. Only a limited number of treatments are available that are effective if started more than 3 hours after the stroke begins. Even if 3 hours have passed, however, prompt action on your part is essential. It is very important to notify the hospital regarding the last time the patient was known to be well (without their current signs and symptoms of stroke).

Table 17-7 Tips on Patient Care

- Patients who experience a transient ischemic attack (TIA) may exhibit most of the same signs and symptoms as patients who are having a stroke. These signs and symptoms may last from minutes up to 24 hours. Therefore, the signs of stroke that you note on arrival may gradually disappear. Patients who appear to have had a TIA should be transported for further evaluation.
- Place the patient's affected or paralyzed extremity in a secure and safe position during patient movement and transport.
- Some patients who have had a stroke may be unable to communicate, but they can often understand what is being said around them. Be aware of this possibility.
- New therapies for stroke are available but must be used as soon as possible after the start of symptoms. Minimize time on the scene, and notify the receiving hospital as soon as possible.

In most situations, patients who have had a seizure require definitive evaluation and treatment in the hospital. Unless the patient has a well-established history of seizures and is completely alert and oriented, supplemental oxygen is strongly advised, both to provide extra oxygen and to prevent the possibility of a recurrent seizure.

Words of Wisdom

Use the same process as with all other patients in determining whether an adequate airway is present and whether the patient is able to sufficiently maintain that airway on his or her own. Do not assume that a patient who has had a seizure is in need of an airway adjunct.

Seizures are usually short-lived. Most seizures will not require a significant amount of intervention on your part because the seizure will have ended by the time you arrive. For patients who are having a seizure, protect them from harm, maintain a clear airway by suctioning as necessary, and administer oxygen as quickly as possible. If head or neck trauma is suspected, provide spinal immobilization. With recurrent seizures, protect the patient from further injury, and manage the airway once the seizure ceases.

For patients who continue to have a seizure, as in status epilepticus, suction the airway, provide positive-pressure ventilations (bag-valve mask [BVM] ventilations), and transport quickly to the hospital. If you have the option to rendezvous with ALS, you should do so. ALS providers have medications that can stop a prolonged seizure.

In all cases, show patience and tolerance because many of the patients are likely to be confused and occasionally frightened. Many patients who experience seizures are frustrated with their condition and may refuse transport. Kindness and professional behavior are required to help convince the patient that transport is necessary for definitive care.

Headache

As discussed earlier, most headaches are harmless and do not require emergency medical care. However, be concerned if the patient complains of a sudden-onset, severe headache or a sudden headache that has associated symptoms. Headaches with fever, seizures or altered mental status, or following head trauma are potentially life threatening. Complete a thorough patient assessment, and transport the patient to the hospital.

Migraine

Treatment of a migraine headache is supportive; however, always assess the patient for other signs and symptoms that might indicate a more serious condition. Applying high-flow oxygen, if tolerated, may help ease the patient's condition. When possible, provide a darkened and quiet environment because patients with migraines are sensitive to light and sound. Do not use lights and siren during transport.

Stroke

Management of a patient having a stroke in the field is based on supporting the ABCs and providing rapid transport to a stroke center. Depending on the location of the stroke in the brain and the signs and symptoms, the patient may require manual airway positioning. Patients may have difficulty swallowing and controlling their own secretions; therefore, use suction as needed. Provide oxygen to maintain a Spo_2 level of at least 94%, and monitor the patient's oxygen saturation with a pulse oximeter. Routine use of oxygen therapy in a stroke patient is not recommended unless the patient is experiencing respiratory distress or is showing signs of hypoxia. If the patient's extremities are paralyzed, they will require protection from injury because the patient may not be able to feel his or her extremities or move them out of harm's way as you prepare and move the patient for transport. Continuously talk to the patient and inform him or her of what is going on. Many patients who are having or who have had a stroke understand what is going on, but they may not be able to communicate with you. The patient may not be able to speak, or when he or she does, inappropriate words may come out. Regardless, the patient will be scared. Reassure the patient, and provide emotional support throughout the call.

Special Populations

The brain gradually deteriorates and shrinks as a part of the normal aging process. These processes increase the risk of brain injury from minor forces because the brain can more readily impact the inside of the skull as a result of the increased space and because the veins that connect the brain to the dura are stretched. A reduced brain mass may also reduce the patient's mental status and capacity. A smaller brain can impair memory function. A geriatric patient with lapses in short-term memory will often ask the same or similar questions repeatedly.

When you are called to care for a geriatric patient with altered mental status, consider the possibility of a stroke or transient ischemic attack (TIA). At the scene of a motor vehicle crash involving an older driver, consider a stroke or TIA as a possible cause in the crash. Be alert for altered mental status and unusual pupil responses (eg, constricted pupils in dim light, unequal pupils).

Take special note of complaints of a headache. Although geriatric patients get tension headaches, they are far less common in the older population. Consider any headache as potentially serious.

As with the general population, older people can experience seizures. Remember, seizures are not necessarily caused by epilepsy. Consider and assess for the possibility of a drug overdose, stroke, head injury, or central nervous system infection. Status epilepticus in a geriatric patient increases the risk of hypoxia, irregular heart rhythm, hypotension, elevated body temperature, low blood glucose level, and, if the patient vomits, aspiration.

Remember, geriatric patients are at a higher risk for central nervous system illnesses and injuries, including brain injury, TIA, stroke, and seizures. Do not be surprised to find a serious head injury from what you might consider a simple bump on the head.

Thrombolytic therapy (blood clot-dissolving drugs) and methods to mechanically remove the blood clot may reverse stroke symptoms and even stop the stroke if given within 3 hours (drugs) or 6 hours (mechanical methods) of the onset of symptoms. These therapies may not work for all patients, and they cannot be given to patients with bleeding-type (hemorrhagic) strokes. Comprehensive stroke centers are able to offer advanced stroke care and in some cases may be able to provide thrombolytic therapy even after the 3- to 6-hour window. Because hospital personnel will ultimately make these treatment decisions, you should proceed under the assumption that the affected area of the brain may be saved. The sooner the treatment is begun, the better the prognosis for the patient.

Spend as little time at the scene as possible. Remember, stroke is an emergency and "time is brain." Treatment may be available for the patient at the hospital, and rapid transport is essential to maximize the possibility of recovery. If you have a choice of hospitals, transport the patient to one that is a designated stroke center.

Seizure

Most patients who have had a seizure will be in a postictal state on your arrival. For those patients who are still having a seizure, continue to assess and treat the ABCs. It may be necessary to maintain the patient's airway with manual airway positioning. Use suction to clear the airway of any excessive secretions or vomitus. Oxygen is rapidly consumed by the body during seizure activity, so you should monitor the patient's oxygen saturation level with a pulse oximeter and apply high-flow oxygen. Administer oxygen even if you are unable to get an accurate pulse oximetry reading because of the patient's seizure activity, shaking, or tremors. Provide emotional support.

It is difficult to safely prepare a patient for transport when he or she is having a seizure. Assess the patient for trauma and immobilize the spine if indicated. Protect the patient from his or her surroundings. Never attempt to restrain a patient having a seizure. Injury could result from tonic-clonic movement. Use soft materials for padding, and move any objects out of the way that may harm your patient.

Not every patient who has had a seizure wants to be transported, but it is usually in the best interest of the patient to be evaluated by a physician in the ED after a seizure. Your goal is to encourage the patient to be seen by a physician. Should the patient refuse transport, be prepared to discuss the situation with the hospital staff on the radio before releasing the patient. Ask yourself the following questions if a patient in a postictal state refuses transport:

- Is the patient awake and completely oriented after the seizure (GCS score of 15)?
- Does your assessment reveal no indication of trauma or complications from the seizure?
- Has the patient ever had a seizure before?
- Was this seizure the "usual" seizure in every way (length, activity, recovery)?
- Is the patient currently being treated with medications and receiving regular evaluations by a physician?

If the answer to all of these questions is "yes," you can consider agreeing to a patient's refusal for transport if the patient can be released to a responsible person and monitored. If the patient responds "no" to any questions, strongly encourage the patient to be transported and evaluated. Follow your local protocols for patients who refuse care and transport.

Altered Mental Status

The signs and symptoms of altered mental status can vary widely, from simple confusion to coma. No matter what the cause, consider altered mental status to be an emergency that requires immediate attention, even when it appears that it may be caused by alcohol intoxication or minor head trauma. Determine the cause (mechanism of injury versus nature of illness) and provide spinal immobilization as indicated, airway and ventilation support, and transport to the appropriate facility.

YOU are the Provider — SUMMARY

1. On the basis of the dispatch information, what type of seizure is the patient most likely experiencing?

Given the patient's age (58 years), loss of consciousness, and the fact that the convulsions affect her extremities and torso, the patient is most likely experiencing a generalized seizure.

2. What are some common causes of seizures in this patient's age group?

Seizures in adults are typically caused by one of three underlying problems: epilepsy, structural brain problems (eg, brain tumors and abscesses, head trauma, and stroke), or metabolic derangements (eg, cerebral hypoxia, hypoglycemia, drug overdose, poisoning, and alcohol withdrawal). Febrile seizures are rare in adults.

3. What additional questions should you ask the patient's sister?

The sister has already stated the patient does not have a history of seizures. She also said she caught her sister as she fell, so the patient did not strike her head. Important questions that need to be answered include: What was the patient doing and what position was she in when the seizure began? Was she sitting or standing? Did the patient describe experiencing an aura? Although neither the patient nor her sister mentioned an aura, this does not rule out a seizure.

How long did the seizure last? Was the patient unconscious following the seizure? If so, how long was she unconscious? Does the patient have a history of recent head trauma?

4. What prehospital assessments can you perform to determine the possible cause of the patient's seizure?

In most cases, you will not be able to determine the underlying cause of the patient's seizure in the prehospital setting.

However, there are a few assessments you can perform and observations you can make that may increase your index of suspicion. Assess the patient's blood glucose level, if trained to do so, to rule out hypoglycemia as the cause of her seizure. If the patient is conscious and able to follow commands, test the patient by using a stroke scale, such as the Cincinnati Prehospital Stroke Scale. You should also assess and closely monitor the patient's vital signs and assess her neurologic status using the Glasgow Coma Scale (GCS).

5. Other than oxygen, what additional treatment is indicated at this point?

Unless the patient was injured during the seizure or you have identified an underlying cause of her seizure that can be treated in the prehospital setting (eg, hypoglycemia), additional treatment is mainly supportive. Maintaining a patent airway and ensuring adequate oxygenation and ventilation are your highest priorities. Provide a calm, quiet environment; reassure and reorient the patient as needed; avoid any loud or bright stimulus, which may cause another seizure; and safely transport her to the hospital. Continuously monitor the patient's ABCs, level of consciousness, and vital signs.

6. What is your field impression of this patient? Why?

From the sister's description, it is likely that the patient experienced a seizure. Her present signs and symptoms (confusion; sudden, severe headache; nausea) and medical history (poorly controlled hypertension) should make you suspicious that she is experiencing a hemorrhagic stroke, which likely caused the seizure. Signs of increased intracranial pressure (ICP) include changes in level of consciousness, nausea and vomiting, seizures, and high blood pressure, among others; your patient is experiencing all of these signs and symptoms.

7. On the basis of your field impression, the patient should be monitored for which additional signs and symptoms?

Your patient's present condition suggests that a cerebral artery is leaking and blood is slowly accumulating in her brain tissue, which will increase the ICP. As the ICP increases, the patient's level of consciousness will deteriorate; therefore, the level of consciousness is the single most important assessment parameter to monitor. Because of the cerebral ischemia caused by the increased ICP, the patient may experience another seizure. As the ICP increases further, the blood pressure often increases and the heart rate commonly decreases. Pressure on the brain stem may cause irregular and ineffective breathing; therefore, assisted ventilation may be necessary. It is very important to continuously monitor your patient's condition and be prepared to intervene if her condition deteriorates.

8. What should be your most immediate action?

Airway, airway, airway! Snoring respirations indicate partial obstruction of the airway by the tongue. Performing the head tilt–chin lift maneuver is the quickest way to correct the problem. The patient is now unconscious and unresponsive; insert an airway adjunct (eg, oral or nasal airway) to help maintain airway patency. Patients with increased ICP often vomit; remain alert to this possibility and have suction readily available. Regardless of the situation, you must ensure the patient's airway remains patent at all times. No airway, no patient—it's that simple!

9. What additional treatment does this patient require?

After establishing a patent airway, your next priority is to assist the patient's breathing. A slow (6 breaths/ min), irregular breathing pattern will not support adequate minute volume; therefore, deliver positive-pressure ventilation, which can be provided with a pocket face mask and one-way valve or a bag-valve mask (BVM). Be sure to attach 100% oxygen to the ventilation device you will be using.

10. What do unequal pupils indicate?

In the context of a traumatic brain injury or hemorrhagic stroke, unequal pupil size is an ominous sign. It indicates significantly increased ICP and compression of one of the oculomotor nerves (the nerves that control the pupillary response). The affected pupil is often fully dilated (blown) and does not constrict when a light source is shone into it.

11. On the basis of your last assessment, what is the patient's Glasgow Coma Scale score?

The GCS assesses three parameters: eye opening, verbal response, and motor response. Your last assessment revealed that the patient was unconscious and unresponsive (she did not open her eyes and was unresponsive to all stimuli) and was exhibiting decorticate (abnormal flexion) posturing. Therefore, she would receive a GCS score of 5, based on the following values (the numeric value for each component is in bold):

Eye opening:

Spontaneous: 4
Responsive to speech: 3
Responsive to pain: 2
None: 1

Best verbal response:

Oriented conversation: 5
Confused conversation: 4
Inappropriate words: 3
Incomprehensible sounds: 2
None: 1

Best motor response:

Obeys commands: 6
Localizes pain: 5
Withdraws from pain: 4
Abnormal flexion: 3
Abnormal extension: 2
None: 1

EMS Patient Care Report (PCR)

Date: 3-16-17	**Incident No.:** 140109	**Nature of Call:** Seizure		**Location:** 106 Scottie Drive	
Dispatched: 1823	**En Route:** 1823	**At Scene:** 1827	**Transport:** 1839	**At Hospital:** 1852	**In Service:** 1909

Patient Information

Age: 58 **Sex:** F **Weight (in kg [lb]):** 77 kg (170 lb)	**Allergies:** Penicillin, codeine **Medications:** Benazepril, Plavix, metformin **Past Medical History:** Hypertension, heart disease, type 2 diabetes mellitus **Chief Complaint:** Severe headache and nausea

Vital Signs

Narrative

Dispatched for a 58-year-old woman experiencing a seizure. On arrival at the scene, found the patient lying supine on her living room floor with a pillow under her head. She was conscious but confused and reported nausea and the "worst headache of my life." The patient's sister witnessed the episode and stated her sister suddenly grabbed both sides of her head and then began "shaking all over." There was no trauma involved; the patient's sister states she caught her before she struck the ground. Per the sister, the patient had never experienced a seizure before today. Past medical history significant for hypertension, heart disease, and type 2 diabetes mellitus. Medications listed above; patient admits to being noncompliant with her prescribed medications. Administered oxygen and obtained vital signs. Blood glucose level was assessed and noted to be 97 mg/dL. Further assessment did not reveal any gross evidence of a seizure (eg, tongue-biting, urinary incontinence). Engine 60 arrived at the scene to provide assistance. As the patient was being loaded into the ambulance, she became unconscious and unresponsive. Reassessment revealed that her respirations were slow, irregular, and shallow. Inserted an oral airway and began assisting the patient's ventilations with a BVM and high-flow oxygen. Requested assistance from engine 60 EMT and began transport to the hospital. Continued to assist the patient's ventilations en route and reassessed her vital signs. Shortly before arriving at the hospital, reassessed the patient and noted her pupils were unequal and she began exhibiting decorticate posturing. Assigned a Glasgow Coma Scale score of 5. Quickly transferred patient to the ED staff and gave verbal report to attending physician.**End of report**

Prep Kit

▶ Ready for Review

- The cerebrum, the largest part of the brain, is divided into right and left cerebral hemispheres, each controlling the opposite side of the body.
- Different areas of the brain control different functions. The front part of the cerebrum controls emotion and thought; the middle part controls touch and movement; and the back part of the cerebrum is involved with vision. In most people, speech is controlled on the left side of the brain, near the middle of the cerebrum.
- Many different disorders can cause brain or other neurologic symptoms. As a general rule, if the problem is primarily in the brain, only part of the brain will be affected. If the problem is in the heart or lungs, the whole brain will be affected.
- Stroke is a common brain disorder and is a leading cause of death. The most effective treatment is time dependent. Seizures and altered mental status are also common brain disorders. You must learn to recognize the signs and symptoms of each condition.
- Other causes of neurologic dysfunction include coma, infections, and tumors.
- Strokes occur when part of the blood flow to the brain is suddenly cut off; within minutes, brain cells begin to die.
- Signs and symptoms of stroke include receptive and/or expressive aphasia, slurred speech, muscle weakness or numbness on one side of the body, facial droop, and sometimes high blood pressure.
- Always perform at least three neurologic tests on patients you suspect of having a stroke: testing speech, facial movement, and arm movement.
- In a transient ischemic attack (TIA), normal body processes break up the blood clot, restoring blood flow and ending symptoms in less than 24 hours. However, patients experiencing a TIA are at a higher risk for a repeat episode or a more serious stroke.
- Because current treatments for stroke must be administered within 3 hours of the onset of symptoms to be most effective, provide prompt transport.
- Always notify the hospital as soon as possible that you are bringing in a patient with a possible stroke, so staff can prepare to test and treat the patient without delay.
- Generalized seizures are characterized by unconsciousness and generalized twitching of all or part of the body.
- Most seizures last 3 to 5 minutes and are followed by a postictal state in which the patient may be unresponsive and have labored breathing or hemiparesis. The patient may have a loss of bladder or bowel control.
- Recognize the signs and symptoms of seizures so you can provide the ED staff with information as you transport the patient.
- Altered mental status is a common neurologic disorder that you will encounter as an EMT. Signs and symptoms vary widely, as do the causes for this condition.
- Among the most common causes of altered mental status are hypoglycemia, intoxication, drug overdose, and poisoning.
- Do not always assume intoxication when you assess a patient with an altered mental status; hypoglycemia is just as likely a cause. Prompt transport with close monitoring of vital signs en route is indicated.

â–¶ Vital Vocabulary

altered mental status Any deviation from alert and oriented to person, place, time, and event, or any deviation from a patient's normal baseline mental status.

aneurysm A swelling or enlargement of the wall of a blood vessel that results from weakening of the vessel wall.

aphasia The inability to understand and/or produce speech.

atherosclerosis A disorder in which calcium and cholesterol build up inside the walls of the blood vessels, forming plaque, potentially leading to a partial or complete blockage of blood flow.

aura A sensation experienced before a seizure; serves as a warning sign that a seizure is about to occur.

cerebrovascular accident (CVA) An interruption of blood flow to the brain that results in the loss of brain function; also called a stroke.

coma A state of profound unconsciousness from which the patient cannot be roused.

delirium A temporary change in mental status characterized by disorganized thoughts, inattention, memory loss, disorientation, striking changes in personality and affect, hallucinations, delusions, or a decreased level of consciousness.

dysarthria Slurred speech.

embolus A blood clot or other substance in the circulatory system that travels to a blood vessel where it causes a blockage.

epilepsy A disorder in which abnormal electrical discharges occur in the brain, causing seizure and possible loss of consciousness.

febrile seizures Seizures that result from sudden high fevers; most often seen in children.

generalized (tonic-clonic) seizure A seizure characterized by severe twitching of all of the body's muscles that may last several minutes or more; formerly known as a grand mal seizure.

hemiparesis Weakness on one side of the body.

hemorrhagic stroke A type of stroke that occurs as a result of bleeding inside the brain.

hypoglycemia An abnormally low blood glucose level.

incontinence Loss of bowel and/or bladder control; may be the result of a generalized seizure.

ischemia A lack of oxygen that deprives tissues of necessary nutrients, resulting from partial or complete blockage of blood flow; potentially reversible because permanent injury has not yet occurred.

ischemic stroke A type of stroke that occurs when blood flow to a particular part of the brain is cut off by a blockage (eg, a blood clot) inside a blood vessel.

partial (focal) seizure A seizure affecting a limited portion of the brain.

postictal state The period following a seizure that lasts 5 to 30 minutes; characterized by labored respirations and some degree of altered mental status.

seizure A neurologic episode caused by a surge of electrical activity in the brain; can be a convulsion characterized by generalized, uncoordinated muscular activity, and can be associated with loss of consciousness.

status epilepticus A condition in which seizures recur every few minutes or last longer than 30 minutes.

stroke An interruption of blood flow to the brain that results in the loss of brain function; also called a cerebrovascular accident (CVA).

syncope A fainting spell or transient loss of consciousness.

thrombosis A blood clot, either in the arterial or venous system. When the clot occurs in a cerebral artery, it may result in the interruption of cerebral blood flow and subsequent stroke.

transient ischemic attack (TIA) A disorder of the brain in which brain cells temporarily stop functioning because of insufficient oxygen, causing stroke-like symptoms that resolve completely within 24 hours of onset.

Assessment *in Action*

You are dispatched to a residence for a patient with a headache. You arrive to find a 68-year-old man sitting up in a recliner in the living room, but he is leaning slightly to the left. His wife reports he had a sudden headache about 1 hour ago. As you assess the patient, you notice that his speech is slurred and he is not moving his left side. You ask the patient to lift his left arm; he lifts his right instead. You also note a left-sided facial droop. A check of his vital signs shows a pulse of 100 beats/min, a blood pressure of 188/110 mm Hg, and respirations of 22 breaths/min. His past medical history includes poorly controlled diabetes and hypertension. He reports a blood glucose level of 70 mg/dL. As you prepare for transport, the patient experiences a generalized seizure.

1. On the basis of the patient's condition, what should you be most concerned with?

   A. Maintaining the ABCs
   B. Determining the type of stroke
   C. Administering oral glucose
   D. Performing further assessment

2. The patient was exhibiting slurred speech, facial droop, and an inability to move his left arm. Which neurologic examination emphasizes these possible stroke signs?

   A. Chicago Prehospital Stroke Scale
   B. Philadelphia Stroke Scale
   C. Cincinnati Prehospital Stroke Scale
   D. Camden Stroke Scale

3. Which of the following occurs when blood flow to a particular part of the brain is cut off by a blockage resulting in tissue damage?

   A. Ischemic stroke
   B. Hemorrhagic stroke
   C. Seizure
   D. Status epilepticus

4. What is the name of the condition when the patient forgets about the injured side after a stroke?

   A. Hemiparesis
   B. Neglect
   C. Aphasia
   D. Ataxia

5. The patient in this scenario experienced a seizure. What criteria must be met for this patient to have status epilepticus?

   A. A seizure lasting greater than 30 minutes
   B. A seizure that was preceded by an aura
   C. The presence of incontinence during the seizure
   D. Multiple seizures with normal consciousness between each event

6. Which of the following is a metabolic cause for a seizure?

   A. Brain tumor
   B. Head trauma
   C. Hypoglycemia
   D. Brain abscess

7. This patient appears to be suffering from a stroke and a seizure. What condition mimics a stroke and also causes a seizure?

   A. Meningitis
   B. Postictal state
   C. Hypoglycemia
   D. Migraine headache

8. Describe how to use the Cincinnati Prehospital Stroke Scale.
9. What is the difference between a stroke and a transient ischemic attack?
10. Explain why it is important to determine the time when the patient was last seen normal.

CHAPTER 18

Gastrointestinal and Urologic Emergencies

National EMS Education Standard Competencies

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Abdominal and Gastrointestinal Disorders

Anatomy, presentations, and management of shock associated with abdominal emergencies

› Gastrointestinal bleeding (pp 705, 710, 715, 718–719)

Anatomy, physiology, pathophysiology, assessment, and management of

› Acute and chronic gastrointestinal hemorrhage (pp 705–707, 710, 714–719)
› Peritonitis (pp 705–708, 714–719)
› Ulcerative diseases (pp 705–706, 708–709, 714–719)

Genitourinary/Renal

› Blood pressure assessment in hemodialysis patients (p 718)

Anatomy, physiology, pathophysiology, assessment, and management of

› Complications related to
  - Renal dialysis (pp 713, 719)
  - Urinary catheter management (not insertion) (p 719)
› Kidney stones (pp 713–719)

Knowledge Objectives

1. Describe the basic anatomy and physiology of the gastrointestinal, genital, and urinary systems. (pp 705–707)
2. Define the term acute abdomen. (p 707)
3. Describe pathologic conditions of the gastrointestinal, genital, and urinary systems. (pp 707–714)

4. Explain the concept of referred pain. (p 708)
5. Recognize that abdominal pain can arise from other body systems. (pp 708–709, 713–714)
6. Identify the signs and symptoms, and common causes, of an acute abdomen. (pp 708–712)
7. Explain the procedures to follow in the assessment and management of acute and chronic gastrointestinal hemorrhage, peritonitis, and ulcerative diseases. (pp 708–712, 714–719)
8. List the most common abdominal emergencies, with the most common locations of direct and referred pain. (p 709)
9. Explain the procedures to follow for patient assessment of gastrointestinal and urologic emergencies. (pp 714–718)
10. Describe the procedures to follow in managing the patient with shock associated with abdominal emergencies. (p 715)
11. Describe the emergency medical care of the patient with gastrointestinal or urologic emergencies. (pp 718–719)
12. Explain the principles of kidney dialysis. (pp 719)

Skills Objective

1. Demonstrate the assessment of a patient's abdomen. (pp 717–718)

Introduction

Abdominal pain is a common complaint, but the cause is often difficult to identify, even for a physician. As an EMT, you do not need to determine the exact cause of acute abdominal pain, but it is helpful for you to understand the pathophysiology and the signs and symptoms of common illnesses. You need to be able to recognize a life-threatening problem and act swiftly in response. Remember, the patient is in pain and is probably anxious, requiring your skills of rapid assessment and emotional support.

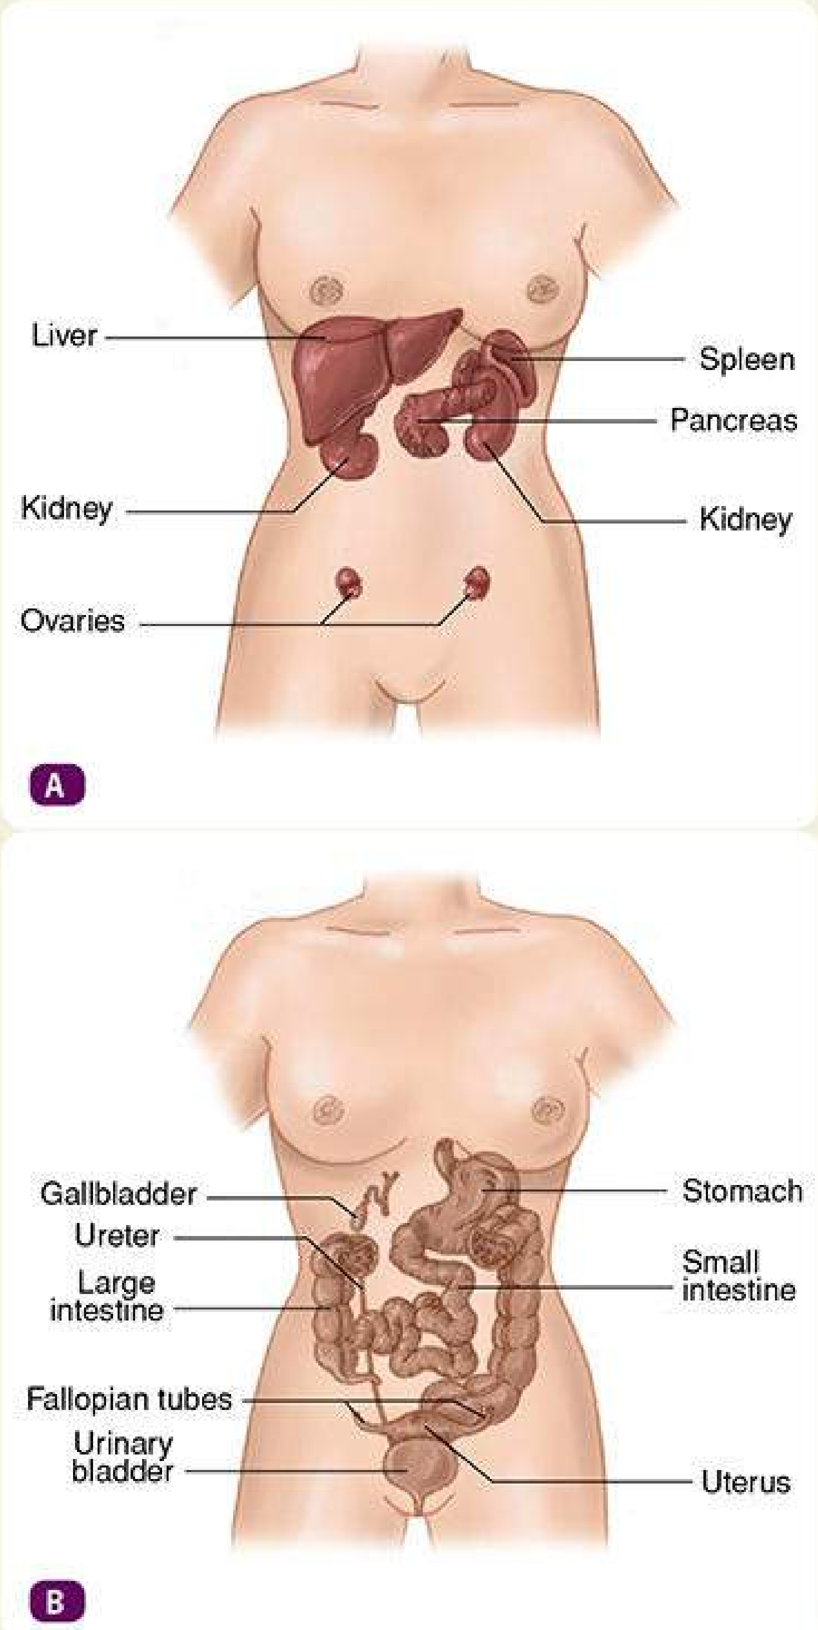

Figure 18-1 The solid and hollow organs of the abdomen. **A.** Solid organs include the liver, spleen, pancreas, kidneys, and ovaries (in women). **B.** Hollow organs include the gallbladder, stomach, small intestine, large intestine, and bladder.

Anatomy and Physiology

The abdominal cavity contains solid and hollow organs that make up the gastrointestinal, genital, and urinary systems **Figure 18-1**. Solid organs include the liver, spleen, pancreas, kidneys, and ovaries (in women). Technically, organs such as the kidneys, ovaries, and the pancreas are retroperitoneal (behind the peritoneum). However, because they lie next to the peritoneum, they can cause abdominal pain. An injury to a solid organ can cause shock and bleeding because of the amount of blood vessels that the organ contains.

Hollow organs include the gallbladder, stomach, small intestine, large intestine, and urinary bladder. If there is a perforation of these hollow organs, the contents of the organ will leak and contaminate the abdominal cavity.

The Gastrointestinal System

The gastrointestinal (GI) system is responsible for the digestion process. Digestion begins when food is put into the mouth and chewed; the salivary glands secrete saliva and begin to break down the food, then it is swallowed. The food travels down the esophagus to the stomach. The stomach is the main organ of the digestive system. Most digestion takes place in the stomach, where gastric juices break down food to a form that can be used by the body.

YOU are the Provider — PART 1

At 0320 hours, you and your partner are dispatched to 1500 East River Road, Apartment 5, for a 79-year-old man with abdominal pain. You proceed to the scene, which is approximately 8 miles from your station. The weather is clear, the temperature is 67°F (19.4°C), and the traffic is light.

1. What is the definition of an acute abdomen?
2. What is your role as an EMT in treating a patient with abdominal pain?

The liver assists in digestion by secreting bile, which aids in the digestion of fats. The liver also filters toxic substances produced by digestion, creates glucose stores, and produces substances necessary for blood clotting and immune function. The gallbladder is a hollow pouch located beneath the liver that acts as a reservoir for bile.

Food then travels down into the small intestine, which consists of three sections: the duodenum, jejunum, and ileum. The duodenum is where digestive juices from the pancreas and liver mix together. The pancreas secretes juice containing enzymes that help break down starches, fats, and proteins. Amylase, which breaks down starches into sugar, is one enzyme the pancreas secretes. The pancreas also produces bicarbonate and insulin. Bicarbonate neutralizes the stomach acid in the duodenum, and insulin helps regulate the levels of glucose in the bloodstream.

The jejunum, the next part of the small intestine, plays a major role in the absorption of digestive products. In fact, the jejunum comprises a large amount of the surface area of the small intestine and does much of the work. The final part of the small intestine is the ileum. The ileum absorbs nutrients that were not absorbed earlier. It also absorbs bile acids so they can be returned to the liver for future use and vitamin B12 for making nerve cells and red blood cells.

The food that was not broken down and used as nutrients then moves into the colon, or large intestine, as waste products. A rhythmic movement called peristalsis moves the waste matter through the intestines. Water is absorbed and stool is formed. The stool passes through the rectum to the anus, where it is defecated.

Additional Abdominal Organs

The spleen is also located in the abdomen but has no digestive system function. The spleen is part of the lymphatic system and plays a significant role in relation to red blood cells and the immune system. It assists in the filtration of blood, aids in the development of red blood cells, and serves as a blood reservoir. The spleen also produces antibodies to help the body fight off disease and infection.

The Genital System

The abdominal space also holds the male and female reproductive organs. The male reproductive system consists of the testicles, epididymis, vasa deferentia, seminal vesicles, prostate gland, and penis. The female reproductive system includes the ovaries, fallopian tubes, uterus, cervix, and vagina.

The Urinary System

The urinary system controls the discharge of certain waste materials filtered from the blood by the kidneys. In the urinary system, the kidneys are solid organs, and the ureters, bladder, and urethra are hollow organs **Figure 18-2**. Ordinarily, the urinary and genital systems are considered together because they share many organs. One system can directly affect the other. For example, if the prostate gland in the male genital system enlarges, then the urethra will narrow, weakening the bladder, and eventually leading to urinary retention.

The body contains two kidneys, one on each side, which lie on the posterior muscular wall of the abdomen behind the peritoneum in the retroperitoneal space. The kidneys play an important role in the regulation of acid-base balance (the body's pH) and blood pressure. Blood pressure regulation is associated with the kidney's ability to remove sodium chloride from the body. Kidney disease is a common cause of hypertension. The kidneys also rid the body of toxic wastes and control the body's balance of fluid and electrolytes. Blood flow in the kidneys is high. Nearly 20% of the output of blood from the heart passes through the kidneys each minute. Large vessels attach the kidneys directly to the aorta and the inferior vena cava. Waste products and water are constantly filtered from the blood to form urine. The kidneys continuously concentrate this filtered urine by reabsorbing the water as it passes through a system of specialized tubes within them. The tubes finally unite to form the renal pelvis, a cone-shaped collecting area that connects the ureter and the kidney.

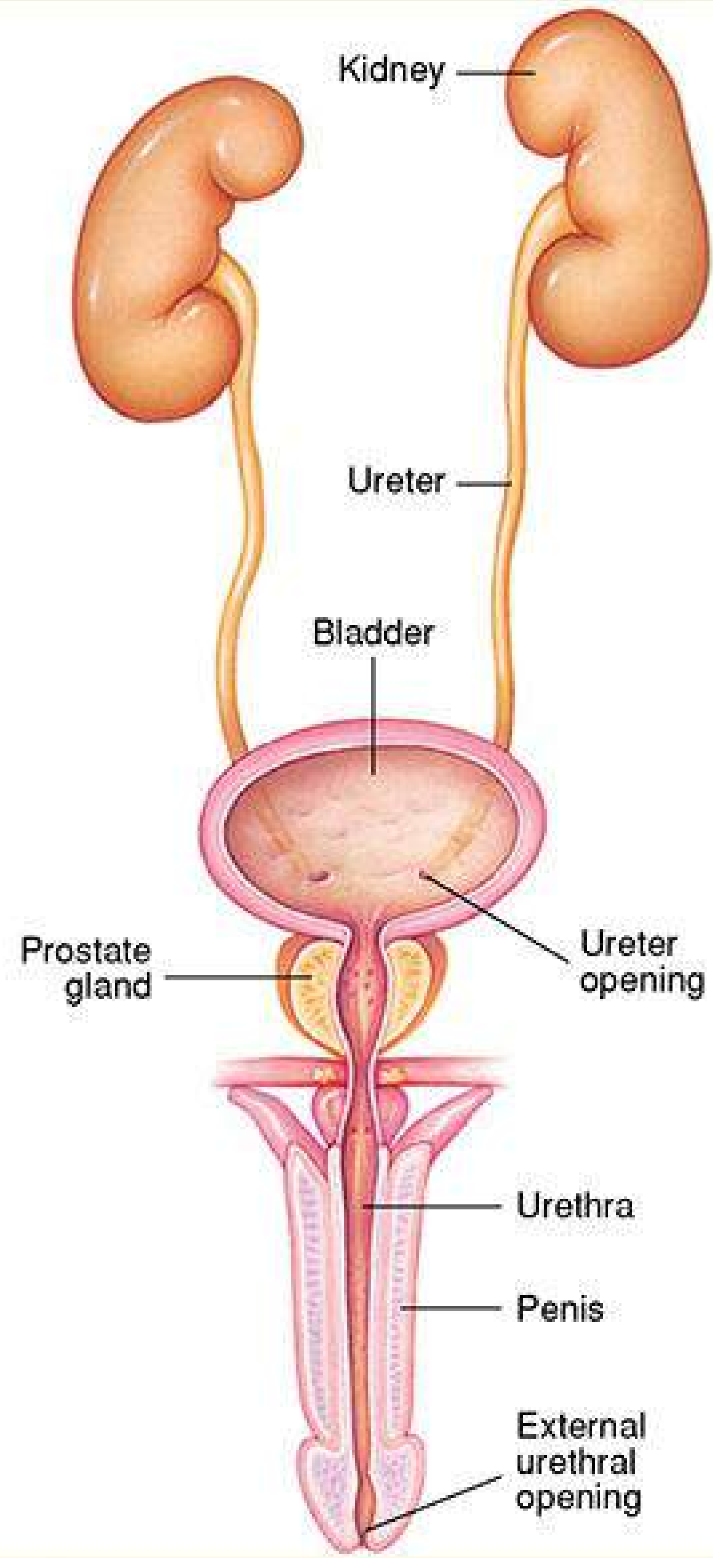

Figure 18-2 The urinary system lies in the retroperitoneal space behind the organs of the digestive system. The urinary system in men and women includes the kidneys, ureters, bladder, and urethra. This diagram shows the male urinary system.

A ureter passes from the renal pelvis of each kidney along the surface of the posterior abdominal wall behind the peritoneum to drain into the urinary bladder. The ureters are small (0.2 inch in diameter), hollow, muscular tubes. Peristalsis, a wavelike contraction of smooth muscle, occurs in these tubes to move the urine to the bladder.

The urinary bladder is located immediately behind the pubic symphysis in the pelvic cavity and is composed of smooth muscle with a specialized lining membrane. The two ureters enter posteriorly at its base on either side. The bladder empties to the outside of the body through the urethra. In the man, the urethra passes from the anterior base of the bladder through the penis. In the woman, the urethra opens at the front of the vagina. The normal adult forms 1.5 to 2 L of urine every day. This waste is extracted and then concentrated in the urine from the 1,500 L of blood that circulate through the kidneys daily.

Pathophysiology

The abdominal cavity is lined by a membrane called the **peritoneum**. The peritoneum also covers the organs of the abdomen. The parietal peritoneum lines the walls of the abdominal cavity, and the visceral peritoneum covers the organs themselves. The abdominal space normally contains a small amount of peritoneal fluid to bathe and lubricate the organs in the abdominal cavity. Any foreign material, such as blood, pus, bile, pancreatic juice, or amniotic fluid, can cause irritation of the peritoneum, called **peritonitis**.

Acute abdomen is a medical term referring to the sudden onset of abdominal pain, often associated with severe, progressive problems that require medical attention. Peritonitis will usually develop if the acute abdomen is not treated, and can be fatal.

Peritonitis typically causes **ileus**, or paralysis of the muscular contractions that normally propel material through the intestine. The retained gas and feces, in turn, cause abdominal distention. Distention usually begins after the muscular contractions cease. In the presence of such paralysis, nothing that is eaten can pass normally out of the stomach or through the bowel. In this situation, the only way the stomach can empty itself is by **emesis**, or vomiting. For this reason, peritonitis is frequently associated with nausea and vomiting. These symptoms do not point to a particular cause because they can accompany almost every type of gastrointestinal disease or injury.

YOU are the Provider — PART 2

When you arrive at the scene and enter the patient's residence, you find him lying on the couch on his side with his knees drawn up to his abdomen. He is markedly diaphoretic (sweaty) and pale and is in obvious severe pain. You introduce yourself and begin your assessment.

Recording Time: 0 Minutes	
Appearance	Lying on his side, diaphoretic, in obvious pain
Level of consciousness	Conscious and alert; restless
Airway	Open; clear of secretions or foreign bodies
Breathing	Rapid, shallow respirations
Circulation	Radial pulse, weak and rapid; skin is pale and diaphoretic

Your partner administers oxygen at 15 L/min via a nonrebreathing mask as you continue your assessment. The patient tells you that his abdominal pain began suddenly and has been severe from the onset. He describes the pain as severe and indicates that it radiates to his lower back. He denies nausea, vomiting, or any other symptoms. As you examine his abdomen, your partner prepares to take his vital signs.

3. What is the proper technique of assessing a patient's abdomen? What should you assess for?
4. What is the difference between radiating pain and referred pain?

Peritonitis is also associated with a loss of body fluid into the abdominal cavity. The loss of fluid usually results from abnormal shifts of fluid from the bloodstream into body tissues. This fluid shift decreases the volume of circulating blood and may lead to decreased blood pressure or even shock. The patient may have normal vital signs or, if the peritonitis has progressed further, the patient may present with tachycardia and hypotension. When peritonitis is accompanied by hemorrhage, the signs of shock are much more apparent.

Fever may or may not be present, depending on the cause of the peritonitis. Patients with **diverticulitis** (inflammation in small pockets at weak areas in the muscle walls) or **cholecystitis** (inflammation of the gallbladder) may have a substantial elevation in temperature. However, patients with acute appendicitis may have a temperature within normal limits until the appendix ruptures and an abscess starts to form.

Abdominal Pain

Abdominal pain can have different qualities because two different types of nerves supply the peritoneum. The nerves from the spinal cord that supply the skin of the abdomen also supply the parietal peritoneum. Therefore, the parietal peritoneum and the skin of the abdomen can perceive much the same sensations: pain, touch, pressure, heat, and cold. These sensory nerves can easily identify and localize a point of irritation. In contrast, the visceral peritoneum is supplied by the autonomic nervous system. These nerves are far less able to localize sensation. This means that your patient will not be able to describe exactly where the pain is located. The visceral peritoneum is stimulated when distention or contraction of the hollow abdominal organs activates the stretch receptors. Patients sometimes describe it as a “deep“ pain. Other painful sensations that occur because of an irritated visceral peritoneum may be perceived at a distant point on the surface of the body, such as the back or shoulder. This phenomenon is called **referred pain**.

Referred pain is the result of connections between the body’s two separate nervous systems. The nerves connecting the somatic nervous system and autonomic nervous system cause the stimulation of the autonomic nerves to be perceived as stimulation of the spinal sensory nerves. For example, acute cholecystitis may cause pain in the right shoulder because the autonomic nerves serving the gallbladder lie near the spinal cord at the same anatomic level as the spinal sensory nerves that supply the skin of the shoulder **Figure 18-3**.

The most common abdominal emergencies, with the most common locations of direct and referred pain, are listed in **Table 18-1**.

Causes of Acute Abdomen

Almost any problem with an abdominal organ can cause an acute abdomen. Some of the more common causes are discussed here. Because the visceral peritoneum is usually irritated first, early abdominal pain tends to be vague and poorly localized. As the parietal peritoneum becomes irritated, pain becomes more severe and may be more specifically located.

Ulcers

The stomach and duodenum are subjected to high levels of acidity. To prevent damage to these organs, protective layers of mucus line both organs. In peptic ulcer disease (PUD), the protective layer is eroded, allowing the acid to eat into the organ itself over the course of weeks, months, or even years.

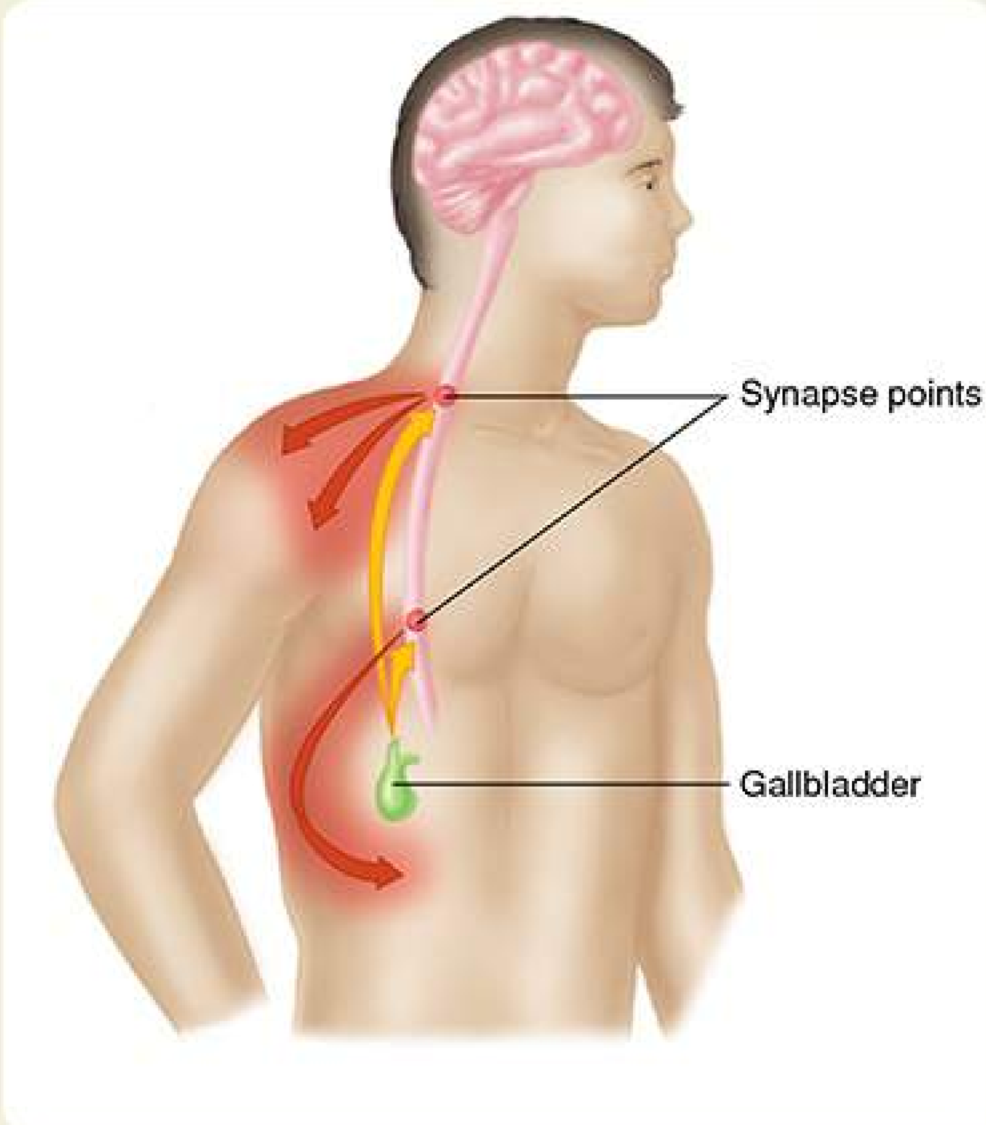

Figure 18-3 Acute cholecystitis causes referred pain in the right shoulder as well as in the abdomen.

Table 18-1 Common Abdominal Conditions	
Condition	**Localization of Pain**
Appendicitis	Right lower quadrant (direct); around navel (referred); rebound tenderness (pain felt on the rebound after palpation)
Cholecystitis	Right upper quadrant (direct); right shoulder (referred)
Ulcer	Upper midabdomen or upper part of back
Diverticulitis	Left lower quadrant
Abdominal aortic aneurysm (ruptured or dissecting)	Low part of back and lower quadrants
Cystitis (inflammation of the bladder)	Lower midabdomen (retropubic)
Kidney infection	Costovertebral angle
Kidney stone	Right or left flank, radiating to genitalia
Pancreatitis	Upper abdomen (both quadrants); back
Pneumonia	Referred pain to the upper abdomen
Hernia	Anywhere in the abdominal area
Peritonitis	Anywhere in the abdominal area

Most peptic ulcers are the result of infection of the stomach with *Helicobacter pylori (H pylori)*. Another major cause is chronic use of nonsteroidal anti-inflammatory drugs (NSAIDs). Alcohol and smoking can also affect the severity of PUD by increasing gastric acidity.

PUD affects both men and women equally, but tends to occur more often in the older population. As people age, the immune system's ability to fight infection decreases, making infection more likely. The geriatric population, in general, also uses NSAIDs frequently for arthritis and other musculoskeletal conditions.

Patients with peptic ulcers experience a classic sequence of burning or gnawing pain in the stomach that subsides or diminishes immediately after eating and then reemerges 2 to 3 hours later. The pain usually presents in the upper abdomen, but sometimes may be found below the sternum. With some patients, the pain occurs immediately after eating. Nausea, vomiting, belching, and heartburn are common symptoms. If the erosion is severe, gastric bleeding can occur, resulting in **hematemesis** (vomiting blood) and **melena** (black, tarry stools containing blood).

Some ulcers will heal without medical intervention, but often complications can occur from bleeding or perforation (a hole through the wall of the stomach). More serious ulcerative conditions can cause severe peritonitis and an acute abdomen.

Gallstones

The gallbladder is a storage pouch for digestive juices and waste from the liver. Gallstones can form and block the outlet from the gallbladder, causing pain. Sometimes the blockage will pass, but if not, it can lead to severe inflammation of the gallbladder, called cholecystitis. This is a condition in which the wall of the gallbladder becomes inflamed. In severe cases, the gallbladder may rupture, causing inflammation to spread and irritate surrounding structures such as the diaphragm and bowel.

This condition presents as a constant, severe pain in the right upper or midabdominal region and may refer to the right upper back, shoulder area, or flank. The pain may steadily increase for hours or may come and go. Cholecystitis commonly produces symptoms about 30 minutes after a particularly fatty meal and usually at night. Other symptoms include general gastrointestinal distress such as nausea and vomiting, indigestion, bloating, gas, and belching. People at a higher risk for developing cholecystitis include women, older adults, obese people, and people of Scandinavian, Native American, and Hispanic descent.

Pancreatitis

The pancreas forms digestive juices and is also the source of insulin. Inflammation of the pancreas is called **pancreatitis**. Pancreatitis can be caused by an obstructing gallstone, alcohol abuse, and other diseases. Severe pain may present in the upper left and right quadrants and may often radiate to the back. In addition, the patient may report that the pain is worse after eating. Other signs and symptoms accompanying the pain are nausea and vomiting, abdominal distention, and tenderness. Complications like sepsis or hemorrhage can occur, in which case assessment may also reveal fever or tachycardia.

Appendicitis

The appendix is a small recess in the large intestine. Inflammation or infection in the appendix is called **appendicitis**, and is a frequent cause of acute abdomen. This inflammation can eventually cause the tissues to die and/or rupture, causing an abscess, peritonitis, or shock. Initially, the pain caused by appendicitis is generalized, dull, and diffuse and may center in the umbilical area. The pain later localizes to the right lower quadrant of the abdomen. Appendicitis can also cause referred pain. The patient may also report nausea and vomiting, anorexia (lack of appetite for food), fever, and chills. A classic symptom of appendicitis is rebound tenderness. Rebound tenderness is a result of peritoneal irritation. This can be assessed by pressing down gently and firmly on the abdomen. The patient will feel pain when the pressure is released. Women who are pregnant may not exhibit this symptom.

Gastrointestinal Hemorrhage

Bleeding within the gastrointestinal tract is a symptom of another disease, not a disease itself. Gastrointestinal hemorrhage can be acute, which may be shorter term and more severe, or chronic, which may be of longer duration and less severe. All complaints of bleeding should be considered serious.

A gastrointestinal hemorrhage can occur in the upper or lower gastrointestinal tract. Bleeding in the upper gastrointestinal tract occurs from the esophagus to the upper small intestine. In the esophagus, problems might include esophagitis, esophageal varices secondary to liver failure, or a Mallory-Weiss tear, which results from excessive wretching or vomiting. Hematemesis is frequently seen in patients with upper GI bleeding. The blood is either bright red or has the appearance of coffee grounds depending on where in the GI tract it originated and how briskly it is occurring.

Lower gastrointestinal bleeding occurs between the upper part of the small intestine and the anus. Bowel inflammation, diverticulosis, diverticulitis, cancer, and hemorrhoids are common causes of bleeding in the lower gastrointestinal tract. In lower gastrointestinal bleeding, the bleeding often manifests as melena, or dark tarry stools, as a result of partial digestion of the blood.

Esophagitis

Esophagitis occurs when the lining of the esophagus becomes inflamed by infection or from the acids in the stomach (**gastroesophageal reflux disease [GERD]**). GERD is a condition in which the sphincter between the esophagus and the stomach opens, allowing stomach acid to move up into the esophagus. Also referred to as acid reflux disease, this condition can cause a burning sensation within the chest (heartburn). It is estimated that 60 million people in the United States have GERD. This is approximately 20% of the total population; therefore, GERD is quite common. People diagnosed with GERD may use ant-acids, proton pump inhibitors, and H_2 blockers to treat their condition.

The patient with esophagitis may report pain with swallowing and feeling like an object is stuck in his or her throat. Additional symptoms include heart-burn, nausea, vomiting, and sores in the mouth. In the worst cases, bleeding can occur from the small capillary vessels within the esophageal lining or the main blood vessels.

Esophageal Varices

Esophageal varices occur when the amount of pressure within the blood vessels surrounding the esophagus increases, frequently as a result of liver failure. The esophageal blood vessels eventually drain their blood into the liver. If the liver becomes damaged and blood cannot flow through it easily, blood begins to back up into these portal vessels, dilating the vessels and causing the capillary network of the esophagus to begin leaking. If pressure continues to build, the vessel walls may fail, causing massive upper gastrointestinal bleeding and, quickly afterward, hematemesis.

In industrialized countries, alcohol is the main cause of portal hypertension. Long-term alcohol consumption damages the interior of the liver (cirrhosis), leading to slower blood flow. In developing countries, viral hepatitis is the main cause of liver damage.

Presentation of esophageal varices takes two forms. Initially, the patient shows signs of liver disease—fatigue, weight loss, jaundice, anorexia, edema in the abdomen, abdominal pain, nausea, and vomiting. This very gradual disease process takes months to years before the patient reaches a state of extreme discomfort.

By contrast, the rupture of the varices is far more sudden. The patient may report sudden-onset discomfort in the epigastric region or sternum. He or she may have severe difficulty swallowing, vomiting of bright red blood, hypotension, and signs of shock. If the bleeding is less dramatic, hematemesis and melena are likely. Regardless of the speed of bleeding, damage to these vessels can be life threatening. Spontaneous rupture is often life threatening and significant blood loss at the scene may be evident. Major ruptures can lead to death in a matter of minutes.

Mallory-Weiss Tear

A Mallory-Weiss tear is a tear in the junction between the esophagus and the stomach, causing severe bleeding and potentially death. Primary risk factors include alcoholism and eating disorders. Mallory-Weiss tears affect both men and women equally, but are more prevalent in older adults and older children.

Vomiting is the principal symptom. In women, this syndrome may be associated with severe vomiting related to pregnancy. The extent of the bleeding can range from very minor bleeding, resulting in very little blood loss, to severe bleeding and extreme fluid loss. In extreme cases, patients may experience signs and symptoms of shock, upper abdominal pain, hematemesis, and melena.

Safety Tips

Infection from the bacterium *Clostridium difficile* (commonly referred to as *C. diff*) presents with GI symptoms such as diarrhea. You can spread *C. diff* to other patients if proper hand hygiene is not employed and proper decontamination is not done after each call.

Transmission of *C. diff* occurs in susceptible patients by contact with surfaces contaminated with feces. The bacterium can occasionally be transmitted to patients by contact with the unwashed hands of health care providers. Infections with *C. diff* are generally related to use of antibiotics in patients who are being treated for other infections.

C. diff is not inactivated by alcohol-based hand products. Glove use, good handwashing technique, and cleaning of contaminated surfaces with a chlorine-based cleaning agent are important in preventing spread of this bacterium.

YOU are the Provider PART 3

The patient's vital signs are obtained and recorded. Your assessment of his abdomen reveals that it is tender to palpation and guarding is present. As your partner retrieves the stretcher from the ambulance, the patient tells you that he has high blood pressure, depression, and had his appendix removed 30 years ago. He says he takes Toprol and Diovan. You note that he is becoming more restless and is still experiencing intense pain, which he describes as a 10 on a scale of 0 to 10 (10/10).

Recording Time: 3 Minutes	
Respirations	28 breaths/min; shallow
Pulse	124 beats/min; regular
Skin	Pale, cool, and diaphoretic
Blood pressure	98/60 mm Hg
Oxygen saturation (Spo_2)	96% (on oxygen)

5. What do the patient's vital signs indicate?
6. What do you suspect is the cause of the patient's abdominal pain?

Gastroenteritis

Acute gastroenteritis comprises a family of conditions revolving around a central theme of infection combined with diarrhea, nausea, and vomiting. Bacterial and viral organisms can cause this condition. These organisms typically enter the body through contaminated food or water. Patients may begin to experience an upset stomach and diarrhea as soon as several hours or several days after contact with the contaminated matter. The disease can then run its course in 2 to 3 days or continue for several weeks.

Gastroenteritis may also be caused by noninfectious conditions such as adverse reactions to medications, exposure to certain toxins, or chemotherapy. The symptoms are similar regardless of the underlying cause.

Diarrhea is the principal symptom in both infectious and noninfectious gastroenteritis. Patients may experience large dumping-type diarrhea or frequent small liquid stools. The diarrhea may contain blood and/or pus, and it may have a foul odor or be odorless. Abdominal cramping is frequently reported. Nausea, vomiting, fever, and anorexia are also present. If the diarrhea continues, dehydration will result. As the volume of fluid loss increases, the likelihood of shock increases.

Diverticulitis

Diverticulitis was first recognized around 1900, when the types of foods people ate began to change dramatically. In particular, the amount of fiber within the US diet plummeted as the amount of processed foods eaten increased.

As the amount of fiber consumed as part of the diet decreases, the consistency of the normal stool becomes more solid. This hard stool requires more intestinal contractions, subsequently increasing pressure within the colon. In this environment, small defects within the colonic wall that would otherwise never pose a problem now fail, resulting in bulges in the wall. These small outcroppings eventually turn into pouches, called diverticula. As feces travel through the colon, some may become trapped within these pouches. When bacteria grow there, they cause localized inflammation and infection.

The most common cause of lower GI bleeding in the United States is diverticulosis. Bleeding from diverticulosis is usually bright red (as the blood products do not have time to be digested) and typically painless.

The main symptom of diverticulitis is abdominal pain, which tends to be localized to the left side of the lower abdomen. Classic signs of infection include fever, malaise, body aches, chills, nausea, and vomiting. Bleeding is rare with this condition. Because of the local infections of these pouches, adhesions may develop, narrowing the diameter of the colon and resulting in constipation and bowel obstruction. In severe cases, these infected outcroppings may burst, causing perforation of the affected segment of colon. This may lead to peritonitis, severe infection, and if left untreated, septic shock.

Hemorrhoids

Hemorrhoids are created by swelling and inflammation of the blood vessels surrounding the rectum. They are a common problem, with almost half the population having at least one hemorrhoid by age 50 years. Hemorrhoids may result from conditions that increase pressure on the rectum or irritation of the rectum. Pregnancy, straining at stool, and chronic constipation cause increased pressure. Diarrhea can cause irritation.

Hemorrhoids may be internal (high in the rectum, usually not visible, often painless, and often associated with bright red, brisk bleeding) or external (low in the rectum, often clearly visible, and painful).

Hemorrhoids present as bright red blood during defecation. This bleeding tends to be minimal and is easily controlled. Additionally, patients may experience itching and a small mass on the rectum. Typically, this mass is a clot formed in response to the mild bleeding.

Urinary System

Issues in the urinary system can cause acute abdominal pain. Bladder inflammation, called **cystitis**, is common, especially in women. This condition is generally caused by a bacterial infection and can be referred to as a **urinary tract infection (UTI)**. A bladder infection can be painful. Patients with cystitis usually have lower quadrant abdominal pain. They may also report an urgency and frequency in urination and pressure and pain around the bladder. If the infection is severe, the urethra can become inflamed, causing urinary retention. When you are assessing a patient with cystitis, the patient may report tenderness when you are palpating the abdomen over the bladder (just above the pubic bone). Cystitis can become a serious health problem if the infection spreads to the kidneys.

Kidneys

The kidneys play a major role in maintaining homeostasis, or keeping all body systems in balance. The kidneys preserve this balance by eliminating waste from the blood. When the kidneys fail, the patient loses the ability to excrete waste from the body, leading to a condition called **uremia**. This means that the waste product, urea, which is normally excreted into the urine, remains in the blood.

Chemicals may crystallize in the urine and form **kidney stones** (renal calculi). Kidney stones can grow over time, and if a stone passes into the ureter, it can cause a blockage. Pressure will build up behind the kidney stone and cause swelling in the kidney. Patients with a kidney stone blockage may initially report vague discomfort in the flank, but the pain can become quite intense and typically will radiate to the groin. These patients are often agitated and restless as they try to get into a comfortable position to relieve the pain. They may also report nausea and vomiting. The pain from kidney stones is often caused when the stone moves within the ureter. In many cases, the stone will pass on its own, but in other cases it may have to be surgically removed (or broken up). A slight amount of blood in the urine (hematuria) before or after the stone passes may be present because of irritation of the ureter.

Kidney (renal) failure can be acute or chronic. Acute renal failure is a sudden (possibly over a period of days) decrease in function. It occurs from a variety of causes including hemorrhage, dehydration, trauma, shock, sepsis, heart failure, medications, drug abuse, and kidney stones. Acute renal failure can be reversed with prompt diagnosis and treatment.

Chronic renal failure is irreversible. It is progressive and develops over months and years. It is often caused by diabetes or hypertension. The kidney tissue shrinks and function diminishes. Eventually the patient requires dialysis or a kidney transplant to remove waste products from the bloodstream.

Patients with untreated chronic renal failure or patients with chronic renal failure who have missed scheduled dialysis may exhibit a wide variety of symptoms ranging from simply not feeling well to an altered level of consciousness. In later stages, seizures and coma are possible. Additional signs and symptoms include lethargy, nausea, headaches, cramps, and edema in the extremities and face because of fluid imbalances. Patients with chronic renal failure have a high incidence of heart disease. There is an increased risk of heart failure and cardiac arrest in these patients.

Female Reproductive Organs

Gynecologic problems are a common cause of acute abdominal pain. Always consider that a woman with lower quadrant abdominal pain and tenderness may have a problem related to her ovaries, fallopian tubes, or uterus. Chapter 23, *Gynecologic Emergencies*, covers gynecologic emergencies in depth.

Other Organ Systems

The aorta lies immediately behind the peritoneum. In older people, the wall of the aorta sometimes develops weak areas that swell to form an abdominal aortic aneurysm (AAA). A pulsating mass may be felt in the abdomen, although this is a rare sign and is often hard to detect. Use extreme caution when trying to assess or detect this condition. The development of an aneurysm is rarely associated with symptoms because it occurs slowly, but if the aneurysm tears and ruptures, massive hemorrhage may occur, and the patient will present with signs of acute peritoneal irritation and hemorrhagic shock. The patient may also report radiation of severe pain to the back because the peritoneum can be stripped away from the wall of the main abdominal cavity by the hemorrhage. Back pain is a common symptom when an aneurysm has started to expand and the aortic linings begin to tear. Back pain that cannot be easily explained should be investigated closely in patients who are suspected of having an AAA. The patient generally describes the pain as tearing, which is different than most other descriptions of abdominal pain. The association of acute abdominal signs and symptoms of shock requires prompt transportation. Because this is a fragile situation with a large, leaking artery, avoid unnecessary or vigorous palpation of the abdomen and do not aggressively treat the patient for shock because these actions can cause a small tear to expand. Remember to handle the patient gently during transport.

Pneumonia, especially in the lower parts of the lung, may cause both ileus and abdominal pain. In this situation, the problem lies in an adjacent body cavity, but the intense inflammatory response can reflect in the abdomen.

A **hernia** is a protrusion of an organ or tissue through a hole or opening into a body cavity where it does not belong. Hernias can occur as a result of the following:

- A congenital defect, as around the umbilicus
- A surgical wound that has failed to heal properly
- A natural weakness in an area, such as in the groin

Hernias do not always produce a mass or lump that the patient will notice. At times, the mass will disappear back into the body cavity in which it belongs. In this case, the hernia is said to be reducible. If the mass cannot be pushed back within the body, it is said to be incarcerated.

Special Populations

Geriatric patients are as susceptible to acute abdomen as younger adults. However, the signs and symptoms in geriatric patients might be different. Because of altered pain sensation, geriatric patients with an acute abdomen may not feel any discomfort or may describe the discomfort as mild, even in severe conditions.

Because the older patient has decreased body temperature regulation and response, the patient with an acute abdomen, including peritonitis, may have little or no fever at all.

Because of the older patient's response to the acute abdomen, a delay in identifying the condition and seeking medical attention is possible, putting the patient at risk for complications. You should ask about the patient's medical history, especially the history of recent illness, to identify a potential illness. Ask about abdominal discomfort, when the patient last had a bowel movement and whether she or he was constipated or had diarrhea. Inquire if the patient has had previous bowel obstructions. Inquire as to when the patient last ate, how much fluid he or she has consumed, and whether he or she has vomited. Many geriatric patients think that a few cups of coffee a day is adequate fluid intake, but coffee (especially caffeinated) causes vasoconstriction and dehydration within the digestive system. Quickly determining the severity of the patient's problem can hasten proper treatment and recovery.

Reducible hernias pose little risk to the patient; some people live with them for years. When a hernia is incarcerated, however, its contents may become seriously compressed by the surrounding tissue, eventually compromising the blood supply. This situation, called **strangulation**, is a serious medical emergency. Immediate surgery is required to remove any dead tissue and repair the hernia.

The following signs and symptoms indicate a serious hernia problem:

- A formerly reducible mass is no longer reducible
- Pain at the hernia site
- Tenderness when the hernia is palpated
- Red or blue skin discoloration over the hernia

Any of these signs and symptoms is cause for prompt transport to the emergency department (ED).

Special Populations

Causes of abdominal pain are difficult enough to determine in adults who can provide a good history, but for children who can only tell you they have a stomachache it is even more problematic. It is hard for a parent or caregiver to provide accurate information when pain is so subjective. Confirm with the parent or caregiver the details of the medical history and whether the current problem could be an exacerbation (worsening) of a chronic problem. Chapter 34, *Pediatric Emergencies*, covers the acute abdomen in pediatric patients in depth.

Abdominal pain could mean an infection, be related to something the child ate, or indicate a poisoning. Look for clues that may indicate if the child ingested something poisonous. Consider environmental causes like spider bites (black widow or brown recluse) or metabolic issues like diabetic complications. Confirm the duration and location of the pain and if there has been vomiting.

Assess the child's appearance. Ask if there has been diarrhea or any kind of rash. It is always wise to transport a child with abdominal pain for further assessment.

Words of Wisdom

An acute abdomen usually indicates peritonitis, in which generalized signs can make it challenging to determine exactly where the problem lies, even for physicians. Knowing abdominal assessment steps well and recording your findings in detail are important early factors in the process that leads to diagnosis.

Patient Assessment

Scene Size-up

As always, ensure that the scene is safe and follow standard precautions with a minimum of gloves and eye protection. Consider donning a gown and covering your shoes with disposable, protective covers because there may be feces and urine on the floor and some patients may have active projectile vomiting.

Determine the number of patients at the scene. If your call involves going to the patient's home and he or she does not come to the door, the patient may have had a syncopal episode (fainted). Request police assistance to help you gain access to the patient. Consider the need for additional or specialized medical resources and request them early.

Be alert for clues to help you determine the nature of illness (NOI) or the mechanism of injury. Acute abdomen can be the result of violence, such as blunt or penetrating trauma, so always be vigilant. Chapter 30, *Abdominal and Genitourinary Injuries*, discusses traumatic injuries in detail. Clues will help you develop an early index of suspicion for life threats. For example, a pale and sweating patient who reports tearing pain may have an AAA. Observe the scene closely and interview bystanders or family members if the NOI is not obvious. In some cases, your senses can help give you a clue as to the NOI. For example, gastrointestinal bleeding often has a characteristic odor that you will learn to recognize.

Primary Assessment

Begin assessing the patient by first looking for and treating any life-threatening conditions. Assess the patient's level of consciousness and ABCs; threats to airway, breathing, or circulation are considered life threatening and must be treated immediately. Rapidly observe the patient and his environment. Note the position of the patient. Commonly the patient will have his or her knees drawn up to help alleviate the pain associated with acute abdomen. Consider necessary treatment and transport options and the need for early advanced life support (ALS) assistance.

If the chief complaint indicates a life-threatening problem, assess and treat it immediately. If the chief complaint is a minor problem, it should wait until you have had a chance to assess for and treat any potential life threats.

Ensure that the patient's airway is clear and that the patient's respirations are adequate. Administer oxygen to the patient when needed. As a result of the abdominal pain, the patient may show shallow or inadequate respirations because deep breaths often intensify the pain.

When you are assessing the patient's circulation, remember to assess for major bleeding. Ask the patient about blood in the vomit (hematemesis) or black, tarry stools (melena). The patient's pulse rate and quality, as well as skin condition, may indicate shock. Check the pulses in both arms because a difference in pulse strength may indicate an aortic dissection.

Shock may be caused by hypovolemia or may be the result of a severe infection (septic). If evidence of shock (inadequate perfusion) is present, interventions should include high-flow oxygen, placing the patient supine, and keeping the patient warm. Ensure that you provide prompt treatment for life threats and do not delay transport.

Certain patients should be transported quickly. These include patients who have airway, breathing, or circulation problems, including problems with pulse and perfusion, and patients with suspected internal bleeding. Included in the group to package quickly and transport rapidly are patients who have a poor general impression, especially pediatric and geriatric patients. Pale, cool, diaphoretic skin, tachycardia, hypotension, and altered level of consciousness are all signs of significant illness.

Ensure that the ride during transport is as gentle as possible for the patient. Drive smoothly and steadily. Rapid driving can result in increased vehicle movement, potentially aggravating and possibly worsening the patient's abdominal pain.

YOU are the Provider — PART 4

After providing further treatment, you place the patient onto the stretcher, load him into the ambulance, and proceed to the closest appropriate hospital, which is located 20 miles away. En route, you reassess the patient.

Recording Time: 12 Minutes	
Level of consciousness	Conscious and alert; restless
Respirations	28 breaths/min; shallow
Pulse	130 beats/min; weak and regular
Skin	Cool, pale, and diaphoretic
Blood pressure	100/62 mm Hg
Spo_2	98% (on oxygen)

7. Are there any special considerations for this patient? If so, what are they?

History Taking

If the patient is responsive, begin with obtaining the SAMPLE history. Ask the following questions specific to the signs and symptoms of a gastrointestinal or urologic emergency:

- **Nausea and vomiting.** Do you feel nauseous? Have you vomited? How many times? Over what period of time? Was there red blood? Did it look like coffee grounds?
- **Changes in bowel habits.** Has there been any change in your bowel habits? Have you been constipated? Did the stool look dark and tarry? Have you had diarrhea? Was there any red blood in it?
- **Urination.** Have you been urinating more or less often? Is there pain when you urinate? Is the color dark or unusual? Is there an unusual odor?
- **Weight loss.** Have you had unexplained weight loss recently? How many pounds?
- **Belching or flatulence.** Have you experienced belching or flatulence? For how long?
- **Pain.** What does the pain feel like? How long have you had this pain? Is the pain constant or intermittent? Have you had similar pain in the past? Have you done anything to relieve the pain?
- **Other.** Ask about any other signs or symptoms related to this complaint, such as "Are there any changes you have noted recently that may be contributing to your pain?"
- **Concurrent chest pain.** If the patient reports chest pain, use OPQRST (Onset, Provocation/ palliation, Quality, Region/radiation, Severity, and Timing of pain) to ask the patient what makes the pain better or worse.

Continue with the SAMPLE history. If the patient is a woman and of childbearing age, determine the date of her last menstrual period. This will determine if the patient could possibly be pregnant or raise the suspicion of other obstetric emergencies.

Ask the patient about his or her last oral intake. It is important to determine whether the patient has ingested any substance that could be causing the acute abdomen. If eating causes pain, discomfort, vomiting, or diarrhea, the patient will eat less often or stop eating. Do not give the patient anything by mouth. Food or fluid may only aggravate many of the symptoms. Also, the presence of food in the stomach increases the risk of aspiration.

WORDS OF WISDOM

Consider pertinent negatives, which are a record of normal findings that warrant no care or intervention. It is important to know and document that the patient denies shortness of breath or radiation of abdominal pain.

Finally, determine the events that led up to the patient's present illness. Question the patient about any recent trauma.

The SAMPLE history may not affect the interventions you perform, but it will help provide needed information for the physician in the ED to aid in determining the cause of the acute abdomen.

Secondary Assessment

In some situations, patients are comfortable only when lying in one particular position, which tends to relax muscles adjacent to the inflamed organ and thus lessen the pain. Therefore, the position of the patient may provide you with an important clue. For example, a patient with appendicitis may draw up the right knee. A patient with pancreatitis may lie curled up on one side.

Information gathered in the history-taking portion of the patient assessment may be used to focus your physical examination of the abdomen. A normal abdomen is soft and not tender to the touch. Pain and tenderness are the most common symptoms of an acute abdomen. The pain may be sharply localized or diffuse and will vary in its severity. Localized pain gives a clue to the problem organ or area causing it. Tenderness may be minimal or so great that the patient will not allow you to touch the abdomen. In some instances, the muscles of the abdominal wall become rigid in an involuntary effort to protect the abdomen from further irritation. This boardlike muscle spasm, called **guarding**, can be seen with major problems such as a perforated ulcer or pancreatitis.

Remember, the patient with peritonitis usually has abdominal pain, even when lying quietly. The patient may have difficulty breathing and may take rapid, shallow breaths because of the pain. Usually, you will find tenderness on palpation of the abdomen or when the patient moves. The degree of pain and tenderness is usually related directly to the severity of peritoneal inflammation.

Use the following steps to assess the abdomen:

1. Explain to the patient what you are going to do in terms of assessing the abdomen.
2. Place the patient in a supine position with the legs drawn up and flexed at the knees to relax the abdominal muscles, unless there is any trauma, in which case the patient will remain supine and stabilized. Determine whether the patient is restless or quiet, and whether motion causes pain.
3. Expose the abdomen and visually assess it. Does the abdomen appear distended (enlarged)? Do you see any pulsating masses (indicates an aortic aneurysm)? Is there bruising to the abdominal wall? Are there any surgical scars?
4. Ask the patient where the pain is most intense. Palpate in a clockwise direction beginning with the quadrant *after* the one the patient indicates is tender or painful; end with the quadrant the patient indicates is tender or painful. If the most painful area is palpated first, the patient may guard against further examination, making your assessment more difficult and less reliable.
5. Remember to be very gentle when palpating the abdomen. Occasionally, an organ within the abdomen will be enlarged and very fragile. Rough palpation could cause further damage. If you see a pulsating mass, do not touch it; doing so could cause the aorta to rupture.
6. Palpate the four quadrants of the abdomen gently to determine whether each quadrant is tense (guarded) or soft when palpated **Figure 18-4**.

Figure 18-4 Check for tenderness or rigidity by gently palpating the abdomen.

YOU are the Provider PART 5

With an estimated time of arrival at the hospital of 22 minutes, you reassess the patient and then call in your radio report. The patient remains conscious and alert, but restless, and is still experiencing 10/10 abdominal pain.

Recording Time: 17 Minutes

Level of consciousness	Conscious and alert; restless
Respirations	28 breaths/min; shallow
Pulse	128 beats/min; weak and regular
Skin	Cool, clammy, and diaphoretic
Blood pressure	6/58 mm Hg
Spo$_2$	97% (on oxygen)

The patient's condition is unchanged on arrival at the hospital. You give your verbal report to the charge nurse. After further assessment and treatment in the emergency department, the patient is taken to surgery. You later learn that he had an expanding abdominal aortic aneurysm, which was successfully repaired.

8. Could you have done anything definitively for this patient in the field? Why or why not?

7. Note whether the pain is localized to a particular quadrant or diffuse (widespread).
8. Palpate and wait for the patient to respond, looking for a facial grimace or a verbal "ouch." Do not ask the patient, "Does it hurt here?" as you palpate.
9. Determine whether the patient exhibits rebound tenderness (may be tender when direct pressure is applied, but very painful when pressure is released). This is an indicator of peritonitis. When you are palpating for rebound tenderness, you should use extreme caution.
10. Determine whether the patient can relax the abdominal wall on command. Guarding or rigidity may be present, which can indicate peritoneal irritation.

Findings of a high respiratory rate with a normal pulse rate and blood pressure may indicate the patient is unable to ventilate properly because deep breathing causes pain. A high respiratory rate and pulse rate with signs of shock, such as pallor and diaphoresis (profuse sweating), may indicate septic or hypovolemic shock. When treating a patient who has a dialysis shunt in his or her arm, it is important not to take a blood pressure in the same arm as the shunt to avoid damaging it.

Special Populations

Older patients may not exhibit rigidity or guarding like a younger adult. Abdominal pain can sometimes be related to cardiac conditions. Abdominal pain is frequently caused by bowel impaction or obstruction. Obstructions can be very serious and can lead to bowel ruptures that often are life threatening. Older patients may also not exhibit the same pain response ability because of deterioration of their sensory systems. Provide transport to an appropriate facility that can meet the needs of a geriatric patient.

Words of Wisdom

When palpating the abdomen of a patient with abdominal complaints, it is important to palpate clockwise, beginning in the quadrant next to the area of the described pain.

Reassessment

Because it is often difficult to determine the cause of an acute abdominal emergency, it is extremely important to reassess your patient frequently to determine whether the patient's condition has changed. Remember, the condition of a patient with an acute abdomen can change rapidly from stable to unstable.

Vital signs must be reassessed and compared with the patient's baseline vital signs. If anything changes en route to the hospital, manage the problem and document any changes or additional treatment.

Reassess the patient and then ask and answer the following questions (where appropriate):

- Has the patient's level of consciousness changed?
- Has the patient become more anxious?
- Has the appearance of the skin changed?

- Has the pain gotten better or worse?
- Has bleeding increased or decreased?
- Is current treatment improving the patient's condition?
- Has an already identified problem gotten better or worse?
- What is the nature of any newly identified problems?

Interventions generally include treatment for shock and providing emotional support. Administer oxygen, cover the patient with a blanket for warmth, and provide gentle transport for the patient without delay. Place the patient in a position of comfort. You will find that patients want to be supine with their knees drawn up. If the patient wants to lay on his or her side, try to make that possible. Be sure that you can observe and maintain the patient's airway because vomiting is common. If the patient's pain is extreme or he or she is showing significant signs of shock, consider the use of ALS assistance (if available) for intravenous fluids and pain management. If transport time is extended and rapid transport is needed, consider air medical transport if available.

Emergency Medical Care

Although you cannot treat the causes of acute abdomen, you can take steps to provide comfort and lessen the effects of shock by reassuring the patient and making the patient feel at ease. Treat the patient for shock even when obvious signs of shock are not apparent. Position patients who are vomiting to maintain a patent airway. Contain the vomitus to prevent the spread of infections (by using a biohazard bag). Airborne bacteria and viruses produced from vomiting can be easily transmitted to others. Ensure you are wearing gloves, eye protection, and a gown to prevent contamination of yourself, and wear a mask to prevent breathing in any infectious organisms. When you have released your patient to the hospital staff, clean the ambulance and any equipment you have used, preferably with an antibacterial cleaner. Do not forget to wash your hands even though you were wearing gloves.

Providing the patient low-flow oxygen may decrease nausea and anxiety. If the patient is having problems breathing, high concentrations of oxygen are more appropriate. Loosen restrictive clothing and transport gently in a position of comfort. Constantly reassess your patient's condition for signs of deterioration.

Dialysis Emergencies

Patients with end-stage renal disease (ESRD), also referred to as chronic renal failure, are treated with either peritoneal dialysis or hemodialysis. In these processes, the patient's blood is filtered and cleansed of the toxins and then returned to the body. The treatment eliminates waste, normalizes the blood chemistry, and reduces excess fluid. If a patient misses a dialysis treatment, weakness and pulmonary edema can be the first in a series of conditions that can become progressively more serious if normal balance is not returned to the patient's body.

The only time you will most likely see such a machine is if your service transports patients to and from dialysis centers. If there is a dialysis machine in a private residence, treatments will most likely be performed by a trained dialysis technician.

In hemodialysis, the patient's blood circulates through a dialysis machine that functions in much the same way as the normal kidneys. Most patients undergoing long-term hemodialysis have some sort of shunt, a surgically created connection between a vein and an artery. The patient is connected to the dialysis machine through this shunt, which allows blood to flow from the body into the dialysis machine and back to the body. It is usually located in the forearm or upper arm **Figure 18-5**.

Figure 18-5 Expose and visualize fistulas or shunts to determine if there is an infection or if you need to control bleeding.

In peritoneal dialysis, large amounts of specially formulated dialysis fluid are infused into (and back out of) the abdominal cavity. This fluid stays in the cavity for 1 to 2 hours, allowing equilibrium to occur. Peritoneal dialysis is very effective but carries a high risk of peritonitis. With proper training, however, peritoneal dialysis can be performed in the home.

The adverse effects of dialysis include hypotension, muscle cramps, nausea and vomiting, hemorrhage from the access site, and infection at the access site. If your call involves a patient on dialysis, start with the ABCs: assess and manage the airway, breathing, and circulation. Provide high-flow oxygen if indicated and manage any bleeding from the access site. Position the patient sitting up in cases of pulmonary edema or supine if the patient is in shock, and transport promptly.

Some dialysis patients also have urinary catheters. The catheter is placed in the bladder so the urine can run into a bag. These catheters can often be a source of infection. The patient may report fever and general malaise (illness) in addition to any symptoms specific to kidney failure. Leave the device in place. Treat any signs and symptoms and transport the patient for further evaluation.

During transport, unless there is a life-threatening event, make all attempts to deliver the patient to a hospital with dialysis capability.

YOU are the Provider SUMMARY

1. What is the definition of an acute abdomen?

Acute abdomen is a term used to describe the sudden (acute) onset of abdominal pain that is not caused by a traumatic injury. It is generally associated with severe, progressive symptoms that require medical attention. Acute abdominal pain can be caused by dysfunction of one or more of the abdominal organs, such as the liver, spleen, gallbladder, stomach, pancreas, kidneys, large or small intestines, or appendix.

2. What is your role as an EMT in treating a patient with abdominal pain?

The underlying cause of a patient's abdominal pain, acute or chronic, is often difficult to identify—even for a physician. As an EMT, it is far more important for you to recognize life-threatening conditions and provide prompt emergency care than it is to identify the underlying cause of the patient's pain. Patients who are in pain, especially when the pain occurs suddenly, are often very anxious and scared; providing emotional support is an important part of your role.

3. What is the proper technique of assessing a patient's abdomen? What should you assess for?

Although assessment of the abdomen may help localize the source of a patient's pain, it should not be prolonged. Place the patient in a supine position with the legs drawn up and flexed at the knees; this position will relax the abdominal muscles and may alleviate some of his or her pain. Look at the abdomen first; does it appear distended (enlarged)? Do you see any pulsating masses (indicates an aortic aneurysm)? Is there bruising of the abdominal wall? Ask the patient where the pain is most intense and assess that area last. If the most painful area is palpated first, the patient may guard against further examination, making your assessment more difficult and less reliable. Gently palpate the four abdominal quadrants to determine whether each quadrant is rigid or soft, or tender, and note the presence of any masses. Pay particular attention to the patient's facial expressions when palpating each abdominal quadrant; they may yield valuable information. Note whether the pain is localized to a particular quadrant or diffuse (wide-spread). Determine whether the patient can relax the abdominal wall on command; if he or she cannot, the abdomen is said to be rigid. Avoid vigorous palpation of the abdomen; doing so will only cause the patient more pain and can worsen his or her condition, especially if one of the abdominal organs is enlarged and fragile.

4. What is the difference between radiating pain and referred pain?

Radiating pain "moves" from its point of origin to other parts of the body, such as the pain from pancreatitis, which may radiate to the back, or pain from a kidney stone blockage, which may radiate to the groin. With radiating pain, there is pain at point A and point B, with a "trail" of pain in between the two points.

Referred pain originates in a particular organ but is described or perceived by the patient as pain in a different location or pain at the point of origin and another location. For example, the origin of pain associated with cholecystitis—inflammation of the gall-bladder—is usually the right upper quadrant of the abdomen. However, the patient commonly reports pain in the right shoulder. In some cases, the patient reports pain in both the right upper quadrant and the right shoulder. Unlike radiating pain, there is no pain in between the two points.

5. What do the patient's vital signs indicate?

The patient's vital signs indicate shock. His respirations are rapid (tachypnea); he has a rapid heart rate (tachycardia); his skin is cool, pale, and diaphoretic (sweaty); and his blood pressure—considering the fact the he has a history of hypertension—is low. Whether the patient has an intra-abdominal infection (peritonitis) or intra-abdominal bleeding, the end result, if untreated, will be the same—death!

It is more important to recognize life-threatening conditions (eg, shock) than it is to determine the exact cause of a patient's abdominal pain, or any pain for that matter. You must begin immediate treatment aimed at maintaining adequate perfusion, such as applying high-flow oxygen (your partner has already done this), keeping him warm, and rapidly preparing for transport.

6. What do you suspect is the cause of the patient's abdominal pain?

Although only a physician can determine the exact cause of the patient's pain, a severe abdominal pain that radiates to the lower back is characteristic of abdominal aortic aneurysm.

The typical patient with an abdominal aortic aneurysm is a man in his late 60s or older. As long as the aneurysm is not expanding, the patient usually will be asymptomatic. When the aneurysm starts to expand, however, the patient has a sudden onset of abdominal pain, which is classically described as a ripping or searing sensation in the abdomen that radiates to the back. When an aortic aneurysm starts expanding and producing symptoms, rupture may be imminent. If aortic rupture occurs, the patient often bleeds to death (exsanguination) very quickly. If the aneurysm is leaking, however, blood will accumulate in the abdominal cavity and cause signs of shock; this is what may be happening to your patient.

7. Are there any special considerations for this patient? If so, what are they?

As with any patient exhibiting signs of shock, your priority is to provide transport to an appropriate medical facility without delay. Patients with a suspected aortic aneurysm must be handled carefully; avoid rough driving and unnecessary bumps in the road. Because this is a fragile situation, with a large, leaking artery, avoid further palpation of the abdomen. Some patients with an abdominal aortic aneurysm have a pulsating mass that can be palpated (and sometimes seen) near the umbilicus. If you see a pulsating mass, *do not* touch it; doing so could cause the aorta to rupture.

Avoid anything that will make the patient more anxious; anxiety causes increases in heart rate and blood pressure. An acute increase in blood pressure, even a slight one, may be all that is needed to cause an aortic rupture. In this particular patient, you should avoid elevating the patient's legs, unless otherwise instructed to do so by medical control. Elevating the lower extremities may cause a surge of blood back to the heart, resulting in an increase in blood pressure.

8. Could you have done anything definitively for this patient in the field? Why or why not?

No. Definitive care (eg, surgically repairing the aneurysm) can only be provided at the hospital. Although paramedics can start intravenous lines and give pain medications, these interventions are simply aimed at controlling pain and partially treating shock, not fixing the aneurysm. Your role as an EMT is to recognize the patient's condition is serious, provide emergency medical treatment, and transport without delay.

Narrative

Dispatched for 79-year-old man with abdominal pain. On arrival at the scene, found the patient lying on his side on a couch in his living room; his knees were drawn up to his abdomen. He was conscious and alert, but very restless and in severe pain. His skin was cool, pale, and diaphoretic. The patient states that the pain, which began suddenly, is in his abdomen and is severe. He further states that the pain radiates to his lower back. Pain severity, per patient, is a 10 on a scale of 0 to 10. Patient denies nausea, vomiting, or any other symptoms. History is significant for hypertension, depression, and an appendectomy 30 years ago. Applied high-flow oxygen via nonrebreathing mask, obtained vital signs, and performed further assessment. Vital signs revealed tachycardia, tachypnea, a relatively low blood pressure, and an oxygen saturation level of 96%. Assessment of abdomen revealed that it was diffusely tender to palpation and guarded. No abdominal distention was noted. Covered patient with blanket to keep him warm, placed him onto the stretcher, loaded him into the ambulance, and began transport to the hospital. Continued oxygen therapy en route and continuously monitored his condition. He remained conscious and alert, but restless, and stated that his pain was still a 10/10. Called radio report to the hospital; no further orders were given by the attending physician. Delivered patient to the emergency department without incident. Verbal report was given to charge nurse.**End of report**

Prep Kit

Ready for Review

- The acute abdomen is a medical emergency, requiring prompt but gentle transport.
- The pain, tenderness, and abdominal distention associated with an acute abdomen may be signs of peritonitis, which may be caused by any condition that allows pus, blood, feces, urine, gastric juice, intestinal contents, bile, pancreatic juice, amniotic fluid, or other foreign material to lie within or adjacent to the peritoneum.
- In addition to abdominal disease or injury, problems in the gastrointestinal, genital, and urinary systems may also cause peritonitis.
- Signs and symptoms of acute abdomen include pain, nausea, vomiting, and a tense, distended abdomen.
- Pain is common directly over the inflamed area of the peritoneum, or it may be referred to another part of the body. Referred pain occurs because of the connections between the two different nervous systems supplying the parietal peritoneum and the visceral peritoneum.
- Do not give the patient with an acute abdomen anything by mouth.
- A patient in shock or with any life-threatening condition should be transported without delay. Call for advanced life support assistance if your patient's condition deteriorates during transport.

Vital Vocabulary

acute abdomen A condition of sudden onset of pain within the abdomen, usually indicating peritonitis; immediate medical or surgical treatment is necessary.

appendicitis Inflammation or infection of the appendix.

cholecystitis Inflammation of the gallbladder.

cystitis Inflammation of the bladder.

diverticulitis Inflammation in small pockets at weak areas in the muscle walls.

emesis Vomiting.

gastroesophageal reflux disease (GERD) A condition in which the sphincter between the esophagus and the stomach opens, allowing stomach acid to move up into the esophagus, usually resulting in a burning sensation within the chest; also called acid reflux.

guarding Involuntary muscle contractions (spasm) of the abdominal wall; an effort to protect the inflamed abdomen.

hematemesis Vomiting blood.

hernia The protrusion of an organ or tissue through an abnormal body opening.

ileus Paralysis of the bowel, arising from any one of several causes; stops contractions that move material through the intestine.

kidney stones Solid crystalline masses formed in the kidney, resulting from an excess of insoluble salts or uric acid crystallizing in the urine; may become trapped anywhere along the urinary tract.

melena Black, foul-smelling, tarry stool containing digested blood.

pancreatitis Inflammation of the pancreas.

peritoneum The membrane lining the abdominal cavity (parietal peritoneum) and covering the abdominal organs (visceral peritoneum).

peritonitis Inflammation of the peritoneum.

referred pain Pain felt in an area of the body other than the area where the cause of pain is located.

strangulation Complete obstruction of blood circulation in a given organ as a result of compression or entrapment; an emergency situation causing death of tissue.

uremia Severe kidney failure resulting in the buildup of waste products within the blood. Eventually brain functions will be impaired.

urinary tract infection (UTI) An infection, usually of the lower urinary tract (urethra and bladder) that occurs when normal flora bacteria enter the urethra and grow.

You are dispatched to a homeless shelter for a patient with abdominal pain. Upon arrival you find a 63-year-old man leaning over the toilet vomiting and clutching his abdomen. The patient tells you that he has had the pain for 6 hours but he began vomiting and having throat pain about 30 minutes ago. He states that he had someone call 9-1-1 when the pain became unbearable and he started throwing up bright red blood. This is the first time he has had these symptoms. The pain is in his stomach and throat and he describes it as sharp. He rates the pain as a 10 on a scale of 1 to 10 and states that nothing makes the pain worse or better. He has no allergies and doesn't take any medications although he states that he has a history of a "big liver," high blood pressure, and alcoholism. His last oral intake was a six-pack of beer 4 hours ago. Vital signs are a pulse of 104; respirations of 22; blood pressure 86/58; Spo$_2$ 97% on room air; skin is pale, cool, and diaphoretic.

1. Which of the following conditions could the patient have, based on what you know thus far?

   A. Peptic ulcers
   B. Cholecystitis
   C. Diverticulitis
   D. Nephritis

2. Your partner notes blood in the patient's vomit. The medical term for this is:

   A. hematemesis.
   B. melena.
   C. hematochezia.
   D. steratorrhea.

3. The patient tenses his abdominal muscles during your assessment. This is called:

A. rebound tenderness.
B. tetany.
C. splinting.
D. guarding.

4. You suspect upper gastrointestinal bleeding. All of the following fit into this category, EXCEPT?

A. Esophageal varices
B. Ulcerative colitis
C. Esophagitis
D. Mallory-Weiss tear

5. Based on the patient's presentation and your initial assessment findings you suspect:

A. gastroenteritis.
B. pancreatitis.
C. esophageal varices.
D. cholecystitis.

6. Appropriate management for this patient would include:

A. high-flow oxygen.
B. oral glucose.
C. activated charcoal.
D. placing the patient supine.

7. En route to the emergency department, the patient's condition seems to worsen. Some of his vital signs have changed, while others have not. What is the last vital sign to change in the setting of shock?

A. Heart rate
B. Blood pressure
C. Respiratory rate
D. Pulse oximetry reading

8. What assessment findings support your working diagnosis?

9. What information should you ask the patient about when assessing the nature of illness?

CHAPTER 19

Endocrine and Hematologic Emergencies

© Jones & Bartlett Learning. Courtesy of MIEMSS.

National EMS Education Standard Competencies

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Endocrine Disorders

Awareness that

› Diabetic emergencies cause altered mental status (pp 729, 735–736, 740–741)

Anatomy, physiology, pathophysiology, assessment, and management of

› Acute diabetic emergencies (pp 727–741)

Hematology

Anatomy, physiology, pathophysiology, assessment, and management of

› Sickle cell crisis (pp 742, 744–745)
› Clotting disorders (pp 742–745)

Knowledge Objectives

1. Describe the anatomy and physiology of the endocrine system and its main function in the body. (p 727)
2. Discuss the role of glucose as a major source of energy for the body and its relationship to insulin. (p 728)
3. Define the terms diabetes mellitus, hyperglycemia, and hypoglycemia (pp 728–730)
4. Describe the differences and similarities between hyperglycemic and hypoglycemic diabetic emergencies, including their onset, signs and symptoms, and management considerations. (pp 729–730)
5. Distinguish between the individual types of diabetes and how their onset and presentations are different. (pp 730–732)
6. Describe the interventions for providing emergency medical care to both a conscious and unconscious patient with an

altered mental status and a history of diabetes who is having symptomatic hyperglycemia. (p 733)

7. Describe the interventions for providing emergency medical care to both a conscious and unconscious patient with an altered mental status and a history of diabetes who is having symptomatic hypoglycemia. (pp 733–734)
8. Explain the process for assessing and managing the airway of a patient with an altered mental status, including ways to differentiate a hyperglycemic patient from a hypoglycemic patient. (pp 733–735, 741)
9. Explain some age-related considerations when managing a pediatric patient who is experiencing symptomatic hypoglycemia. (p 734)
10. Discuss the steps the EMT should follow when conducting a primary and secondary assessment of a patient with an altered mental status who is suspected of having diabetes. (pp 734–736)
11. Explain when it is appropriate to obtain medical direction when providing emergency medical care to a patient with diabetes. (p 737)
12. Explain some age-related considerations when managing an older patient who has undiagnosed diabetes. (p 737)
13. Provide the forms, dose, administration, indications, and contraindications for giving oral glucose to a patient with a decreased level of consciousness who has a history of diabetes. (p 738)
14. Discuss the composition and functions of blood. (pp 741–742)
15. Describe the pathophysiology of sickle cell disease, complications, and management of sickle cell disease. (pp 742, 745)
16. Describe two types of blood clotting disorders, and the risk factors, characteristics, and management of each. (pp 742–745)

Skills Objectives

1. Demonstrate the assessment and care of a patient with hypoglycemia and a decreased level of consciousness. (pp 729–730, 734–741)
2. Demonstrate how to administer oral glucose paste to a patient who is experiencing a low glucose level. (p 739, Skill Drill 19-1)

Introduction

The endocrine system directly or indirectly influences almost every cell, organ, and function of the body. Consequently, patients with an endocrine disorder often are seen with a multitude of signs and symptoms that require a thorough assessment and immediate treatment.

This chapter discusses diabetes mellitus type 1 and diabetes mellitus type 2. You will gain an understanding of the role of the pancreas in hormone production and release. The determination of hyper-glycemia versus hypoglycemia is explained in detail, because their presentations can be very similar with subtle differences. Further discussion focuses on the signs and symptoms of low and high blood glucose levels as well as the adverse effects of chronically high blood glucose levels.

This chapter also discusses common hematologic emergencies that are often missed in patients. Although hematologic disorders can be difficult to assess and treat in a prehospital setting, your actions may save a patient's life.

Endocrine Emergencies

Anatomy and Physiology

The **endocrine system** is a communication system that controls functions inside the body. This system, along with the other systems, maintains the body's homeostasis. **Endocrine glands** secrete messenger **hormones**, which are chemical substances produced by a gland. Hormones travel through the blood to the end organs, tissues, or cells that they are intended to affect. When the hormone arrives, the cell, tissue, or organ receives the message and an action or cellular process takes place.

Endocrine disorders are caused by an internal communication problem. If a gland is not functioning normally, it may produce more hormone (hypersecretion) than is needed or it may not produce enough hormone (hyposecretion). A gland may be functioning correctly, but the receiving organ may not be responding. The receiving organ in these cases is less responsive to the amount of hormone it would take under normal circumstances to initiate an action or cellular response.

The brain needs two things to survive: **glucose** and oxygen. **Insulin** is necessary for glucose to enter the cells for metabolism. Without the proper balance of hormones (ie, without enough insulin), the cell does not get fed.

The pancreas produces and stores two hormones that play a major role in glucose metabolism: glucagon and insulin. A small portion of the pancreas is filled with the islets of Langerhans. Within these islets are alpha and beta cells. The alpha cells produce glucagon and the beta cells produce insulin.

In a person without diabetes, the pancreas stores and secretes insulin and glucagon in response to the level of glucose in the blood **Figure 19-1**. When a person eats, the level of glucose in his or her blood rises. In response, the pancreas secretes insulin into the blood; this allows the glucose to enter the body's cells and be used for energy. It also allows glucose to be stored in the form of glycogen in the liver and skeletal muscles for use at a later time. As blood glucose levels return to normal, insulin stops being secreted and the body is said to be in a fed state.

YOU are the Provider — PART 1

A call for service comes in at 1500 hours. The call details from dispatch describe a 23-year-old man with weakness and nausea. You arrive on scene to find a previously healthy man who has had flulike symptoms for the last 6 days. The patient's medical history is unremarkable. Your interview reveals that he has two family members with diabetes mellitus. While obtaining the patient's history and performing a physical examination, you find that your patient has symptoms related to eating and drinking. The patient tells you that he has been experiencing the symptoms for a little more than a week. You suspect the symptoms have been occurring much longer though because of his weight loss, unquenchable thirst, unrelenting hunger, and increased frequency of urination.

1. What processes are being described by the patient?
2. What hormone is missing in diabetes mellitus type 1?

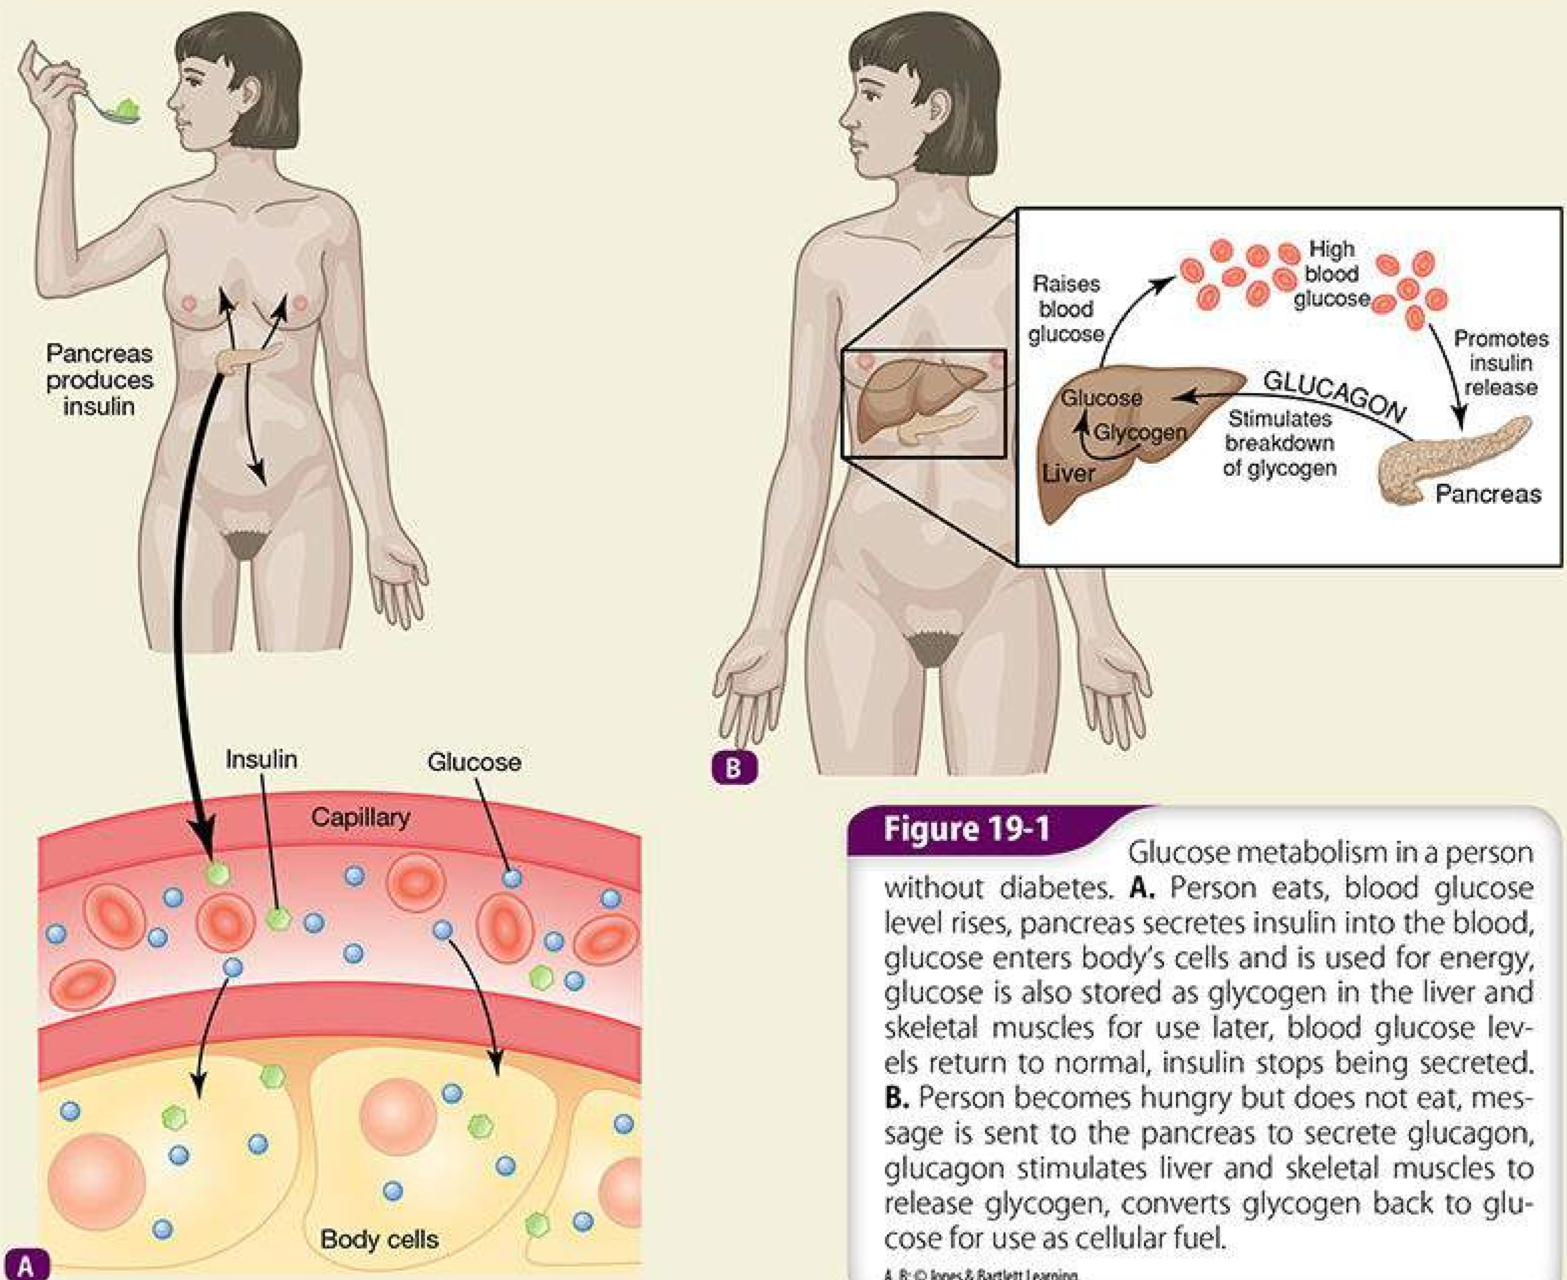

Figure 19-1 Glucose metabolism in a person without diabetes. **A.** Person eats, blood glucose level rises, pancreas secretes insulin into the blood, glucose enters body's cells and is used for energy, glucose is also stored as glycogen in the liver and skeletal muscles for use later, blood glucose levels return to normal, insulin stops being secreted. **B.** Person becomes hungry but does not eat, message is sent to the pancreas to secrete glucagon, glucagon stimulates liver and skeletal muscles to release glycogen, converts glycogen back to glucose for use as cellular fuel.

As time passes, the body will become hungry again. If the hungry individual skips or delays a meal, a message is sent to the pancreas to secrete glucagon. Glucagon then stimulates the liver and the skeletal muscles to release glycogen and converts it back to glucose for use as cellular fuel.

Pathophysiology

According to the American Diabetes Association, in 2012 diabetes mellitus affected approximately 9.3% of the population. **Diabetes mellitus** is a disorder of glucose metabolism, such that the body has an impaired ability to get glucose into the cells to be used for energy. The patient with diabetes has either impaired insulin production or not enough functional receptors on the surface of the cells for the insulin to bind to. Glucose cannot get into the cell, the cell goes unfed, and the level of glucose in the blood remains and continues to rise **Figure 19-2**.

Without treatment, blood glucose levels become too high, which in severe cases may cause life-threatening illness, or coma and death. When diabetes mellitus is properly managed, a process that involves both the patient and physician, the patient can live a relatively normal life. However, people who do not manage their diabetes well often experience severe complications, including blindness, cardiovascular disease, and kidney failure, which dramatically affect the length and quality of life.

There are three types of diabetes: diabetes mellitus type 1, diabetes mellitus type 2, and pregnancy-induced gestational diabetes. A detailed discussion of gestational diabetes can be found in Chapter 33, *Obstetrics and Neonatal Care*.

Treatments for diabetes include medications and injectable hormones that lower the patient's blood glucose level. These hormones and medications, whether administered correctly or incorrectly, can create a medical emergency for the patient with diabetes. If left unrecognized and untreated, a low blood glucose level (hypoglycemia) can be life threatening. You must also recognize the signs and symptoms of a high blood glucose level (hyperglycemia) so you can provide the appropriate treatment and deliver the patient to the next level of care.

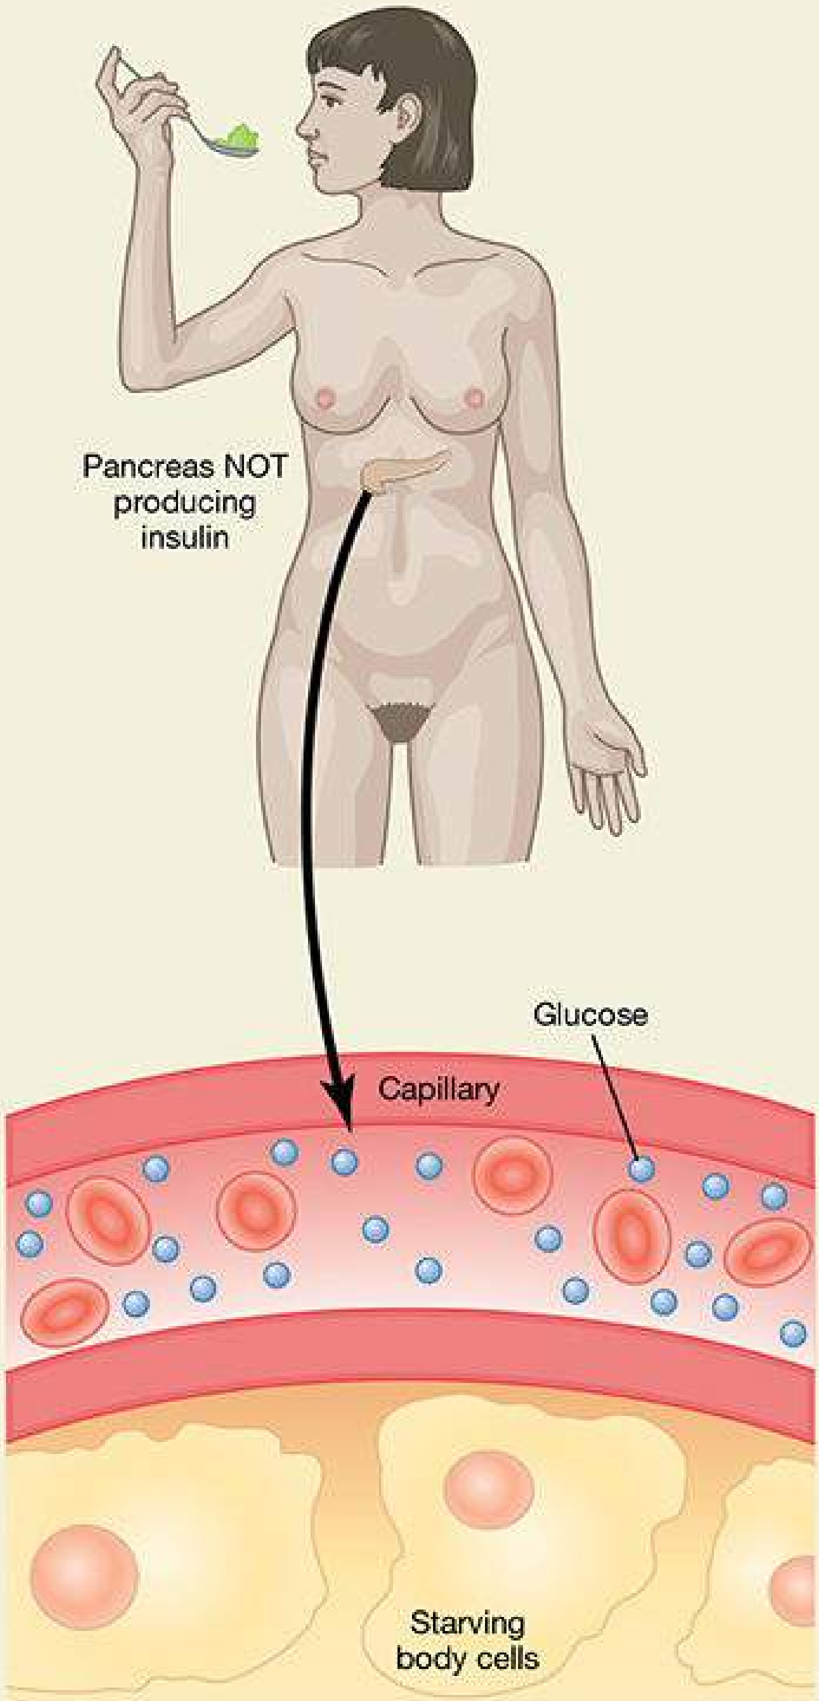

Figure 19-2 Diabetes is defined as the lack of or ineffective action of insulin. Without insulin, cells begin to "starve" because insulin is needed to allow glucose to enter and nourish the cells.

Hyperglycemia is a state in which the blood glucose level is above normal. **Hypoglycemia** is a state in which the blood glucose level is below normal **Figure 19-3**. Hyperglycemia and hypoglycemia can occur with both diabetes mellitus type 1 and type 2. In the field you will encounter many patients displaying the signs and symptoms of high and low blood glucose levels.

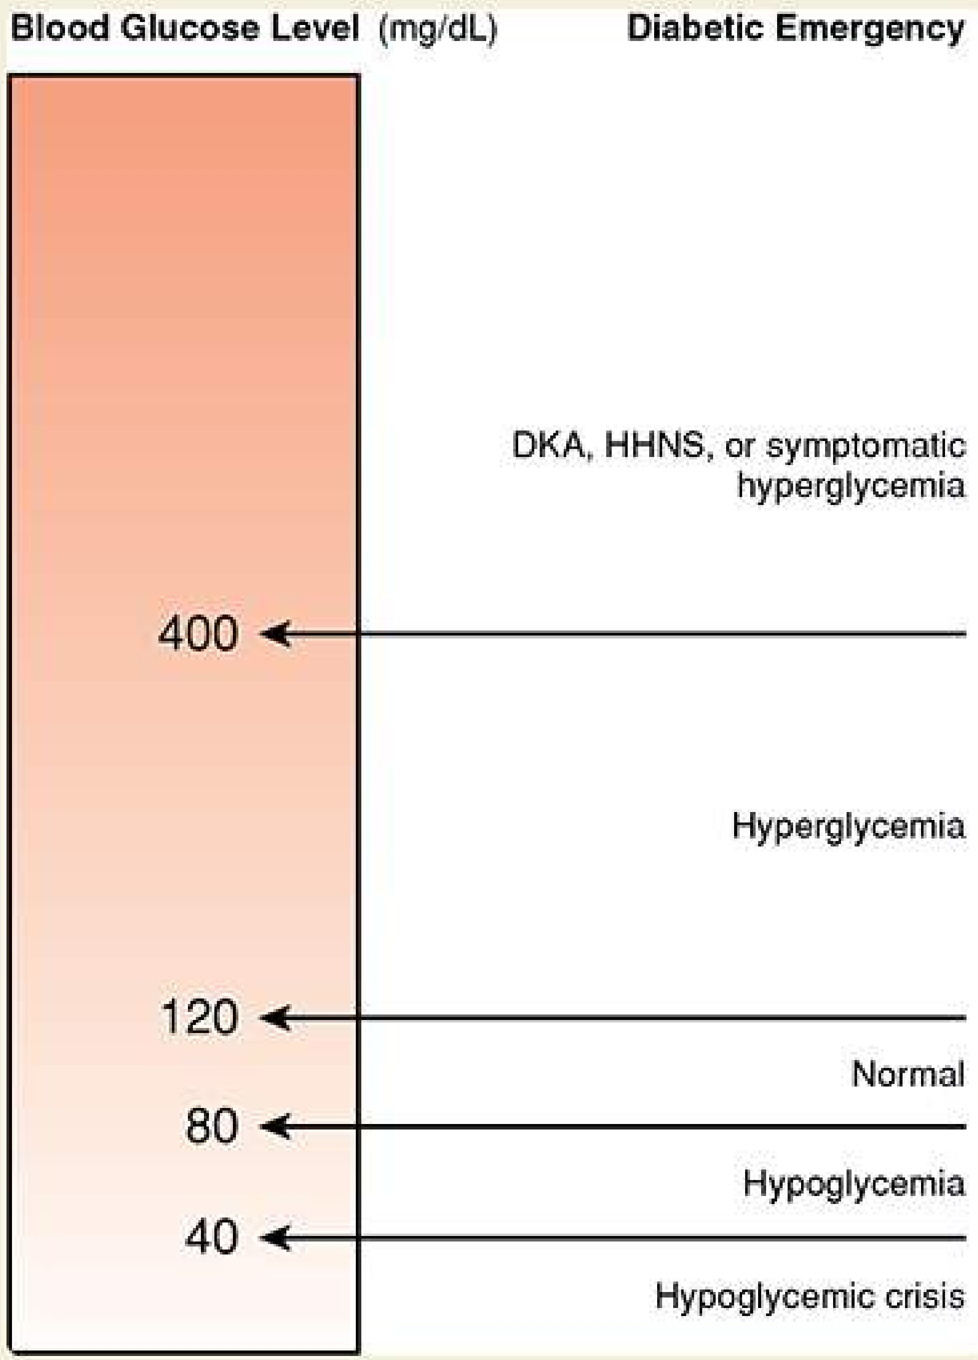

Figure 19-3 The left column illustrates blood glucose levels; the right column illustrates the conditions associated with that particular level of blood glucose. Notice that the normal range is rather small in comparison to the other ranges.

Hyperglycemia and hypoglycemia can be quite similar in their presentation. As an EMT, you must look for the subtle differences that define one disorder from the other Table 19-1. Patients at both extremes, with very low and very high blood glucose levels, can present with altered mental status. Patients with severe hypoglycemia are more likely to have a depressed level of consciousness than patients with hyperglycemia. Be careful not to incorrectly label patients as being intoxicated.

Altered mental status related to diabetic emergencies can often mimic alcohol intoxication, and intoxicated patients often have abnormal glucose levels. Be thorough and check a fingerstick glucose level for all patients with altered mental status.

Table 19-1 Hyperglycemia *Versus* Hypoglycemia

History	Hyperglycemia	Hypoglycemia
Onset	Gradual (hours to days)	Rapid (within minutes)
Skin	Warm and dry	Pale, cool, and moist
Infection	Common	Uncommon
Gastrointestinal tract		
Thirst	Intense	Absent
Hunger	Present and increasing	Absent
Vomiting/abdominal pain	Common	Uncommon
Respiratory system		
Breathing	With diabetic ketoacidosis (DKA) there are rapid, deep (Kussmaul) respirations	Normal; may become shallow or ineffective if hypoglycemia is severe and mental status is depressed
Odor of breath	With DKA there may be a sweet, fruity odor	Normal
Cardiovascular system		
Blood pressure	Normal to low	Normal to low
Pulse	Rapid, weak, and thready	Rapid, weak
Nervous system		
Con-sciousness	Restlessness, possibly progressing to coma; abnormal or slurred speech; unsteady gait	Irritability, confusion, seizure, or coma; unsteady gait
Treatment		
Response	Gradual, within 6 to 12 hours following medical treatment	Immediate improvement after administration of glucose

Hypoglycemia can develop if a person with diabetes takes his or her medications (pills or insulin) as prescribed but fails to eat enough food. Alternatively, a person with diabetes may intentionally or accidentally take too much medication, resulting in low blood glucose levels despite normal dietary intake. All hypoglycemic patients require prompt treatment with oral glucose paste (if alert and able to protect their airway) or injection of glucose (dextrose) or glucagon by an advanced life support (ALS) provider.

Diabetes Mellitus Type 1

Type 1 diabetes is an autoimmune disorder in which the individual's immune system produces antibodies against the pancreatic beta cells. Essentially, this disease is about the missing pancreatic hormone insulin. Insulin is the "key" to the "door" of the cell. Without insulin, glucose cannot enter the cell, and the cell cannot produce energy.

The onset of this disorder usually happens from early childhood through the fourth decade of life. The patient's immune system progressively destroys the ability of the pancreas to produce insulin. Without the insulin from the pancreatic beta cells, the patient must obtain insulin from an external source. Patients with type 1 diabetes cannot survive without insulin. Patients who inject insulin often need to check their blood glucose levels up to six times a day or more using a lancet and a small capillary blood sample read by a glucometer **Figure 19-4**.

Many people with type 1 diabetes have an implanted insulin pump, which continuously measures the body's glucose levels and provides an (adjustable) infusion of insulin and correction doses of insulin based on carbohydrate intake at mealtimes **Figure 19-5**. The presence of an insulin pump limits the number of times patients have to check their fingerstick glucose level. Unfortunately, insulin pumps can malfunction and hyperglycemic or hypoglycemic diabetic emergencies can develop. Always inquire about the presence of an insulin pump—particularly in patients with type 1 diabetes—and ask the patient if it is working properly.

Type 1 diabetes is the most common metabolic disease of childhood. A patient with new-onset type 1 diabetes will have symptoms related to eating and drinking:

- Polyuria
- Polydipsia
- Polyphagia
- Weight loss
- Fatigue

Normal blood glucose level is between 80 and 120 mg/dL. The body's metabolism is sensitive to the levels of particular substances, such as glucose, in the blood. The kidneys filter the blood and thus manage all of the substances present in the blood. At normal levels, glucose remains in the blood as it is filtered.

B

C

Figure 19-4 The blood glucose self-monitoring kit with digital meter is a device used by patients at home and by EMTs in the field in many EMS systems. Three types are shown.

A Accu-Chek® Aviva used with permission of Roche Diagnostics; B © Stockbyte/Thinkstock; C © instamatic/iStock.

When a patient's blood glucose level is above normal, the kidney's filtration system becomes overwhelmed and glucose spills into the urine. The increased amount of glucose in the urine causes more water to be pulled out of the bloodstream into the urine. This results in more frequent urination, or **polyuria**.

Figure 19-5 An insulin pump.

JIM BARCUS/MCT/Landov.

Increased urine production and urination also cause dehydration and increased thirst and can lead to severe electrolyte abnormalities. An increase in fluid consumption, called **polydipsia**, occurs in an attempt to quench this thirst.

In the early phase of diabetes, patients may report severe hunger and increased food intake, a condition known as **polyphagia**. Over time though, particularly if diabetes remains undiagnosed or untreated, appetite will decrease and patients often lose weight.

The autoimmune destruction of the pancreatic beta cell takes time to progress. For this reason initial symptoms are typically subtle and not readily apparent to the patient. As the lack of insulin becomes more profound, the patient will notice increasing fatigue and malaise along with vague symptoms of generalized illness.

When the body's cells do not receive the glucose they require for energy, the body resorts to burning fat for energy. When the body burns fat rather than glucose, acid waste is produced. These acids are called ketones. As ketone levels go up in the blood, the ketones also begin to spill into the urine (just like the excess glucose). When the kidneys become saturated with glucose and ketones, they do not work properly to maintain acid-base balance in the body. The body responds with a backup system and the patient begins to breathe faster and deeper. This respiratory pattern is the body's attempt to reduce the acid level by releasing more carbon dioxide (CO_2) through the lungs. This breathing pattern is known as **Kussmaul respirations**.

If fat metabolism and ketone production continue, a life-threatening illness called **diabetic ketoacidosis (DKA)** can develop in patients with diabetes. DKA may present as:

- Generalized illness, accompanied by:
  - Abdominal pain
  - Body aches

- Nausea
- Vomiting
- Altered mental status or unconsciousness (if severe)

If DKA is not rapidly recognized and treated, it can result in death.

When a patient with DKA has an altered mental status, ask the patient's family and friends about the patient's history and presentation. Obtain a glucose level with a fingerstick using a lancet and a glucometer (this is covered in Chapter 9, *Patient Assessment*). The patient with DKA will generally have a fingerstick glucose level higher than 400 mg/dL.

This presentation of the patient with type 1 diabetes in DKA does not only occur when there is an absolute lack of insulin. DKA may also present in cases of a relative lack of insulin, which may occur when there is an acute illness, or an untreated infection or other stressor on the body that leaves the patient with type 1 diabetes in a weakened condition.

Diabetes Mellitus Type 2

Type 2 diabetes is caused by resistance to the effects of insulin at the cellular level. Recall that we described insulin as the key to the door of the cell. Insulin resistance means the lock is unable to accept the key. As a review, in diabetes mellitus type 1 no insulin is produced, so there are no keys. In diabetes mellitus type 2 there are fewer insulin receptors, so there are not enough locks.

Obesity predisposes patients to type 2 diabetes; there is an association between obesity and increased resistance to the effects of insulin. As the number of obese people continues to rise, so does the number of patients with type 2 diabetes.

When diabetes begins, the individual's pancreas produces more insulin in an attempt to make up for the increased levels of blood glucose and dysfunction of cellular insulin receptors. Over time this response becomes inefficient. The blood glucose levels continue to rise and do not respond when the pancreas secretes insulin, a process called insulin resistance. In some cases, insulin resistance can be improved by exercise and dietary modification.

In many instances diet and exercise alone cannot control insulin resistance, and oral medications must be started to better control blood glucose levels. Oral medications used to treat type 2 diabetes vary widely. Some of them increase the secretion of insulin and pose a high risk of hypoglycemic reaction, while others do not Table 19-2. Injectable medications and various insulin preparations are also used for type 2 diabetes when oral medications alone will not regulate blood glucose.

Insulin is a hormone that is destroyed when taken by mouth, so it must be injected. Many of the oral medications listed either encourage the pancreas to produce more insulin or the cells to stimulate receptors for insulin. Other medications decrease the effects of glucagon and decrease the release of glucose stored in the liver (glycogen) so as to not increase the blood glucose levels during sleep or sedentary periods. None of the available medications is the perfect solution for every patient, however.

Diabetes mellitus type 2 is often diagnosed at a yearly medical examination. In some cases, the patient's physician discovers diabetes mellitus type 2 when treating the patient for a complaint related to high blood glucose levels. Examples of such complaints include recurrent infection, change in vision, or numbness in the feet.

Words of Wisdom

The patient with diabetes needs to be vigilant about maintaining a proper glucose level through diet, exercise, and, often, taking medication. If patients with diabetes have prolonged hyperglycemia or other associated conditions, serious long-term complications may develop.

Table 19-2 Common Oral Medications Used to Treat Type 2 Diabetes

Glipizide (Glucotrol)*
Glyburide (DiaBeta, Glynase, Micronase)*
Metformin (Glucophage)
Pioglitazone (Actos), rosiglitazone (Avandia)
Sitagliptin (Januvia)

*These medications increase the risk of hypoglycemia.

Symptomatic Hyperglycemia

Symptomatic hyperglycemia occurs when blood glucose levels are very high. The patient is in a state of altered mental status resulting from several combined problems. In type 1 diabetes, hyperglycemia leads to ketoacidosis with dehydration from excessive urination. In type 2 diabetes, hyperglycemia leads to a nonketotic hyperosmolar state of dehydration due to the discharge of fluids from all of the body systems and eventually out through the kidneys, leading to a much more ominous situation of fluid imbalance. Hyperglycemia does not always result in a crisis event. If an individual has hyperglycemia for a protracted length of time, it is not uncommon for the consequences of diabetes to present. These are wounds that do not heal, numbness in the hands and feet, blindness, renal failure, and gastric motility problems, to name a few.

When blood glucose levels are not controlled in diabetes mellitus type 2, a condition known as **hyperosmolar hyperglycemic nonketotic syndrome (HHNS)** can develop. This condition is similar to DKA in type 1 diabetes. The onset of this disorder is often associated with a profound infection or illness; however, this is not always the case.

Key signs and symptoms of HHNS include:

- Hyperglycemia
- Altered mental status, drowsiness, lethargy
- Severe dehydration, thirst, dark urine
- Visual or sensory deficits
- Partial paralysis or muscle weakness
- Seizures

Higher glucose levels in the blood cause the excretion of glucose in the urine. Patients respond by increasing their fluid intake precipitously (polydipsia) causing an equally precipitous excretion of fluid (polyuria). In HHNS, however, the patient cannot drink enough fluid to keep up with the exceedingly high glucose levels in the blood. The kidneys become overwhelmed and the patient's blood becomes much more concentrated than normal. As HHNS progresses, the urine becomes rather dark and concentrated. The term hyperosmolarity describes very concentrated blood as a result of relative dehydration. As HHNS progresses the patient may become unconscious or have seizure activity due in part to the severe dehydration that results.

Symptomatic Hypoglycemia

Symptomatic hypoglycemia is an acute emergency in which a patient's blood glucose level drops and must be corrected swiftly. A low blood glucose level can occur in patients who inject insulin or use oral medications that stimulate the pancreas to produce more insulin. When insulin levels remain high, glucose is rapidly taken out of the blood to fuel the cells. If glucose levels fall too low, there may be an insufficient amount to supply the brain. The mental status of the patient declines and he or she may become aggressive or display unusual behavior. If blood glucose remains low, unconsciousness and permanent brain damage can quickly follow.

YOU are the Provider — PART 2

You perform a primary assessment of the patient while your partner applies high-flow oxygen via a nonrebreathing mask. You attempt to obtain more information from the patient, but he is slow to answer your questions and is slightly confused. He can tell you that he has been getting progressively worse over the last 3 to 5 days. The patient's friends and wife tell you he has been experiencing weight loss for the last month but he seems to be eating more and more.

Recording Time: 0 Minutes	
Appearance	Weak and confused
Level of consciousness	Conscious, slow to respond, and confused
Airway	Open; clear of secretions or foreign bodies
Breathing	Increased rate and depth
Circulation	Radial pulses, rapid and weak; skin, warm and dry with poor turgor

The patient's wife tells you that he has been urinating frequently and has been drinking large quantities of water, soda, and milk. Your partner assesses his blood glucose level with the glucometer.

3. What should you expect the patient's blood glucose level to read? Why?
4. What is causing the patient's frequent urination and deep, rapid breathing?

Symptomatic hypoglycemia can occur for many different reasons. Some of the more common reasons for a low blood glucose level to develop are the patient or caregiver administered:

- A correct dose of insulin with a change in routine (the patient exercised more, consumed a meal later than usual, or skipped the meal)
- More insulin than necessary
- A correct dose of insulin without the patient eating a sufficient amount
- A correct dose of insulin and the patient developed an acute illness

Hypoglycemia develops much more quickly than hyperglycemia. In some instances, it can occur in a matter of minutes. Hypoglycemia can be associated with the following signs and symptoms:

- Normal to shallow or rapid respirations
- Pale, moist (clammy) skin
- Diaphoresis (sweating)
- Dizziness, headache
- Rapid pulse
- Normal to low blood pressure
- Altered mental status (aggressive, confused, lethargic, or unusual behavior)
- Anxious or combative behavior
- Seizure, fainting, or coma
- Weakness on one side of the body (may mimic stroke)
- Rapid changes in mental status

Hyperglycemia is a complex metabolic condition that usually develops over time and involves all the tissues of the body. Correcting this condition may take many hours in a well-controlled hospital setting. Hypoglycemia, however, is an acute condition that can develop rapidly. A patient with diabetes who has taken his or her standard insulin dose and missed lunch may have symptomatic hypoglycemia before dinner. The condition is just as quickly reversed by giving the patient glucose. Without the glucose, however, the patient can sustain permanent brain damage. Minutes count.

Special Populations

Low blood glucose level events are not uncommon in pediatric patients. Most children adapt well to the routine of managing their diabetes, but during periods of growth their blood glucose may be more difficult to regulate. Some toxic ingestions and overdose cause hypoglycemia in children. Children cannot store excess glucose as effectively as adults; therefore, the blood glucose level can drop even in children without diabetes after a severe injury or illness. As an EMT, you must have a high index of suspicion for a low glucose level when you encounter a child who has an altered mental status or depressed level of consciousness.

Patient Assessment of Diabetes

Scene Size-up

Evaluate scene safety as you arrive on scene and as you approach the patient. Make sure that all hazards are addressed. Remember that patients with diabetes often use syringes to administer insulin. It is possible you may be stuck by a used needle that was not disposed of properly. Insulin syringes on the night-stand, insulin bottles in the refrigerator, a plate of food, or a glass of orange juice are important clues that may help you decide what is possibly wrong with your patient. Evaluate each situation quickly and make sure necessary personal protective equipment is readily available. Use standard precautions. As you approach, question bystanders on events leading to your arrival.

Although your report from dispatch may be for a patient with an altered mental status, keep open the possibility that trauma may have occurred because of a medical incident. Determine mechanism of injury and/or nature of illness. Do not let your guard down even on what appears to be a routine call.

Primary Assessment

Perform a primary assessment to form a general impression of the patient. How does the patient look? Does he or she appear anxious, restless, or listless? Is the patient apathetic or irritable? Is the patient interacting appropriately with his or her environment? These initial observations may lead you to suspect high or low blood glucose values. Identify life threats, and provide lifesaving interventions, particularly airway management. Determine the patient's level of consciousness using the AVPU scale. If a patient who you suspect has diabetes is unresponsive, call for ALS immediately. An unconscious patient may have undiagnosed diabetes. In patients with altered mental status, you may be able to determine whether a diabetic emergency exists by assessing the patient's blood glucose level if you have the proper equipment and training. Perform cervical spine immobilization, when necessary, and provide rapid transport. At the emergency department (ED), diabetes and its complications can be quickly diagnosed.

Remember that even though a person has diabetes, the diabetes may not be causing the current problem; heart attack, stroke, or another medical emergency may be the cause. For this reason, you must always carry out a thorough, careful primary assessment, paying attention to the ABCs.

While you are forming your general impression, assess the patient's airway and breathing. Patients showing signs of inadequate breathing, a pulse oximetry level less than or equal to 94%, or altered mental status should receive high-flow oxygen at 12 to 15 L/min via nonrebreathing mask. A patient who is hyperglycemic may have rapid, deep respirations (Kussmaul respirations) and sweet, fruity breath. A patient who is hypoglycemic will have normal or shallow to rapid respirations. If the patient is not breathing or is having difficulty breathing, open the airway and insert an airway adjunct, administer oxygen, and assist ventilations. Continue to monitor the airway while you provide care.

Once you have assessed airway and breathing and have performed the necessary lifesaving interventions, check the patient's circulatory status. A patient with dry and warm skin indicates hyperglycemia, whereas a patient with moist and pale skin indicates hypoglycemia. The patient with symptomatic hypoglycemia will have a rapid, weak pulse.

Whether you decide to transport at this stage of the assessment will depend on the patient's level of consciousness and the ability to swallow. Patients with an altered mental status and impaired ability to swallow should be transported promptly. Patients who have the ability to swallow and are conscious enough to maintain their own airway may be further evaluated on scene and interventions performed.

History Taking

Investigate the chief complaint or the history of the present illness. Responsive patients usually are able to provide their own medical history. If the patient has eaten but has not taken insulin, it is more likely that hyperglycemia is developing. If the patient has taken insulin but has not eaten, the problem is more likely to be hypoglycemia. A patient with diabetes will often know what is wrong. If the patient is not thinking or speaking clearly (or is unconscious), ask a family member or bystander the same questions.

Physical signs such as tremors, abdominal cramps, vomiting, a fruity breath odor, or a dry mouth may guide you in determining whether the patient is hypoglycemic or hyperglycemic.

You will need to obtain a SAMPLE history from your patient or the family or bystanders if the patient is unable to speak. In addition, be sure to ask the following questions of a patient known to have diabetes:

- Do you take insulin or any pills that lower your blood sugar?
- Do you wear an insulin pump? Is it working properly?
- Have you taken your usual dose of insulin (or pills) today?
- Have you eaten normally today?
- Have you had any illness, unusual amount of activity, or stress?

When you are assessing a patient who might have diabetes, check to see whether he or she has an emergency medical identification device—a wallet card, necklace, or bracelet—or ask the patient or a family member. Remember that the environment, bystanders, and medical identification devices may provide important clues about your patient's condition.

Secondary Assessment

In some instances where the patient is critically ill or injured or the transport time is short, you may not have time to conduct a secondary assessment. In other instances, the secondary assessment may occur on scene or en route to the ED.

First, assess unresponsive patients from head to toe with a secondary assessment of the entire body, looking for clues to their condition. The patient may have experienced trauma resulting from dizziness or from changes in level of consciousness.

As with every call, you should perform a secondary assessment when time permits. With unconscious patients or patients with an altered mental status, you must assume the role of detective and look for problems or injuries that are not obvious because the patient is unable to communicate these to you. Although an altered mental status may be caused by a blood glucose level that is too high or too low, the patient may have sustained trauma or have another metabolic problem. An altered mental status may also be caused by something else, such as intoxication, poisoning, or a head injury. A systematic examination of the patient may provide you with information essential to proper patient care.

When you suspect a diabetes-related problem, a secondary assessment should focus on the patient's mental status and ability to swallow and protect the airway. Obtain a Glasgow Coma Scale score to track the patient's neurologic status.

Obtain a complete set of vital signs, including a measurement of the patient's blood glucose level using a glucometer, if available and local protocols allow. Blood glucose level is commonly determined via a portable glucometer, similar to the one your patient may use at home. The portable blood glucose monitor measures the glucose level in whole blood using either capillary or venous samples. In hypoglycemia, respirations are normal to rapid, pulse is weak and rapid, and skin is typically pale and clammy with a low blood pressure. In hyperglycemia, respirations may be deep and rapid; pulse may be rapid, weak, and thready; and skin may be warm and dry with a normal blood pressure. At times the blood pressure may be low. It should be easier for you to identify abnormal vital signs when you know the blood glucose level is too high or too low. Remember, the patient may have abnormal vital signs and a normal blood glucose value. When this is the case, something else may be causing the patient's altered mental status, vomiting, or other complaints.

It is important to read and understand the operator's manual before using a portable glucometer because the specifications of the device may vary depending on the manufacturer. Some glucometers indicate low ("Lo") when they detect a glucose reading less than 20 mg/dL, whereas others display "Lo" when they detect a reading less than 30 mg/dL. The same is true with a high ("Hi") reading; some glucometers read "Hi" at 550 mg/dL and some at 600 mg/dL; therefore, it is important to know both the upper and lower ranges at which your glucometer functions.

The normal range for glucose levels in blood in nonfasting adults and children is 80 to 120 mg/dL; the blood glucose level in neonates should be above 70 mg/dL.

Reassessment

It is important to reassess the patient with diabetes frequently to assess changes. Is there an improvement in the patient's mental status? Are the ABCs still intact? How is the patient responding to the interventions performed? How must you adjust or change the interventions? In many patients with diabetes, you will note marked improvement with appropriate treatment. Document each assessment, your findings, the time of the interventions, and any changes in the patient's condition. Base your administration of glucose on serial readings if you have access to a glucometer. If a glucometer is not available, a deteriorating level of consciousness indicates that you need to provide more glucose. Again, the use of glucometers and the administration of glucose will be based on your service's protocols and standing orders.

YOU are the Provider — PART 3

Your partner reports that the patient's blood glucose reading on the glucometer is 456 mg/dL. You continue to assess the patient while your partner obtains his vital signs. The patient's wife calls his doctor, who requests that you transport him to the closest hospital. A community hospital is located about 15 miles away.

Recording Time: 5 Minutes	
Respirations	30 breaths/min; deep
Pulse	120 beats/min; weak radial pulses
Skin	Pink, warm, and dry; poor turgor
Blood pressure	112/54 mm Hg
Oxygen saturation (Spo_2)	95% (on oxygen)

5. What other factors can cause hyperglycemia in patients with diabetes?
6. How can you distinguish symptomatic hyperglycemia from symptomatic hypoglycemia?

If your patient is hypoglycemic, conscious, and able to swallow without the risk of aspiration, encourage him or her to take glucose tablets. If those are not available, household sources of glucose may be used, such as juice or other drinks that contain sugar. Do not be afraid to give too much sugar. Do not give sugar-free drinks that are sweetened with saccharin or other synthetic sweetening compounds, because they will have little or no effect. If you are permitted by local protocol, you may also assist the patient in administering a gel preparation or sugar drink. If your hypoglycemic patient is unconscious, or if there is any risk of aspiration, the patient will need intravenous (IV) glucose or intramuscular (IM) or intranasal (IN) glucagon, which most EMTs are not authorized to give. Your responsibility is to provide prompt transport to the hospital, where the proper care can be given. If you are working in a tiered system, AEMTs and paramedics are able to start an IV line and administer IV glucose.

A patient with symptomatic hypoglycemia (rapid onset of altered mental status, hypoglycemia) needs glucose immediately. A patient with symptomatic hyper-glycemia (**acidosis**, dehydration, hyperglycemia) needs insulin and IV fluid therapy. These patients need prompt transport to the hospital for appropriate medical care.

Words of Wisdom

Intranasal glucagon is now available for use in some areas of the country to treat symptomatic hypoglycemia. This has the advantage of not requiring injection yet still achieving rapid absorption even in patients with markedly decreased levels of consciousness. Be aware of this medication and understand your local protocols regarding its use and indications.

Safety Tips

Before you give a conscious patient glucose tablets, anything to eat or drink, or instant glucose, you must ensure that there is no danger of aspiration. One rule of thumb: if patients can lift the cup or squirt the glucose into their own mouths, they are most likely not in danger of aspiration. Watch them carefully!

When there is any doubt about whether a conscious patient with diabetes is going into symptomatic hypoglycemia or symptomatic hyperglycemia, most protocols will err on the side of giving glucose, even though the patient may have hyperglycemia or diabetic ketoacidosis. Untreated hypoglycemia will result in loss of consciousness and can quickly cause significant brain damage or death. The condition of a patient in symptomatic hypoglycemia is far more critical and far more likely to cause permanent problems than the condition of a patient with hyperglycemia or diabetic ketoacidosis. Furthermore, the amount of sugar that is typically given to a patient with symptomatic hypoglycemia is unlikely to make a patient in diabetic ketoacidosis significantly worse. When in doubt, consult medical control.

Determining whether the blood glucose level is too high or too low in a patient with diagnosed diabetes can be difficult when signs and symptoms are confusing and you have no way to test for a blood glucose value. In these situations, perform a thorough assessment and contact the hospital to help sort out the signs and symptoms. The hospital should be a resource for you to help problem-solve situations and provide guidance on how to manage your patient.

Safety Tips

Managing problems related to diabetes and altered mental status poses minimal risk to you because exposure to body fluids is generally very limited. However, some patients can become confused and even aggressive at times. Follow standard precautions, as you would with any other patient. Always use gloves and carefully wash your hands after obtaining and checking a blood sample or coming into contact with any airway secretions.

Special Populations

You may encounter an older patient who has undiagnosed diabetes. The patient is likely to report that he or she has not been feeling well for a while but has not seen a physician. A patient with undiagnosed diabetes or one who is in denial or ignores the advice of his or her physician may call 9-1-1 when the signs and symptoms become pronounced. Nonhealing wounds (which can lead to infection), blindness, renal failure, atypical (silent) myocardial infarction presentation, and other complications are associated with poorly controlled or uncontrolled diabetes. As an EMT, you may be the first to recognize and suggest medical treatment to an older patient. It is important that you recognize the signs and symptoms of diabetes.

Communication with hospital staff is important for continuity of care. Hospital personnel need to be informed about the patient's history, the present situation, your assessment findings, and your interventions and their results.

Document clearly your assessment findings as the basis for your treatment. Patients who refuse transport because their symptoms improve after taking oral glucose may require even more thorough documentation. Patients who receive treatment in the field for hypoglycemia are at great risk for developing symptomatic hypoglycemia in the near future and should be strongly discouraged from refusing further treatment or transportation to the hospital. Many long-acting forms of insulin and most oral diabetic medications remain in the bloodstream far longer than the glucose used to treat these patients. Follow your local protocols for patients who refuse treatment or transport.

Emergency Medical Care for Diabetic Emergencies

Giving Oral Glucose

There are three types of oral glucose preparations available commercially. The most common for EMS providers is a rapidly dissolving gel **Figure 19-6**. The second preparation comes in a large chewable tablet form. The third preparation is a liquid formulation. Glucose gel acts to increase a patient's blood glucose levels. If authorized by your system, you should administer glucose gel to any patient with a decreased level of consciousness who has a history of diabetes. The only contraindications to oral glucose are an inability to swallow and unconsciousness, because aspiration (inhalation of the substance) can occur. Oral glucose itself has no side effects if it is administered properly; however, the risk of aspiration in a patient who does not have a gag reflex is substantial. A conscious patient (even if confused) who does not really need glucose will not be harmed by it. Therefore, do not hesitate to give glucose under these circumstances.

Figure 19-6 Oral glucose is commercially available in gel and tablet form. One tube of gel equals one 15-gram dose.

Courtesy of Paddock Laboratories, Inc.

YOU are the Provider — PART 4

Because of the patient's signs and symptoms, history, and a glucometer reading that indicates a high glucose level, you determine that oral glucose is not indicated. The patient is placed onto the stretcher and loaded into the ambulance. Shortly after departing the scene, you reassess his mental status and vital signs.

Recording Time: 11 Minutes	
Level of consciousness	Conscious but confused
Respirations	30 breaths/min; deep
Pulse	124 beats/min; weak radial pulses
Skin	Pink, warm, and dry; poor turgor
Blood pressure	108/56 mm Hg
Spo_2	96% (on oxygen)

7. What additional treatment should you provide to this patient?

Be sure to wear gloves before placing anything into a patient's mouth. After you have confirmed that the patient is conscious and able to swallow and have obtained an online or off-line order, follow these steps to administer oral glucose **Skill Drill 19-1**:

1. Examine the tube to ensure that it is not open or broken. Check the expiration date Step 1.
2. Squeeze a generous amount onto the bottom third of a bite stick or tongue depressor Step 2.
3. Open the patient's mouth.
4. Place the tongue depressor on the mucous membranes between the cheek and gum, with the gel side next to the cheek Step 3. Once the gel is dissolved, or if the patient loses consciousness or has a seizure, remove the tongue depressor. Repeat until the entire tube has been used. Note that the patient should not swallow the glucose; it acts more quickly when dissolved in the mouth.

Skill Drill 19-1 Administering Glucose

Step 1

Make sure that the tube of glucose is intact and has not expired.

Step 2

Squeeze a generous amount of oral glucose onto the bottom third of a bite stick or tongue depressor.

Step 3

Open the patient's mouth. Place the tongue depressor on the mucous membranes between the cheek and the gum with the gel side next to the cheek. Repeat until the entire tube has been used.

Words of Wisdom

Remember the "six rights" of medication administration:

- Right patient
- Right medication
- Right dose
- Right time
- Right route

• Right documentation

As an EMT, you know the importance of reassessment. The patient with diabetes experiencing an altered mental status event that you treat with a glucose product is one of the most important patients to reassess frequently. As rapidly as you may see a response to your treatment, you can see a deterioration. Be very mindful of the airway when giving an oral medication like a glucose product—not only from the standpoint of placing something into the mouth but for resultant regurgitation of that product, which can be aspirated. Any time you change a patient's mental status with a drug, follow-up must be provided. Therefore, it is always best to provide transport to the next level of care.

Words of Wisdom

Diabetes is a systemic disease affecting all tissues of the body, especially the kidneys, eyes, small arteries, and peripheral nerves. Therefore, you are likely to be called to treat patients with a variety of complications of diabetes, such as heart disease, visual disturbances, renal failure, stroke, and ulcers or infections of the feet or toes. With the exception of heart attack and stroke, most of these will not be acute emergencies. Considering that diabetes is a major risk factor for cardiovascular disease, patients with diabetes should always be suspected of having a potential for heart attack, particularly older patients, even when they do not present with classic symptoms such as chest pain and shortness of breath.

The Presentation of Hypoglycemia

Recognition of the patient with hypoglycemia requires an intuitive approach. There are many classic, by-the-book presentations of hypoglycemia. However, each of the altered mental status presentations is identified in much the same way. The discovery comes from a rapid examination utilizing a list of possible conditions to rule out, leading to the ultimate identification of hypoglycemia.

Seizures

Although seizures are rarely life threatening, you should consider them to be very serious, even in patients with a history of chronic seizures. Seizures, which may be brief or prolonged, are caused by infections, poisoning, hypoglycemia, trauma, or decreased levels of oxygen, or they may be idiopathic (of unknown cause). In children, they may be caused by fever or undiagnosed epilepsy. Although brief seizures are not harmful, they may indicate a more dangerous and potentially life-threatening underlying condition. Because seizures can be the result of a head injury, consider trauma as a cause. In the patient with diabetes, you should also consider hypoglycemia.

Emergency medical care of seizures includes ensuring that the airway is clear and placing the patient on his or her side, if there is no possibility of cervical spine trauma. Do not attempt to place anything in the patient's mouth (eg, a bite stick or an oral airway). Be sure to have suctioning equipment ready in case the patient vomits. Provide oxygen or artificial ventilation if the patient is cyanotic or appears to be breathing inadequately, and provide prompt transport.

Altered Mental Status

Although altered mental status is often caused by complications of diabetes, it may also be caused by a variety of other conditions, including poisoning, infection, head injury, part of the postictal state (period following a seizure), and decreased perfusion to the brain. In diabetes, altered mental status can be caused by hypoglycemia and by ketoacidosis.

The mnemonic AEIOU-TIPS is easily remembered and covers a multitude of conditions that can lead to altered mental status. As such many of these conditions covered by the mnemonic can be confused for a misdiagnosis when the patient's blood glucose level is not assessed. AEIOU-TIPS stands for:

- Alcohol
- Epilepsy, endocrine, electrolytes
- Insulin
- Opiates and other drugs
- Uremia (kidney failure)
- Trauma, temperature
- Infection
- Poisoning, psychogenic causes
- Shock, stroke, seizure, space-occupying lesion, subarachnoid hemorrhage

Most of the items on the preceding list can be associated with or can cause hypoglycemia. A patient might have a seizure due to hypoglycemia. A patient with an altered mental status after a heroin overdose might also be hypoglycemic. Remember to consider diabetic emergencies in patients who present with any of these emergencies, which can alter or depress mental status. Also remember that patients who present with trauma and are unconscious may have become unconscious as a result of a low blood glucose level and secondarily became injured. Always suspect and check for low blood glucose in a patient with altered mental status.

Begin emergency medical care of altered mental status by ensuring that the airway is clear. Be prepared to provide artificial ventilation and suctioning in case the patient vomits, and provide prompt transport.

Misdiagnosis of Neurologic Dysfunction

Occasionally, patients with hypoglycemia or hyper-glycemia are thought to be intoxicated, especially if their condition has caused a motor vehicle crash or other incident. Confined by police at a police station, a patient with diabetes is at risk. In such situations, an emergency medical identification bracelet, necklace, or card may help to save the patient's life. Often, only a blood glucose test performed at the scene or in the ED will identify the real problem. In some EMS systems, you will be trained and allowed to perform the blood glucose testing at the scene. Otherwise, you must always suspect hypoglycemia in any patient with an altered mental status.

Certainly, diabetes and alcoholism can coexist in a patient. But you must be alert to the similarity in symptoms of acute alcohol intoxication and diabetic emergencies. Likewise, hypoglycemia and a head injury can coexist, and you must appreciate the potential for hypoglycemia even when the head injury is obvious.

Relationship to Airway Management

Patients with an altered mental status, particularly those who are difficult to awaken, may not have a gag reflex. When the gag reflex is not working, patients cannot expel foreign materials in their mouths (including vomit), and their tongues will often relax and obstruct the airway. Therefore, you must carefully monitor the airway in patients with hyperglycemia, hypoglycemia, or with a diabetic complication such as stroke or seizure. Place the patient in a lateral recumbent position, and make sure suction is readily available.

Hematologic Emergencies

Hematology is the study of blood-related diseases. The focus of this section is on three disorders that can create a prehospital emergency:

- Sickle cell disease (also called hemoglobin S disease)
- Hemophilia A (also called classic hemophilia or factor VIII deficiency)
- Thrombophilia

The composition of blood, the mechanisms that these three conditions present to the patient, and, more importantly, the symptoms you must recognize as a provider are discussed.

Anatomy and Physiology

Blood and Its Parts

Blood is made up of four components:

- Erythrocytes (red blood cells)
- Leukocytes (white blood cells)
- Platelets
- Plasma

Each of the components of the blood serves a purpose in maintaining a person's homeostatic balance. Each of the body's other systems provides for and utilizes the blood in a very specific way. In turn the blood transports oxygen and carbon dioxide into and out of tissues to sustain the function of the organ system and tissues.

Red blood cells (RBCs) make up 42% to 47% of a person's total blood volume. RBCs contain an important protein, hemoglobin, which carries 97% of the oxygen in the blood and some of the carbon dioxide.

White blood cells (WBCs) make up 0.1% to 0.2% of a person's blood cell volume. In a healthy person, WBCs collect dead cells and provide for their correct disposal. In times of health, WBC levels are low. When an infection develops, WBCs and all of their complementary defense systems are activated and their numbers grow.

Platelets make up 4% to 7% of a person's blood cell volume and are essential for clot formation. When damage occurs to your skin or to a blood vessel, platelets are sent to the site of injury to assist in forming a blood clot to stop the bleeding. Without this protective response, bleeding from a simple cut could be uncontrollable.

Plasma serves as the transportation media for all of the blood components as well as proteins and minerals.

Pathophysiology

Sickle Cell Disease

Sickle cell disease, also called *hemoglobin S disease*, is an inherited blood disorder that affects the RBCs. The name sickle cell comes from the first case report of the disease in 1910, when Dr. James Herrick wrote that the red blood cells looked like a sickle **Figure 19-7**. The odd-shaped cells protect the individual from contracting malaria. The protection is useful to people who live in the sub-Saharan African malaria belt, but it is not useful to people who do not live in regions endemic for malaria.

There are several variants that make up this genetic disease. It is sufficient to simply understand that the issues of sickle cell can happen to any of the variants. This disease is common among people of African, Caribbean, and South American ancestry. It is present but less common in Mediterranean and Middle Eastern people. All newborns in the US are tested for sickle cell disease shortly after birth, regardless of their race or ethnic background.

The sharp and misshapen cells lead to dysfunction in oxygen binding and unintentional clot formation. These unintentional clots may result in a blockage known as **vasoocclusive crisis**.

People with sickle cell disease can experience hypoxia, or a lack of oxygen in the body's cells and tissues. The blockages that result from sickle cell crises or vasoocclusive crises can result in substantial pain and organ damage, which can trigger calls to EMS for help.

The life span of normal RBCs is approximately 110 to 120 days; sickled cells have a much shorter life span. This results in more cellular waste products in the bloodstream, which can contribute to sludging (clumping) of the blood. Maintaining hydration status is important to these patients as is maintaining their general health, since insufficient hydration leads to increased clumping of cells.

Complications associated with sickle cell disease include:

- Anemia
- Gallstones
- Jaundice
- Splenic dysfunction

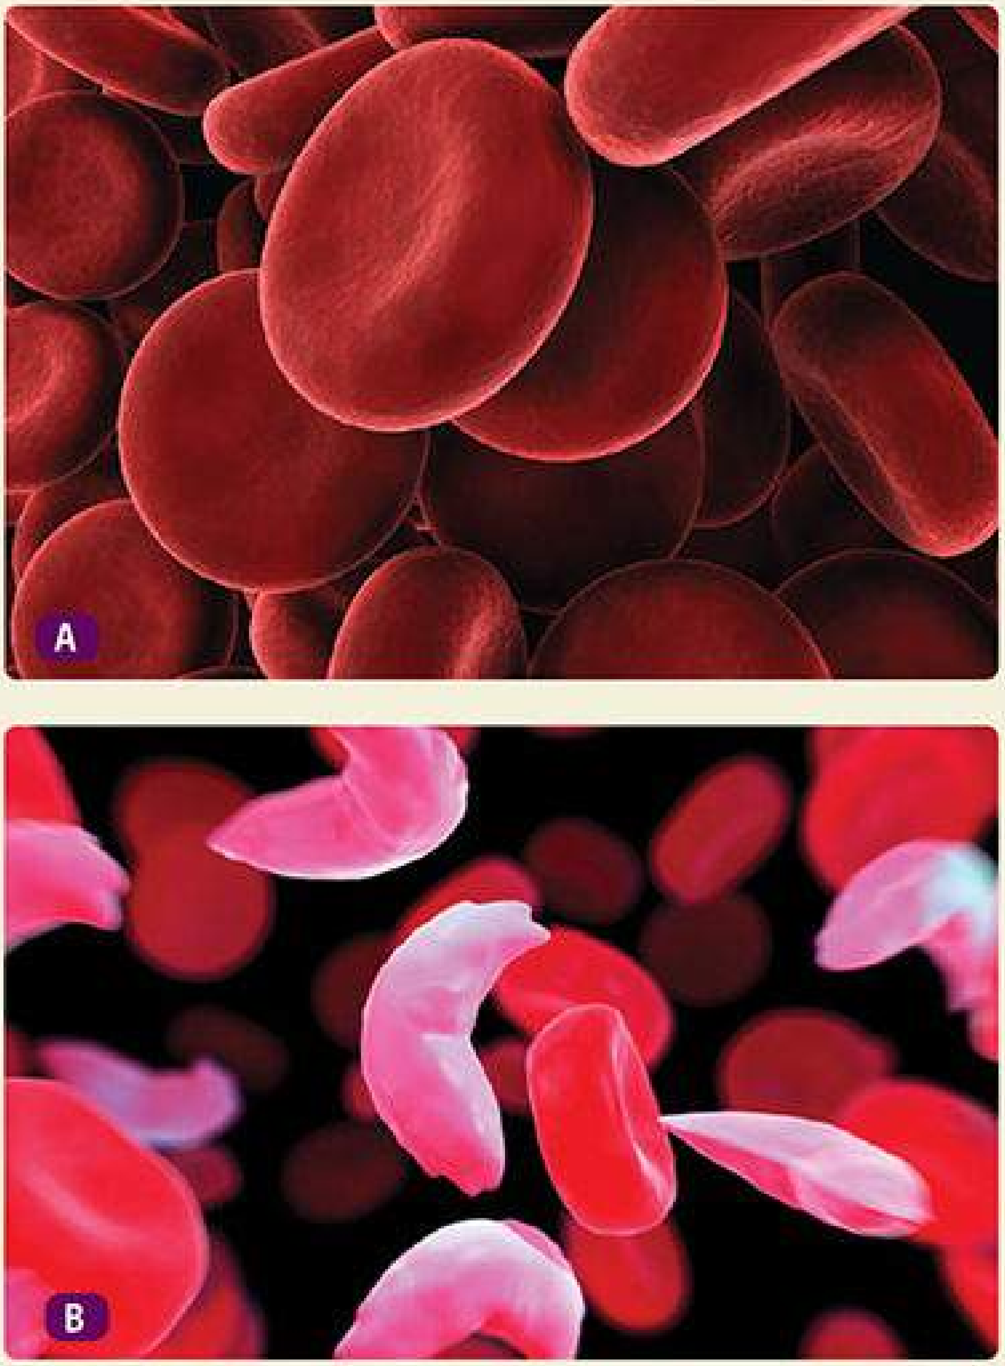

Figure 19-7 **A.** Normal red blood cells. **B.** Sickle cells.

A: © Sebastian Kaulitzki/Shutterstock; B: © Science Picture Co/Science Source.

- Vascular occlusion with ischemia:
  - Acute chest syndrome (hypoxia, dyspnea, chest discomfort, and fever)
  - Stroke
  - Joint necrosis (specifically the head of the femur and the humerus)
  - Pain crises
  - Acute and chronic organ dysfunction/failure

— Retinal hemorrhages

— Increased risk of infection

Many of these complications are very painful and potentially life threatening. In the face of these complications the sickle cell patient is also more susceptible to infections.

Hemophilia

Hemophilia is rare; according to the Hemophilia Federation of America, there are only about 20,000 Americans who have the disorder.

Hemophilia A affects mostly males. Males inherit the condition from a mother who is a carrier but does not have the disease; females only inherit the condition if their mother is a carrier and their father has the disease.

People with hemophilia A have a decreased ability to create a clot after an injury. A healthy individual will clot in as little as 13 seconds from a paper cut, and not longer than about 7 minutes from something more serious that requires direct pressure. Having an extended bleeding time from the inability to clot can be life threatening.

A patient who is otherwise healthy but has hemophilia A can have a minor trauma, such as a simple ankle sprain while playing soccer. Most people would ignore the sprain and simply continue to play the game. The patient with hemophilia A would begin to swell from uncontrolled bleeding in the region of the injury and continue to do so, making the seemingly minor injury a significant problem.

Acute bleeding from any source may be life threatening depending on where the bleeding occurs. Patients with hemophilia A typically have intravenous factor VIII replacement infusions, which help the blood clot, either close at hand or with them.

Common complications of hemophilia A include:

- Long-term joint problems, which may require a joint replacement
- Bleeding in the brain (intracerebral hemorrhage)
- **Thrombosis** due to treatment

Thrombophilia

Thrombophilia is a disorder in the body's ability to maintain the viscosity and smooth flow of blood through the venous and arterial systems. In thrombophilia, the concentration of particular elements in the blood creates what amounts to clogging or blockage issues.

Thrombophilia is a general term for many different conditions that result in the blood clotting more easily than normal. This results from either inherited (genetic) disorders, medications, or other factors. Patients with cancer are at increased risk of forming life-threatening blood clots. Whatever the risk factors, the common theme is that clots can spontaneously develop in the blood of the patient.

Deep Vein Thrombosis

Deep vein thrombosis (DVT) is a common medical problem in sedentary patients and in patients who have had recent injury or surgery. While several risk factors increase the chance that a patient will develop a DVT, there are several methods to prevent blood clot formation, including blood-thinning medications, compression stockings, and mechanical devices—all of which you may encounter in the field.

YOU are the Provider — PART 5

You reassess the patient and then call your radio report to the receiving hospital. The patient is still conscious, but confused. Your estimated time of arrival at the hospital is 8 minutes.

Recording Time: 17 Minutes	
Level of consciousness	Conscious, but confused
Respirations	28 breaths/min; deep
Pulse	118 beats/min; weak radial pulses
Skin	Pink, warm, and dry; poor turgor

Blood pressure	110/58 mm Hg
Spo_2	97% (on oxygen)

You arrive at the hospital and transfer patient care to the attending physician. After further assessment and treatment in the emergency department, the patient is admitted to the medical intensive care unit.

8. What treatment is provided at the hospital for patients with symptomatic hyperglycemia that cannot be provided in the prehospital setting?

DVT is a particularly worrisome risk for patients who have had joint replacement surgery. Be suspicious of this in a patient with a recent history of joint replacement who complains of leg swelling. Travelers, truck and long-distance bus drivers, and bedridden nursing home patients are all at higher risk for DVT because they are sedentary for long periods of time.

If DVT develops in an individual, anticoagulation therapy may be administered. A patient with DVT may be treated in the hospital with IV medications and then transitioned to oral medications before discharge. Some patients are sent home with self-administered subcutaneous injectable medications to treat or prevent DVT. Oral medications are typically administered for at least 3 months after diagnosis of a DVT to ensure another DVT does not develop. Patients prescribed medications to treat DVT are at increased risk of bleeding complications (ie, gastrointestinal bleeding), and minor trauma is more likely to produce severe internal or external hemorrhage.

A life threat can develop if the clot from the DVT travels from the patient's lower extremity to the lung, causing a pulmonary embolus. Pulmonary emboli can cause chest pain, difficulty breathing, or, if the clots are large, sudden cardiac arrest. Pulmonary embolism is discussed in Chapter 15, *Respiratory Emergencies*.

Patient Assessment of Hematologic Disorders

Scene Size-up

Although your report from dispatch may be for a patient with an unknown medical problem, most patients presenting with a sickle cell crisis have had a crisis before and will relay that information to the dispatcher. As you approach the scene, ensure your safety by assessing for hazards. Standard precautions should consist of gloves and eye protection at a minimum. Remember to evaluate each situation quickly and make sure the necessary personal protective equipment is readily available.

Determine whether this is your only patient and whether trauma was involved. Decide whether you will need any additional resources. Patients experiencing a vasoocclusive crisis are often in extreme pain and would benefit from ALS providers being able to administer analgesics.

Remember that trauma may have occurred because of a medical incident. Determine the mechanism of injury and/or nature of illness.

Primary Assessment

An African American patient or any patient of Mediterranean descent who reports severe pain may have undiagnosed sickle cell disease.

Perform cervical spine immobilization, if indicated. Remember that even though a person has a history of sickle cell disease, sickle cell disease may not be causing the current problem; trauma or another type of medical emergency may be the cause. For this reason, you must always perform a thorough, careful primary assessment, paying attention to the ABCs and immediately correcting any life-threatening issues.

Perform a primary assessment to form an initial general impression of the patient. How does the patient look? Does the patient appear anxious, restless, or listless? Is the patient apathetic or irritable? Determine the patient's level of consciousness.

While you are forming your general impression, assess the patient's airway and breathing. Patients showing signs of inadequate breathing or altered mental status should receive high-flow oxygen at 12 to 15 L/min via nonrebreathing mask. A patient who is experiencing a sickle cell crisis may have increased respirations as a result of severe pain or exhibit signs of pneumonia. If the patient is having difficulty breathing, open the airway and insert an airway adjunct, administer oxygen, and assist ventilations. Continue to monitor the airway as you provide care.

Once you have assessed the airway and breathing and have performed the necessary interventions, check the patient's circulatory status. An increased heart rate represents a compensatory mechanism, in an attempt to force the sickled cells through smaller blood vessels.

In patients with suspected hemophilia, be alert for signs of acute blood loss such as pallor, weak pulse, and hypotension. Note any bleeding of unknown origin, such as nosebleeds, bloody sputum, and blood in the urine or stool. Owing to blood loss, patients with hemophilia may exhibit signs of hypoxia.

Whether you decide to rapidly transport the patient will depend on the severity of the patient's pain and the patient's wishes. Patients with a history of sickle cell disease, but those who have not had a crisis in some time, may require emotional support and refuse transport. However, transport to an ED should always be recommended to any patient who is experiencing a sickle cell crisis or hemophilia.

History Taking

If the patient is conscious, what is the chief complaint or history of present illness?

Responsive medical patients are able to provide their own medical history to help you identify a cause for their severe pain. Physical signs, such as swelling of the fingers and toes, priapism, and jaundice may guide you in determining whether the patient is experiencing a sickle cell crisis. Also important to ascertain is whether the pain is isolated to a single location or if pain is felt throughout the entire body. Is the patient having any visual disturbances? Is the patient experiencing any gastrointestinal problems, such as nausea, vomiting, or abdominal cramping? Is the patient reporting any chest pain or shortness of breath?

In a patient with known sickle cell disease, ask the following questions in addition to obtaining a SAMPLE history:

- Have you had a crisis before?
- When was the last time you had a crisis?
- How did your last crisis resolve?
- Have you had any illness, unusual amount of activity, or stress lately?

Secondary Assessment

Next, systematically examine the patient, focusing on major joints at which cells congregate. Evaluate and document mental status using the AVPU scale.

Obtain a complete set of vital signs, including a measurement of the patient's oxygen saturation level. In patients experiencing a sickle cell crisis, respirations are normal to rapid, pulse is weak and rapid, and skin is typically pale and clammy with a low blood pressure.

Use pulse oximetry, if available. However, keep in mind that the oxygen saturation reading you obtain may be inaccurate as a result of the patient's anemic state.

Reassessment

It is important to reassess the patient frequently to determine if there have been changes in his or her condition. For example, are there changes in the patient's mental status? Are the ABCs still intact? How is the patient responding to the interventions performed? Should you adjust or change the interventions? Document each assessment, your findings, the time of the interventions, and any changes in the patient's condition.

Administer supplemental oxygen via nonre-breathing mask at 12 to 15 L/min to attempt to compensate for decreased cellular oxygenation related to the sickled cells or hemophilia.

At the hospital, care for sickle cell patients can include analgesics for pain, penicillin to treat infection, IV fluid for hydration, and, depending on the severity of the crisis, a blood transfusion.

Distinguishing a true sickle cell crisis from other nonspecific causes of pain can be difficult. Remember to perform a thorough assessment and consult with medical control as soon as feasible.

Hospital care for a patient with hemophilia may include IV therapy to treat hypotension, and a transfusion of plasma. Analgesics may also be appropriate.

Communication with hospital staff is important for continuity of care. Inform hospital personnel about the patient's history, the present situation, your assessment findings, and your interventions and their results.

Document clearly your assessment findings as the basis for your treatment. Follow your local protocols for patients who refuse treatment or transport.

Emergency Medical Care for Hematologic Disorders

Emergency care for patients with hematologic disorders is mainly supportive and symptomatic. Patients showing signs of inadequate breathing or altered mental status should receive high-flow oxygen at 12 to 15 L/min via nonrebreathing mask and should be placed in a position of comfort and transported rapidly to the hospital.

YOU are the Provider SUMMARY

1. What processes are being described by the patient?

This presentation can be typical of many illnesses until you begin to ask the correct questions. The 3-to-5-day, subtle flulike presentation is often how diabetes mellitus type 1 presents. People must eat to have energy, but the lack of insulin deprives cells of the fuel they need, and therefore no energy is produced.

The onset of diabetes mellitus type 1 takes some time to progress. For this reason symptoms are initially subtle and are overlooked by the patient. As the lack of insulin becomes more profound, the patient will notice increasing fatigue and malaise along with weight loss.

The patient is experiencing (1) polydipsia, (2) polyuria, and (3) polyphagia.

Without insulin, glucose accumulates in the blood. Glucose spills into the urine until it reaches the kidney's maximum level to excrete. The glucose in the urine pulls a substantial amount of water with it resulting in large amounts of urination (polyuria), causing dehydration. The patient experiences thirst, causing him or her to drink large amounts of fluid; this is polydipsia. Finally, eating in excess (polyphagia) occurs in the face of weight loss. Polyphagia develops because of the starvation of the patient at the cellular level.

Many times the patient does not recognize these symptoms, but family and friends might.

2. What hormone is missing in diabetes mellitus type 1?

The missing hormone is insulin. Insulin is the key to the door of the cell. Without insulin, nutrition cannot get into the cell.

3. What should you expect the patient's blood glucose level to read? Why?

Based on the description of increased food intake with weight loss, increased fluid intake, and increased urination, this patient appears to be in diabetic ketoacidosis. In these cases, the blood glucose level will be in the mid 400s to 500s or even higher.

4. What is causing the patient's frequent urination and deep, rapid breathing?

The frequent urination is occurring because the patient is drinking large amounts of fluid. An increase in his blood glucose level resulted in glucose spilling into the urine. He is excreting large amounts of urine because glucose in the urine pulls water out with it.

Deep, rapid breathing, known as Kussmaul respirations, is caused by the ketones that are accumulating in the blood and are being eliminated from the lungs during exhalation. Kussmaul respirations often have a fruity or sweet odor.

5. What other factors can cause hyperglycemia in patients with diabetes?

Changing meal times, insulin dosage changes, or a variation in exercise can result in a hyperglycemic or hypoglycemic event. The patient in this chapter's scenario has new-onset diabetes and is in DKA. An infection could put an otherwise well-regulated patient with type 1 diabetes into DKA rather easily.

Noncompliance with medication use can also result in hyperglycemic episodes.

6. How can you distinguish symptomatic hyperglycemia from symptomatic hypoglycemia?

A key to distinguishing a hyperglycemic emergency from a hypoglycemic emergency is the time of symptom onset. Hyperglycemia, ketoacidosis, and dehydration typically progress over hours to days. By contrast, hypoglycemia has an acute onset—often over a period of a few minutes.

Symptomatic hyperglycemia and symptomatic hypoglycemia also present with relatively different signs and symptoms. Signs and symptoms of symptomatic hyperglycemia include tachycardia; signs of dehydration (warm, dry skin, poor skin turgor, and sunken eyes); deep, rapid breathing (Kussmaul respirations), which indicates the respiratory system is attempting to eliminate ketones from the body; a sweet or fruity (acetone) breath odor; and mental status changes ranging from confusion to coma.

Symptomatic hypoglycemia presents with signs and symptoms similar to hypoxemia and shock, including rapid, shallow respirations; pale, cool, clammy (diaphoretic) skin; tachycardia; weakness, which may be confined to one side of the body and mimic a stroke; and varying degrees of mental status change, including confusion, irritability, combativeness, seizures, and coma.

7. What additional treatment should you provide to this patient?

The patient's signs and symptoms clearly point to symptomatic hyperglycemia, specifically DKA. Symptomatic hyperglycemia requires definitive care that can only be provided at the hospital. Prehospital treatment at the EMT level is aimed at providing supportive care (ie, maintaining the ABCs) and promptly transporting the patient to the hospital. En route, closely monitor the patient's mental status and breathing adequacy; if his respirations become slow and/or shallow—especially if his mental status deteriorates further—assist his ventilations with a bag-valve mask (BVM).

Some patients with symptomatic hyperglycemia become so dehydrated that hypovolemic shock develops; therefore, it is important to closely monitor the patient's perfusion status (eg, heart rate, peripheral pulse quality, blood pressure, mental status). If signs of shock are observed, keep the patient warm and in a supine position. Although the patient is extremely thirsty, do not give him anything to drink; doing so increases the risk of aspiration if he vomits.

8. What treatment is provided at the hospital for patients with symptomatic hyperglycemia that cannot be provided in the prehospital setting?

Symptomatic hyperglycemia is a complex medical problem that causes numerous complications; it cannot be treated in the prehospital setting and it cannot be changed quickly. Insulin is needed to restore circulating blood glucose to a normal level, and IV fluids are needed to correct dehydration.

This underscores the importance of performing a rapid assessment, initiating treatment without delay, and promptly transporting the patient to the hospital.

If your transport time will be prolonged, consider an intercept with an advanced life support unit, if available; AEMTs and paramedics are trained to start IV lines and administer fluids.

Narrative

9-1-1 dispatch for a patient with weakness/nausea. Arrived on scene and found the patient, a 23-year-old man, lying on the couch in his living room. He was conscious, but confused. His airway was patent, and his breathing was deep and rapid. The patient's wife advised that he has been sick for the past few days. He has been urinating excessively and has been drinking a lot of water. Further assessment of the patient revealed that his radial pulse was rapid and weak; his skin was pink, warm, and dry; and he had poor skin turgor. Applied high-flow oxygen via nonrebreathing mask at 15 L/min and performed further assessment. Breath sounds were clear to auscultation bilaterally, pupils were equal and reactive to light, there were no gross signs of trauma, and the patient had a sweet, fruity odor on his breath. Vital signs were obtained and blood glucose level was assessed and noted to be 456 mg/dL. The patient's wife spoke with his physician, who requested EMS transport to the closest appropriate facility. Patient was placed onto stretcher and loaded into the ambulance. Mental status and vital signs were reassessed and transport was begun. Continued to monitor patient en route; his mental status and vital signs remained unchanged. Continued oxygen therapy, which maintained his oxygen saturation above 95%. Notified receiving facility of our impending arrival; no further medical direction was given. Delivered patient to emergency department; his condition was unchanged. Gave verbal report to attending physician, transferred patient care, and returned to service.**End of report**

Ready for Review

- Diabetes is a disorder of glucose metabolism or difficulty metabolizing carbohydrates, fats, and proteins.
- There are two types of diabetes. Type 1 diabetes typically develops in childhood and requires daily insulin to control blood glucose. Type 2 diabetes typically develops in middle age and often can be controlled with diet, activity, and oral medications.
- Both types of diabetes are serious systemic diseases, especially affecting the kidneys, eyes, small arteries, and peripheral nerves.
- Patients with diabetes have chronic complications that place them at risk for other diseases, such as heart attack, stroke, and infections. Most often, however, you will be called on to treat the acute complications of blood glucose imbalance. These include hyperglycemia (excess blood glucose) and hypoglycemia (insufficient blood glucose).
- Hyperglycemia is typically characterized by excessive urination and resulting thirst, in conjunction with the deterioration of body tissues.
- Hyperglycemia is usually associated with dehydration and ketoacidosis and can result in marked rapid (often deep) respirations; warm, dry skin; a weak pulse; and a fruity breath odor. Hyperglycemia must be treated in the hospital with insulin and IV fluids.
- Symptoms of hypoglycemia classically include confusion; rapid respirations; pale, moist skin; diaphoresis; dizziness; fainting; and even coma and seizures. This condition is rapidly reversible with the administration of glucose or sugar. Without treatment, however, permanent brain damage and death can occur.
- Because a blood glucose level that is either too high or too low can result in altered mental status, you must perform a thorough history and patient assessment to determine the nature of the problem. When the problem cannot be determined, it is best to treat the patient for hypoglycemia.
- Be prepared to give oral glucose to a conscious patient who is confused or has a slightly decreased level of consciousness; however, do not give oral glucose to a patient who is unconscious or otherwise unable to swallow properly or protect his or her own airway.
- In all cases, providing emergency medical care and prompt transport is your primary responsibility.
- Sickle cell disease is a blood disorder that affects the shape of red blood cells.
- Symptoms of sickle cell disease are pain in the joints, fever, respiratory distress, and abdominal pain.
- Patients with sickle cell disease have chronic complications that place them at risk for other diseases, such as heart attack, stroke, and infection. Most often, however, you will be called on to treat the acute complications of severe pain.
- Patients with hemophilia are not able to control bleeding because clots do not develop as they should.
- Emergency care in the prehospital setting is supportive for patients with sickle cell disease or a clotting disorder such as hemophilia.

Vital Vocabulary

acidosis A pathologic condition that results from the accumulation of acids in the body.

diabetes mellitus A metabolic disorder in which the ability to metabolize carbohydrates (sugars) is impaired, usually because of a lack of insulin.

diabetic ketoacidosis (DKA) A form of hyperglycemia in uncontrolled diabetes in which certain acids accumulate when insulin is not available.

endocrine glands Glands that secrete or release chemicals that are used inside the body.

endocrine system Regulates metabolism and maintains homeostasis.

glucose One of the basic sugars; it is the primary fuel, in conjunction with oxygen, for cellular metabolism.

hematology The study and prevention of blood-related disorders.

hemophilia A congenital abnormality in which the body is unable to produce clots, which results in uncontrollable bleeding.

hormone A chemical substance produced by a gland that regulates the activity of organs and tissues.

hyperglycemia An abnormally high blood glucose level.

hyperosmolar hyperglycemic nonketotic syndrome (HHNS) A life-threatening condition resulting from high blood glucose that typically occurs in older adults, and which causes altered mental status, dehydration, and organ damage.

hypoglycemia An abnormally low blood glucose level.

insulin A hormone produced by the islets of Langerhans (endocrine gland located throughout the pancreas) that enables glucose in the blood to enter cells; used in synthetic form to treat and control diabetes mellitus.

Kussmaul respirations Deep, rapid breathing; usually the result of an accumulation of certain acids when insulin is not available in the body.

polydipsia Excessive thirst that persists for long periods, despite reasonable fluid intake; often the result of excessive urination.

polyphagia Excessive eating; in diabetes, the inability to use glucose properly can cause a sense of hunger.

polyuria The passage of an unusually large volume of urine in a given period; in diabetes, this can result from the wasting of glucose in the urine.

sickle cell disease A hereditary disease that causes normal, round red blood cells to become oblong, or sickle shaped.

symptomatic hyperglycemia A state of unconsciousness resulting from several problems, including ketoacidosis, dehydration because of excessive urination, and hyperglycemia.

symptomatic hypoglycemia Severe hypoglycemia resulting in changes in mental status.

thrombophilia A tendency toward the development of blood clots as a result of an abnormality of the system of coagulation.

thrombosis A blood clot, either in the arterial or venous system.

type 1 diabetes An autoimmune disorder in which the individual’s immune system produces antibodies to the pancreatic beta cells, and therefore the pancreas cannot produce insulin; onset in early childhood is common.

type 2 diabetes A condition in which insulin resistance develops in response to increased blood glucose levels; can be managed by exercise and diet modification, but is often managed by medications.

vasoocclusive crisis Ischemia and pain caused by sickle-shaped red blood cells that obstruct blood flow to a portion of the body.

Assessment *in Action*

You are working a detail for the women's state volleyball championship at the local university gym when you are dispatched to the visiting team locker room for a player who is feeling weak and dizzy. You are met at the locker room door by the coach who points to a young woman lying supine on a bench. The coach informs you that the player has a history of diabetes and takes insulin on a regular basis. As you approach the patient, you run through some of the information that you know about diabetes.

1. Diabetes is a metabolic disorder in which the body's ability to metabolize _________ is impaired.

   A. protein
   B. fats
   C. glucose
   D. electrolytes

2. When the concentration of glucose drops in the blood, the body will release _______, a hormone that will assist other organs in the process of converting stored sugars into usable sugars.

   A. insulin
   B. epinephrine
   C. glucagon
   D. dopamine

3. Patients with diabetes who overexert themselves are prone to rapid:

   A. drops in their ability to sweat.
   B. increases in their blood pressure.
   C. drops in their blood glucose levels.
   D. increases in their blood glucose levels.

4. Which of the following organs can rapidly sustain permanent damage when the body's glucose level is too low?

   A. Brain

B. Heart
C. Kidney
D. Liver

5. Based on the information described in the scenario, which question should you ask this patient first?

   A. "Are you having any pain?"
   B. "When was the last time you ate?"
   C. "Do you feel short of breath?"
   D. "When was your last menstrual cycle?"

6. What other sudden onset signs and symptoms may your patient exhibit?

   A. A slow, bounding pulse
   B. Rapid, deep respirations
   C. Nausea and vomiting
   D. Pale, moist skin

7. Your partner prepares to perform a fingerstick to check the patient's glucose level. A normal glucose level is:

   A. 20 mg/dL.
   B. 80 mg/dL.
   C. 140 mg/dL.
   D. 200 mg/dL.

8. List and explain three signs and/or symptoms that can give you clues about the presence of diabetic ketoacidosis.
9. Differentiate between hyperglycemia and hypoglycemia. Explain which you think is more ominous and why.
10. Describe the likely problem presented in the scenario.

CHAPTER
20

Immunologic Emergencies

National EMS Education Standard Competencies

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Immunology

Recognition and management of shock and difficulty breathing related to

› Anaphylactic reactions (pp 757–764)

Anatomy, physiology, pathophysiology, assessment, and management of

› Hypersensitivity disorders and/or emergencies (pp 753–764)
› Anaphylactic reactions (pp 753–764)

Knowledge Objectives

1. Define the terms allergic reaction and anaphylaxis. (p 753)
2. Explain the difference between a local and a systemic response to allergens. (p 753)
3. List the five categories of stimuli that could cause an allergic reaction or an extreme allergic reaction. (p 755)
4. Differentiate the primary assessment for a patient with a systemic allergic or anaphylactic reaction and a local reaction. (pp 757–759)
5. Explain the importance of managing the ABCs of a patient who is having an allergic reaction. (p 757)
6. Discuss the steps in the primary assessment that are specific to a patient who is having an allergic reaction. (pp 757–758)
7. Explain the factors involved when making a transport decision for a patient having an allergic reaction. (p 758)
8. Review the process for providing emergency medical care to a patient who is experiencing an allergic reaction. (pp 760–764)
9. Explain the rationale, including communication and documentation considerations, when determining whether to administer epinephrine to a patient who is having an allergic reaction. (pp 761–764)
10. Describe some age-related contraindications to using epinephrine to treat an allergic reaction in a geriatric patient. (p 764)

Skills Objectives

1. Demonstrate how to remove the stinger from a honeybee sting and proper patient management following its removal. (pp 760–761)
2. Demonstrate how to use an EpiPen auto-injector. (pp 762–763, Skill Drill 20-1)

Introduction

Death as a result of allergic reaction is rare, but is possible. As an EMT, you will often respond to calls involving an allergic reaction. When managing allergy-related emergencies, you must be aware of the possibility of acute airway obstruction and cardiovascular collapse and be prepared to treat these life-threatening complications. You must also be able to distinguish between the body's usual response to a sting or bite and an allergic reaction, which may require epinephrine. Your ability to recognize and manage the many signs and symptoms of allergic reactions may be the only thing standing between a patient's life and imminent death.

This chapter describes **immunology**, the study of the body's immune system, and the five categories of stimuli that may provoke allergic reactions—in particular, insect bites and stings. You will learn what to look for in assessing patients who may be having an allergic reaction and how to care for them, including administration of epinephrine.

Anatomy and Physiology

The **immune system** protects the human body from substances and organisms that are foreign to the body. Without the immune system for protection, life as you know it would not exist. You would be under constant attack from any type of invader, such as a bacterium or virus, that wanted to make your body a home. Fortunately, most people have immune systems that are well equipped to detect unauthorized visits or invading attacks by foreign substances. Once a foreign substance invades the body, the body goes on alert and initiates a series of responses to inactivate the invader.

Pathophysiology

There are many conditions related to the immune system, but an allergic reaction is the only immunologic emergency you will treat as an EMT. Contrary to what many people think, an **allergic reaction**, an exaggerated **immune response** to any substance, is not caused directly by an outside stimulus, such as a bite or sting. Rather, it is a reaction by the body's immune system, which releases chemicals to combat the stimulus. Among these chemicals are **histamines** and **leukotrienes**, both of which contribute to an allergic reaction. Given the right person and the right circumstances, almost any substance can become an **allergen**. However, some people do not experience allergic reactions the first time they are exposed to an allergen. First, the person becomes *sensitized* (exposed for the first time) to the substance, and then his or her immune system learns to recognize it. When the patient is exposed to the substance again, an allergic reaction occurs. As a result, some patients may not have any idea what is causing their allergic reaction—or may not realize they are having one at all—so you must be able to recognize the signs and symptoms and maintain a high index of suspicion. An allergic reaction may be mild and local—characterized by itching, redness, or tenderness—or it may be severe and systemic, a condition known as **anaphylaxis** **Figure 20-1**.

Anaphylaxis is an extreme allergic reaction that is life threatening and involves multiple organ systems. In severe cases, anaphylaxis can rapidly result in shock and death. Two of the most common signs of anaphylaxis are widespread **urticaria**, or hives, small areas of generalized itching or burning that appear as multiple, small, raised areas on the skin **Figure 20-2**, and **angioedema**, areas of localized swelling **Figure 20-3**. Another often-observed sign is **wheezing**, a high-pitched, whistling breath sound that is typically heard on expiration, usually resulting from bronchospasm/bronchoconstriction and increased mucus production. You may also note hypotension due to vasodilation, as well as increased capillary permeability (wherein fluid from the bloodstream seeps into the tissues). One symptom that is often overlooked in patients experiencing an allergic reaction is persistent gastrointestinal dysfunction (eg, nausea, vomiting, and abdominal cramps).

YOU are the Provider — PART 1

You and your partner respond to a call involving a 33-year-old man experiencing shortness of breath. Upon arrival, you observe a conscious patient in obvious respiratory distress, breathing rapidly with audible wheezing, whose skin is flushed red and covered in hives. When you attempt to question the patient, you find he can only speak in two-to-three word sentences.

1. What, if any, additional resources should you request?
2. What intervention(s) should you perform without delay?

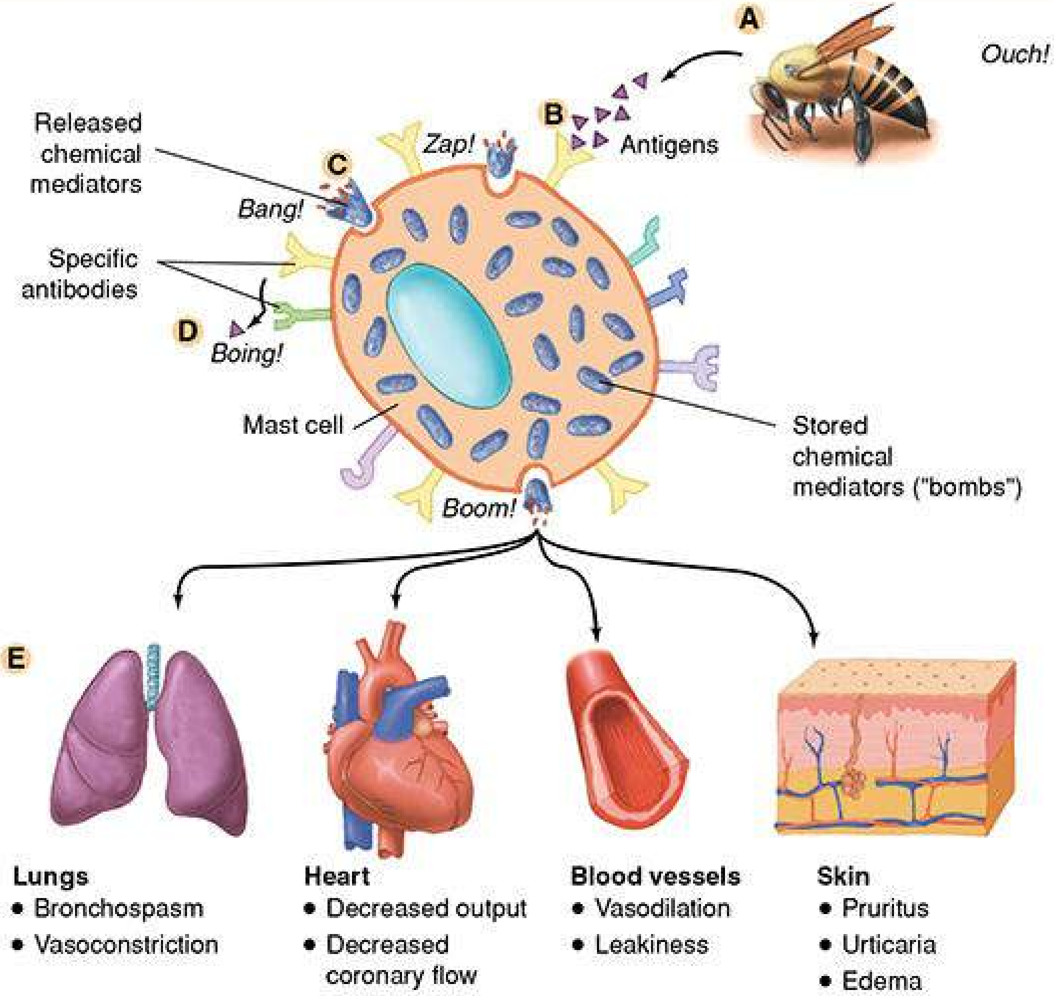

Figure 20-1 The sequence of events in anaphylaxis. **A.** The antigen is introduced into the body. **B.** The antigen-antibody reaction at the surface of a mast cell. **C.** The release of mast cell chemical mediators. **D.** Specific antibody reacts with its corresponding antigen. **E.** Chemical mediators exert their effects on end organs.

Figure 20-2 Urticaria, or hives, may appear following exposure to an allergen and is characterized by multiple, small, raised areas on the skin. Urticaria may be one of the warning signs of an impending anaphylactic reaction.

Figure 20-3 Angioedema, localized swelling associated with allergic reactions. If the site of swelling includes the lips, tongue, larynx, or other such structures, airway obstruction may occur.

Common Allergens

The most common allergens fall into one of the following five general categories:

- **Food.** Certain foods, such as shellfish and peanuts, may be the most common trigger of anaphylaxis. These foods account for 30% of deaths from anaphylaxis, most commonly in adolescents and young adults. Symptoms of a food allergy may take more than 30 minutes to appear and may not include the presence of skin signs, such as hives. However, the reaction can be quite severe and involve the respiratory and/or cardiovascular systems. It is possible for a patient to be unaware of the exposure; for example, a person allergic to peanuts may eat something without knowing that one of the ingredients is peanuts.
- **Medication.** The second most common source of anaphylactic reactions is medication, particularly antibiotics (eg, penicillin) and nonsteroidal anti-inflammatory drugs (NSAIDs). If the medication is injected, the reaction may be immediate (within 30 minutes) and severe **Figure 20-4**. Reactions to oral medications may take more than 30 minutes to appear, but can also be very severe.
- **Plants.** People who inhale dust, pollen, mold, mildew, or other organic materials to which they are sensitive may experience an allergic reaction. Some common plant allergens include ragweed, ryegrass, maple, and oak.
- **Chemicals.** Certain chemicals, makeup, soap, hair dye, latex, and various other substances can cause severe allergic reactions. Latex is of particular concern to health care providers; patients can be sensitive to it, but so can you! Up to 12% of health care providers will become sensitized to latex. For some, simply being in the same room as someone wearing powdered latex gloves can cause a reaction. It is a good practice to routinely use latex alternatives such as nitrile gloves. Follow your local protocol.
- **Insect bites and stings.** When an insect bites or stings you, the act of injecting its venom is called envenomation.

Envenomation by a honeybee, wasp, ant, yellow jacket, or hornet may cause a localized reaction, causing swelling and itching at the site, or a severe and systemic reaction (ie, anaphylaxis).

Figure 20-4 A severe allergic reaction to medication.

Insect Stings

There are more than 100,000 species of bees, wasps, and hornets in the world. According to the Cleveland Clinic Center for Continuing Education, approximately 3% of adults and 1% of children are allergic to the venom of these stinging insects, accounting for at least 50 deaths in the United States per year. Deaths from anaphylactic reactions to stinging insects far outnumber deaths from snake bites. In about half of these deaths, the victim had never experienced a reaction to prior stings.

The stinging organ of most bees, wasps, and hornets is a small, hollow spine projecting from the abdomen. Venom can be injected through this spine directly into the skin. The stinger of the honeybee is barbed, so the bee cannot withdraw it **Figure 20-5A**. Therefore, the bee leaves a part of its abdomen embedded with the stinger and dies shortly after flying away. If the stinger is not removed from the skin (discussed later in this chapter), it can continue to inject venom for up to 20 minutes. Wasps and hornets do not have this handicap; they can sting repeatedly **Figure 20-5B**. Because these insects usually fly away after stinging, it is often impossible to identify which species was responsible for the injury.

Figure 20-5 Most stinging insects inject venom through a small, hollow spine that projects from the abdomen. **A.** The stinger of the honeybee is barbed; the honeybee cannot withdraw its stinger once it has stung someone. **B.** The wasp's stinger is unbarbed, meaning that it can inflict multiple stings.

A: © manfredxy/ShutterStock.; B: © Heintje Joseph T. Lee/ShutterStock.

Some ants, especially the fire ant **Figure 20-6A**, also strike repeatedly, injecting a particularly irritating **toxin**, or poison, at the bite sites. It is not uncommon for a patient to rapidly sustain multiple ant bites, usually on the feet and legs **Figure 20-6B**.

Signs and symptoms of insect stings and bites include sudden pain, swelling, localized heat, widespread urticaria, and redness in light-skinned people, usually at the site of injury. There may be itching and sometimes a **wheal**, which is a raised, swollen, well-defined area on the skin **Figure 20-7**. Applying ice sometimes makes them less irritating. The swelling associated with an insect bite may be dramatic and sometimes frightening to the patient or to you. However, as long as these manifestations remain localized, they are not usually serious.

In more severe (anaphylactic) cases, patients may experience bronchospasm and wheezing, chest tightness and coughing, dyspnea, anxiety, gastrointestinal complaints, and hypotension. Occasionally, respiratory failure occurs. If untreated, an anaphylactic reaction can proceed rapidly to death. In fact, more than two-thirds of patients who die of anaphylaxis do so within the first 30 minutes, so rapid treatment and transport is essential.

Figure 20-6 **A.** The fire ant. **B.** Fire ants inject an irritating toxin at multiple sites. Bites are generally found on the feet and the legs and appear as multiple small, raised pustules.

Scene Size-up

First and foremost, ensure the scene is safe. The patient's environment or recent activity may indicate the source of the reaction, such as a sting or bite from an insect, a food allergy at a restaurant, or a new medication. A respiratory problem reported by dispatch may be an allergic reaction, but until a field impression of allergic reaction is firmly established, be mindful of other potential causes of respiratory distress as well. Do not neglect the possibility that traumatic injury may also be present, secondary to the medical emergency. Follow standard precautions with a minimum of gloves and eye protection. Consider the need for additional resources, such as advanced life support (ALS) personnel.

Primary Assessment

When a patient presents with an allergic reaction, you should quickly identify and treat any immediate or potential life threats. It is essential that you pay careful attention to the patient's ABCs, as deterioration can occur at almost any time and with very little warning. This is not only paramount during the primary assessment; ABCs should continue to be reassessed repeatedly throughout transport to the emergency department (ED).

Allergic reactions may present as respiratory distress or as cardiovascular distress in the form of shock. Patients experiencing a severe allergic reaction will often appear very anxious. If your general impression finds the person anxious and in distress, immediately call for ALS backup if available. Sometimes patients who are known to have severe allergies wear a medical identification tag (eg, necklace or bracelet). Such clues could provide crucial information in situations where the patient is found unresponsive or is otherwise unable to answer questions about his or her medical history.

The most severe form of allergic reactions, anaphylaxis, can cause rapid swelling of the upper airway. You may have only a few minutes to assess the airway and provide lifesaving measures; however, not all allergic reactions are anaphylactic reactions. So, work quickly to assess the patient to determine the severity of the symptoms and the number of body systems affected.

Quickly assess for increased work of breathing, use of accessory muscles, head bobbing, tripod positioning, nostril flaring, and abnormal breath sounds. Recall that wheezing occurs because of narrowing of the air passages, which is mainly the result of contraction of muscles around the bronchioles in reaction to the allergen, and mobilization of mucus in an attempt to "push out" the allergen. Exhalation, normally the passive, relaxed part of breathing, becomes harder as the patient tries to cough up the secretions or move air past the constricted airways. The fluid in the air passages and the constricted bronchi together produce the wheezing sound. As the patient's condition worsens, breath sounds may even diminish to the point of being almost silent. **Stridor**, a harsh, high-pitched sound heard on inspiration, occurs when swelling in the upper airway (near the vocal cords and throat) begins to close off the airway. It can eventually lead to total obstruction.

As the patient with respiratory failure attempts to compensate by breathing more rapidly, and as respirations become more difficult, the patient may eventually fatigue and may even stop breathing. In the latter case, cardiac arrest will shortly follow respiratory arrest.

YOU are the Provider — PART 2

The closest hospital is 15 minutes away, while the closest ALS ambulance is over 1 hour away. You perform a primary assessment of the patient and note the following:

Recording Time: 0 Minutes	
Appearance	Anxious; widespread hives
Level of consciousness	Conscious and alert, but mildly confused
Airway	Open, clear of obstructions or foreign bodies
Breathing	Rapid with audible wheezing
Circulation	Radial pulse, rapid rate and strong; skin, flushed and warm, covered with urticaria

The patient reports dyspnea and states that his entire body is itching. Your partner applies high-concentration oxygen via a nonrebreathing mask.

3. Is this patient experiencing a local reaction or anaphylaxis?

4. What body system(s) should you focus your secondary assessment on and why?

Assist the patient into a comfortable position, generally in a high-Fowler position, in an effort to maximize ventilations. This will help perfusion to the brain while easing respiratory effort. However, if signs of shock emerge, the patient should immediately be placed in the supine position as tolerated.

Quickly listen to the lungs on each side of the chest. Do not hesitate to initiate high-flow oxygen therapy. For a patient in severe respiratory distress, you may have to assist ventilations using a bag-valve mask (BVM), attached to a high concentration of oxygen. This can be done in an unresponsive patient or a patient with an altered level of consciousness. The positive-pressure ventilations you provide will force air beyond the swelling in the airway and into the lungs while you await more definitive treatment.

Although respiratory complaints are most common, some patients in anaphylaxis may not present with severe respiratory symptoms but primarily with signs and symptoms of circulatory distress, such as hypotension. Palpating for the presence and quality of a radial pulse will help you quickly identify how the circulatory system is responding to the reaction.

Assess for a rapid pulse rate; pale, cool, cyanotic or red, moist skin; and delayed capillary refill, all of which may indicate hypoperfusion. Treatment for shock includes oxygen, proper positioning, (ie, recumbent or supine as tolerated), and preventing the loss of body heat. The definitive treatment for shock resulting from anaphylaxis is epinephrine.

If anaphylaxis is suspected, or if a relatively mild allergic reaction appears to be worsening, immediate transport is warranted. Before leaving the scene, be sure to take along the patient's medications (eg, auto-injectors and inhalers). If the patient is calm and does not exhibit severe signs and symptoms, consider continuing the assessment at the scene. However, if in doubt, always err on the side of emergency transport.

History Taking

Investigate the patient's chief complaint or history of the present illness. Identify signs and symptoms Table 20-1.

If the patient is responsive, begin by obtaining the SAMPLE history (including OPQRST) and the following information specific to allergic reactions:

- **Have any interventions already been completed?** Prior to your arrival, the patient may have begun self-treatment with his or her own medication, such as an epinephrine auto-injector, a bronchodilator inhaler, or antihistamines such as chlorpheniramine (Chlor-Trimeton) or diphenhydramine (Benadryl).
- **Has the patient experienced a severe allergic reaction in the past?** If so, what happened? The patient's answers may indicate how severe the present reaction may become. For example, if the patient was hospitalized or required intubation due to a previous reaction, you should perceive this as an ominous sign and assume that he or she may have another reaction of equal or even greater severity. In such cases, rapid transport and treatment, as well as ALS care, are among the highest priorities.

Table 20-1 Additional Signs and Symptoms of an Allergic Reaction

Respiratory System	Cardiovascular System	Skin	Other Findings
▪ Sneezing or an itchy, runny nose (early sign) ▪ Shortness of breath (dyspnea) ▪ Tightness in the chest or throat ▪ Irritating, persistent dry cough ▪ Hoarseness ▪ Rapid, labored, or noisy respirations ▪ Wheezing and/or stridor (which may progress to a silent chest with anaphylaxis; late sign)	▪ Increase in pulse rate (tachycardia; early sign) ▪ Red, flushed, hot skin (early sign) or pale, cyanotic, cool skin (late sign) as the vascular system fails ▪ Decrease in blood pressure (hypotension) as the blood vessels dilate (late sign)	▪ Flushing, itching, or burning skin, especially common over the face and upper chest ▪ Urticaria over large areas of the body; may be internal or external ▪ Swelling, especially of the face, neck, hands, feet, and/or tongue, either local (angioedema) or generalized ▪ Cyanosis or pallor around the lips ▪ Warm, tingling feeling in the face, mouth, chest, feet, and hands	▪ Decreasing mental status (early sign of hypoperfusion), from mild confusion or lethargy to loss of consciousness or coma ▪ Anxiety; a sense of impending doom ▪ Gastrointestinal problems, including nausea, vomiting, or abdominal cramps ▪ Headache ▪ Itchy, watery eyes ▪ Dizziness

- **Be alert for any statements regarding the ingestion of foods that commonly cause allergic reactions.** What was the patient doing, or what was the patient exposed to, before the onset of symptoms? This information may be the key to effective treatment, regardless of any prior history of allergic reactions.

Inquire about the presence of gastrointestinal complaints such as nausea and vomiting.

Secondary Assessment

If indicated, perform a rapid full-body scan or conduct a physical examination focused on the area(s) of chief complaint.

If the patient is unconscious or otherwise unable to communicate, remove clothing as necessary and observe for the presence of bee stingers, signs of contact with chemicals, and other clues suggestive of a reaction. Remember to look for a medical alert tag, which could indicate a severe allergy to a particular substance.

If you have not already done so, auscultate for abnormal breath sounds such as wheezing or stridor, and carefully inspect the skin for swelling, rashes, or urticaria. A rapidly spreading rash can be concerning because it may indicate a systemic reaction. The skin may appear pale or cyanotic and cool; however, red, hot skin is typical in the early stages, suggesting a systemic reaction as the blood vessels lose their ability to constrict and blood moves outward and closer to the skin. If a systemic reaction continues, the body will have difficulty supplying blood and oxygen to the vital organs. One of the first signs that this has occurred will be altered mental status, as the brain is deprived of oxygen and glucose.

Vital signs help determine whether the body is compensating for the stress imposed upon the body by the reaction. Assess baseline vital signs, including the pulse and respiratory rate, blood pressure, pupillary response, and oxygen saturation. Remember that skin signs may be unreliable indicators of hypoperfusion, as they may vary widely or be hidden by rashes and swelling.

YOU are the Provider — PART 3

After your partner collects the patient's medications, which include an EpiPen and albuterol inhaler, you begin rapid transport to the emergency department (ED). En route, you obtain the SAMPLE history and learn that the patient is allergic to peanuts and that he was eating dinner at a new restaurant 20 minutes before his symptoms began. Since then, his symptoms have intensified and he wonders if his meal contained peanuts. You reassess his vital signs.

Recording Time: 5 Minutes

Respirations	28 breaths/min; labored
Pulse	120 beats/min; weak at the radial artery
Skin	Pale and cool; widespread urticaria; angioedema of the lips
Blood pressure	88/60 mm Hg
Oxygen saturation (Spo_2)	88% (on oxygen)

During the secondary assessment, you note increased swelling of the patient's face and lips. He is having greater difficulty speaking, and auscultation reveals worsening wheezes on exhalation. Your partner removes the nonrebreathing mask and begins assisting the patient's respirations using a BVM attached to high-flow oxygen.

5. During the primary assessment, why did the patient first present with warm skin? What is the significance of the changes in his skin color and temperature to pale and cool?

6. What are the therapeutic effects of epinephrine when given for anaphylaxis?

In a patient experiencing an allergic reaction, pulse oximetry can be a useful method to assess the patient's perfusion status. However, it is important to remember that pulse oximetry is just another tool in your toolbox. The decision to apply oxygen to a patient experiencing an allergic reaction should be based on a careful assessment of the patient's airway patency, work of breathing, and abnormal lung sounds upon auscultation, not solely on the pulse oximetry readings.

Reassessment

En route to the receiving hospital, repeat the primary assessment. Reassess vital signs, and repeat a focused physical examination of the affected body systems. If the patient is unstable, conduct this reassessment every 5 minutes. If the patient is stable, reassess every 15 minutes. The patient experiencing a suspected allergic reaction should be monitored with vigilance. Deterioration of the patient's condition can be rapid and fatal, so special attention should be given to any signs of airway compromise. The patient's anxiety level and mental status should be monitored as well, as these may provide additional indications of the course of the reaction. Monitor for signs of shock, and, if present, treat immediately.

To treat allergic reactions, you must first identify the severity of the reaction. Mild reactions may only require supportive care and monitoring. On the other hand, anaphylaxis can produce severe or rapidly progressing signs and symptoms, requiring more aggressive treatment, including epinephrine and ventilatory support. In either situation, the patient should be transported to a medical facility for further evaluation.

Recheck your interventions. If you administered epinephrine, what was the effect? Has the patient's condition improved? Does the patient need a second dose? If so, remember to consult medical control before administering any subsequent doses for which you have not already obtained authorization. Also, keep in mind that even if the patient experiences relief following the administration of epinephrine, transport to the ED is still warranted, as the medication's effect will wear off and the symptoms may return.

Your documentation should not only include the signs and symptoms found during your assessment, but should also clearly show *why* you chose the care you provided. Finally, be certain to record the patient's response to your treatment.

Emergency Medical Care of Immunologic Emergencies

If the patient appears to be having a severe allergic or anaphylactic reaction, you should administer basic life support and provide prompt transport to the hospital. If the allergic reaction was caused by an insect sting and the stinger is still in place, attempt to remove the stinger by scraping the skin with the edge of a sharp, stiff object such as a credit card **Figure 20-8**. Do not use tweezers or forceps to remove the stinger because this may squeeze more venom into the wound. Gently wash the area with soap and water or a mild antiseptic. Try to remove any jewelry from the area before swelling begins. Position the injection site slightly below the level of the heart, and apply ice or cold packs to the area. Placing ice over the injury site may slow absorption of the toxin, diminish swelling, and relieve pain, but like any other attempt to reduce swelling with ice, you should be careful not to place the ice pack directly on the skin or leave it in place for too long, as doing so may cause more damage. It is not recommended that ice be placed for longer than 10 minutes at a time.

YOU are the Provider — PART 4

Per standing orders, you have online medical control authorization to administer epinephrine. After confirming that the EpiPen is prescribed to the patient and is not beyond its expiration date, you administer it in the lateral aspect of his thigh. Then, as you continue transport, you reassess the patient and note the following:

Recording Time: 10 Minutes	
Level of consciousness	Conscious and alert
Respirations	22 breaths/min; less labored; wheezing continues
Pulse	124 beats/min; stronger at the radial artery
Skin	Pink, warm, and dry; hives are still present
Blood pressure	104/66 mm Hg
Spo_2	**95% (on oxygen)**

7. In addition to the patient's vital signs, what else should you reassess?
8. How often should you reassess this patient?

Figure 20-8 To remove the stinger of a honeybee, gently scrape the skin with the edge of a sharp, stiff object such as a credit card.

Be alert for signs of airway swelling and other signs of anaphylaxis such as nausea, vomiting, and abdominal cramps, and do not give the patient anything by mouth. Place the patient in the supine position as indicated, and give oxygen if needed. Monitor the patient's vital signs, and be prepared to provide further support as needed.

Epinephrine

The body normally produces epinephrine Table 20-2. **Epinephrine** is a sympathomimetic hormone. This means it mimics the sympathetic (fight or flight) response. Epinephrine has various properties that cause the blood vessels to constrict, which reverses vasodilation and hypotension; this, in turn, elevates the diastolic pressure and improves coronary blood flow. Other properties of epinephrine increase cardiac contractility and relieve bronchospasm in the lungs. Because epinephrine has immediate action, it can rapidly reverse the effects of anaphylaxis. Epinephrine is prescribed by a physician and comes predosed in an epinephrine auto-injector (EpiPen). In some EMS systems, you may be authorized to carry epinephrine as part of your regular on-board medications; in others, you may be permitted to help patients self-administer their own medication. Refer to local protocols or consult online medical control.

Table 20-2	Epinephrine
Indications	Severe allergic reaction causing airway, breathing, or circulatory compromise or an anaphylactic reaction
Contraindications	None in a life-threatening emergency; however, consult medical control when the patient has a history of heart disease or acute coronary syndrome
Actions	Vasoconstriction and increased cardiac contractility, bronchodilation
Side effects	Tachycardia, sweating, pale skin, dizziness, headache, palpitations
Typical dose	Adults: 0.3 mg (EpiPen) Children: 0.15 mg (EpiPen Jr)

Administering an Epinephrine Auto-Injector

All allergic emergency kits should contain a prepared, auto-injectable syringe of epinephrine, ready for intramuscular (IM) injection, along with instructions for its use Figure 20-9.

The adult EpiPen system delivers 0.3 mg of epinephrine via a spring-loaded needle and syringe system; the infant-child system (EpiPen Jr) delivers 0.15 mg. The spring-loaded needle automatically injects the epinephrine when the user firmly presses the device into the lateral thigh (thus the term auto-injector). If the patient is known to have an allergy, he or she may carry his or her own EpiPen. If the patient is able to use the auto-injector on his or her own, your role is limited to assisting him or her if needed.

To use, or help the patient use, the auto-injector, you should first receive a direct order from medical control or follow local protocol. Follow standard precautions, and make sure the medication has been prescribed specifically for that patient. If it has expired or is discolored, do not give the medication. In such an instance, you should inform medical control, and continue to provide emergency transport.

Figure 20-9 Patients who experience severe allergic reactions often carry their own prescription epinephrine, which comes predosed in an auto-injector or a prefilled syringe.

Once you have done these things, follow the steps in **Skill Drill 20-1**.

1. Remove the safety cap from the auto-injector, and, if possible, quickly wipe the patient's thigh with alcohol or some other antiseptic Step 1. (Note: though it is best practice to clean the site, do not delay administration of the drug to do so.) If the patient is displaying signs of life-threatening anaphylaxis, it is possible to administer the auto-injector directly through the patient's clothing.
2. Place the tip of the auto-injector against the lateral part of the patient's thigh, midway between the groin and the knee Step 2.
3. Push the injector firmly against the thigh until a click is heard. This indicates that the injector has activated and medication is being administered. Maintain steady pressure to prevent kickback from the spring in the syringe, and prevent the needle from being pushed out of the injection site too soon. Hold the injector in place until the medication has been injected (10 seconds).
4. Remove the injector from the patient's thigh and dispose of it in the proper biohazard container.
5. Rub the area for 10 seconds Step 3.

YOU are the Provider — PART 5

Following standing orders, you administer a dose of albuterol from the patient's meter-dosed inhaler in order to treat the bronchospasm responsible for his wheezing. A few minutes later, you call the receiving hospital and supply your radio report, including the most recent set of vital signs:

Recording Time: 20 Minutes

Level of consciousness	Conscious and alert
Respirations	18 breaths/min; unlabored; wheezing improved
Pulse	114 beats/min; strong and regular
Skin	Pink, warm, and dry; scattered hives
Blood pressure	128/72 mm Hg
Spo_2	97% (on oxygen by nonrebreathing mask; patient no longer requires positive-pressure assistance)

You deliver the patient to the ED, where the attending physician asks you how much epinephrine the patient has received.

9. What is the dose and concentration of epinephrine contained in an adult EpiPen?

Skill Drill 20-1 Using an EpiPen Auto-injector

Step 1

Remove the auto-injector's safety cap, and quickly wipe the thigh with antiseptic, if possible.

Step 2

Place the tip of the auto-injector against the lateral part of the thigh. Push the auto-injector firmly against the thigh until a click is heard. Hold it in place until all the medication has been injected (10 seconds).

Step 3

Rub the area for 10 seconds.

6. Record the time and dose of the injection on your patient care report.
7. Reassess and record the patient's vital signs after using the auto-injector.
8. If the patient's signs and symptoms do not improve after 5 minutes and the patient has another auto-injector, consider assisting the patient with the administration of a second (and final) dose of epinephrine.

Other allergy kits may contain oral or IM anti-histamines, agents that block the effect of hista-mine. These work relatively slowly, within several minutes to 1 hour. Because epinephrine can have an effect within 1 minute, it is the primary way to save the life of someone having a severe anaphylactic reaction.

Because epinephrine constricts blood vessels, it may cause the patient's blood pressure to rise significantly. Other side effects include increased pulse rate, anxiety, cardiac dysrhythmias, pallor, dizziness, chest pain, headache, nausea, and vomiting. In a life-threatening situation, the administration of epinephrine outweighs the risk of side effects. Remember that *patients who do not exhibit signs of respiratory compromise or hypotension and do not meet the criteria for a diagnosis of anaphylaxis should not be given epinephrine.*

Words of Wisdom

Allergic reactions to bites and stings can progress quickly to life threats. With good care, severe signs and symptoms may subside just as quickly. Performing a multisystem examination and documenting your findings are important before and after treatment. Give particular attention to skin signs and respiratory, circulatory, and mental functioning. If the patient's symptoms seem to resolve and he or she no longer desires to go to the hospital, explain that the effects of epinephrine can wear off before the underlying allergic reaction has fully resolved, and life-threatening symptoms may recur.

Administering Intramuscular Epinephrine

Some areas may allow administration of epinephrine by intramuscular injection, using a vial of 1:1,000 concentration epinephrine along with a needle and syringe. The typical adult dose is 0.3 mg, injected into the midanterolateral thigh. The pediatric dose is weight-based, with the most commonly administered dosage being 0.15 mg in the form of the EpiPen Jr, with a maximum single dose of 0.3 mg. It is critical to remember that with IM epinephrine injection, the concentration must be 1:1,000. Other concentrations are available, but are not used in IM injections for anaphylaxis. Be familiar with whether your protocols allow for epinephrine IM injection.

Special Populations

When you encounter a geriatric patient experiencing anaphylaxis, obtain a complete and accurate medical history. Because of the potential side effects of epinephrine, such as increased pulse rate, increased myocardial oxygen demand, and increased workload of the heart, you must weigh the risk versus benefit in epinephrine administration. If the patient has a history of cardiac problems, such as a previous heart attack or coronary artery disease, the administration of epinephrine is relatively contraindicated, meaning potential harm could occur to the patient if he or she receives epinephrine. In situations such as these, if available, online medical control should be contacted for guidance. If the patient is prescribed an EpiPen and has signs and symptoms of anaphylaxis, assist the patient with administration if needed.

YOU are the Provider — SUMMARY

1. What, if any, additional resources should you request?

You should consider requesting the response of an advanced life support (ALS) unit. Consider the time it will take to reach the nearest hospital versus the time needed to rendezvous with an ALS unit, the feasibility of requesting transport by helicopter, etc. Understand and follow your local protocols.

2. What intervention(s) should you perform without delay?

Because the patient's respiratory distress is an immediate life threat, providing high-concentration oxygen is the first action you should take.

3. Is this patient experiencing a local reaction or anaphylaxis?

The presence of widespread urticaria (hives) indicates that the patient is experiencing a systemic allergic reaction. Systemic reactions vary in severity and can range from diffuse (widespread) hives and itching to cardiovascular collapse and death.

A local reaction is characterized by tenderness, redness, itching, and swelling at and immediately adjacent to the bite or sting. In many cases, the reaction is not "allergic" in nature—it is simply irritation and inflammation that is caused by the bite or sting itself.

It is important to perform a careful and thorough assessment of patients who are exposed to something to which they have a confirmed allergy. A seemingly local and mild reaction can become systemic and severe within a matter of minutes.

4. What body system(s) should you focus your secondary assessment on and why?

Further assessment of the patient should focus on body systems that are commonly affected by an allergic reaction—

the respiratory and circulatory systems and the skin. In most cases, a severe allergic reaction occurs within minutes of exposure; however, it may be delayed for up to an hour in some patients.

Your primary assessment has revealed no immediate threats to your patient's airway, breathing, or circulation; however, the presence of a widespread rash indicates a systemic reaction and warrants a more thorough assessment. As you continue to assess the patient, look for clinical signs that indicate a worsening reaction and be prepared to assist ventilations and treat for shock.

Signs of respiratory system involvement include respirations that become rapid, labored, or noisy; wheezing; stridor; an irritating, persistent dry cough; hoarseness; and tightness in the chest or throat.

Signs of circulatory system involvement include tachycardia (initially), followed by pallor, dizziness, and hypotension. A decreasing level of consciousness indicates a decrease in cerebral blood flow; this is usually secondary to vascular dilation and hypotension.

The patient already has widespread hives, and his skin is flushed. However, you should further assess the skin by looking for swelling—especially of the face, tongue, neck, hands, and feet. If the patient reports a warm, tingling feeling in the face, mouth, chest, feet, and hands, this should also be cause for concern.

5. During the primary assessment, why did the patient first present with warm skin? What is the significance of the changes in his skin color and temperature to pale and cool?

When vasodilation and increased capillary permeability occur in the early stages of an allergic reaction, fluid leaks out of the bloodstream and into the subcutaneous (fatty) layer of the skin. This causes swelling, redness, warmth, and urticaria of the skin. But as the reaction progresses, bronchoconstriction impairs oxygenation and ventilation, producing hypoxemia. Clinical signs of hypoxemia, include altered mental status, tachycardia, cyanosis, and a low oxygen saturation (Spo_2).

Tachycardia indicates that the body is attempting to compensate for decreased perfusion and hypoxemia by releasing more epinephrine (adrenaline) into the bloodstream to pump more blood to the body's organs, tissues, and cells.

Hypotension occurs because of widespread vasodilation and a decrease in arterial pressure—again, in response to the body's massive release of histamines. As the blood pressure falls, the brain and other vital organs are deprived of oxygen.

6. What are the therapeutic effects of epinephrine when given for anaphylaxis?

Epinephrine (adrenaline)—a hormone that is normally produced by the body—works to rapidly increase the heart rate, dilate the bronchioles in the lungs, and raise the blood pressure by constricting the blood vessels. During anaphylaxis, however, the body may not produce enough epinephrine to enable these actions; therefore, epinephrine is administered to compensate for the body's slow response.

Epinephrine does not stop the allergic reaction itself; it reverses the negative effects of bronchoconstriction and vasodilation, which are caused by the reaction. Therefore, when epinephrine is administered to the patient, it dilates the bronchioles, which improves breathing, and constricts the blood vessels, which increases the blood pressure and improves perfusion.

7. In addition to the patient's vital signs, what else should you reassess?

Ask him if he still feels like he has a lump in his throat; this was likely the result of mild upper airway swelling caused by angioedema and *must* be reassessed. Even though he did not present with obvious external angioedema, you should still reassess his face, lips, tongue, neck, and other parts of his body for swelling.

Auscultate his breath sounds to determine if wheezing is still present. Scattered wheezing may still be heard, even though the patient is not exhibiting any outward signs of respiratory distress.

Reassess his skin to determine if his hives are resolving or if they are still present. In most cases, hives will persist, at least to some degree, following the administration of epinephrine. You will usually notice improvement in the patient's breathing and perfusion status (eg, mental status, blood pressure, peripheral pulse quality) before you see resolution of hives.

8. How often should you reassess this patient?

This patient should be considered high-priority or critical and, therefore, should be reassessed every 5 minutes en route to the receiving facility.

9. What is the dose and concentration of epinephrine contained in an adult EpiPen?

The adult EpiPen contains 0.3 milligrams (mg) of a 1:1,000 concentration for intramuscular injection. A 1:1,000 concentration contains 1 mg of epinephrine per 1 milliliter (mL). Therefore, 0.3 mL contains 0.3 mg of epinephrine—all of which is injected into the patient's thigh.

EMS Patient Care Report (PCR)

Date: 01-3-16	**Incident No.:** 011709	**Nature of Call:** Shortness of breath		**Location:** 1444 City Park Drive	
Dispatched: 1310	**En Route:** 1310	**At Scene:** 1316	**Transport:** 1322	**At Hospital:** 1339	**In Service:** 1350

Patient Information

Age: 33 **Sex:** M **Weight (in kg [lb]):** 73 kg (160 lb)	**Allergies:** Peanuts; no known drug allergies **Medications:** Prescribed EpiPen and albuterol inhaler **Past Medical History:** Previous allergic reaction to peanuts; required hospitalization **Chief Complaint:** Dyspnea, urticaria, and itching

Vital Signs

Time: 1322	**BP:** 88/60	**Pulse:** 120	**Respirations:** 28	**Spo_2:** 88%

Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** Epinephrine 0.3 mg via EpiPen, albuterol inhaler

Narrative

Medic 85 responded to a local restaurant where a 33-year-old man presented with dyspnea, generalized urticaria, and itching approximately 20 minutes after eating his meal. The patient was conscious and alert; his airway was patent and his breathing was rapid with audible wheezes. The patient was placed on oxygen via nonrebreathing mask. He stated that he was uncertain whether or not his meal had contained peanuts, a food to which he is severely allergic. He further stated that the last time he ingested a product containing peanuts, he had to be hospitalized. Partner retrieved patient's EpiPen and albuterol inhaler while further assessment was performed. Patient was then placed onto the stretcher, loaded into the ambulance, and transported to the hospital. As assessment continued en route, patient's condition began to deteriorate. He remained conscious, but became confused. He began experiencing increasing respiratory distress, as well as hypotension and a falling oxygen saturation. Auscultation revealed bilateral expiratory wheezing in all lung fields. The patient's face and lips began to show signs of swelling. At that time, the nonrebreathing mask was exchanged for a BVM attached to 15 L/min of oxygen, and his respirations were assisted. Patient denied chest discomfort and other past medical history. The patient was unable to self-administer his EpiPen; therefore, it was given by EMS, following standing orders, in the lateral aspect of his right thigh; dose given was 0.3 mg of 1:1,000 concentration. Reassessment showed that his symptoms had begun to resolve; his mental status had improved and he stated that it was easier to breathe. Blood pressure and oxygen saturation also improved. Hives were still present, although they appeared to be resolving. However, the wheezing continued; thus, per standing orders, the patient was assisted in the administration of his albuterol inhaler. Continued to monitor patient's condition throughout transport; he continued to improve and was delivered to the ED staff without incident. Gave verbal report to charge nurse and returned to service.**End of report**

Prep Kit

Ready for Review

- An allergic reaction is a response to chemicals the body releases to combat certain stimuli, called allergens.
- Allergic reactions occur most often in response to five categories of stimuli: food, medication, plants, chemicals, and insect bites and stings.
- The reaction may be mild and local, involving itching, redness, and tenderness, or it may be severe and systemic, including shock and respiratory failure.
- Anaphylaxis is a life-threatening allergic reaction mounted by multiple organ systems, which must be treated with epinephrine.
- Wheezing and skin wheals can be signs of anaphylaxis.
- All patients with suspected anaphylaxis require oxygen.
- When assessing a person who may be having an allergic reaction, you should check for flushing, itching, and swelling skin, hives, wheezing and stridor, a persistent cough, a decrease in blood pressure, a weak pulse, dizziness, abdominal cramps, and headache.
- Because epinephrine can have an effect within 1 minute, it is the primary way to save the life of someone having a severe anaphylactic reaction.
- You may help a patient to administer an epinephrine auto-injector (EpiPen) with authorization from medical control.
- Always provide prompt transport to the hospital for any patient who is having an allergic reaction. Remember that signs and symptoms can rapidly become more severe. Carefully monitor the patient's vital signs en route; be especially alert for airway compromise.

Vital Vocabulary

allergen Substance that cause an allergic reaction.

allergic reaction The body's exaggerated immune response to an internal or surface agent.

anaphylaxis An extreme, life-threatening, systemic allergic reaction that may include shock and respiratory failure.

angioedema Localized areas of swelling beneath the skin, often around the eyes and lips, but it can also involve other body areas as well.

envenomation The act of injecting venom.

epinephrine A substance produced by the body (commonly called adrenaline), and a drug produced by pharmaceutical companies that increases pulse rate and blood pressure; the drug of choice for an anaphylactic reaction.

histamines Chemical substances released by the immune system in allergic reactions that are responsible for many of the symptoms of anaphylaxis, such as vasodilation.

immune response The body's response to a substance perceived by the body as foreign.

immune system The body system that includes all of the structures and processes designed to mount a defense against foreign substances and disease-causing agents.

immunology The study of the body's immune system.

leukotrienes Chemical substances that contribute to anaphylaxis; released by the immune system in allergic reactions.

stridor A harsh, high-pitched respiratory sound, generally heard during inspiration, that is caused by partial blockage or narrowing of the upper airway; may be audible without a stethoscope.

toxin A poison or harmful substance.

urticaria Small areas of generalized itching and/ or burning that appear as multiple raised areas on the skin; hives.

wheal A raised, swollen, well-defined area on the skin resulting from an insect bite or allergic reaction.

wheezing A high-pitched, whistling breath sound that is most prominent on expiration, and which suggests an obstruction or narrowing of the lower airways; occurs in asthma and bronchiolitis.

Assessment *in Action*

You and your partner are dispatched to 1284 NW 152 Avenue for a child experiencing respiratory distress. On arrival, a frantic woman meets you at the door and begs you to hurry. She informs you that her 12-year-old son was playing in the backyard when he felt a sudden pain on the back of his leg. You find the child on the back porch, in obvious distress, leaning forward in a chair with his elbows on his knees, struggling to catch his breath. Due to severe dyspnea, he is unable to answer your questions. You also notice that his left arm is in a cast. Your partner immediately applies a nonrebreathing mask as you complete the primary assessment. The child's respirations are rapid and shallow, and his pulse is rapid and thready. His skin is pale with patches of raised red spots on his hands, arms, and face. Your partner conducts a systematic rapid physical exam as you obtain vital signs and a SAMPLE history from the mother. When you inquire about allergies, the mother tells you the child had a very mild reaction to a bee sting several months ago. His medical history also includes asthma, anxiety, and a recent fracture of his arm. Your partner informs you that he heard wheezes in all lung fields and observed additional raised red spots on the child's chest.

1. The raised red spots are most likely:

   A. angioedema.
   B. acne.
   C. urticaria.
   D. a fungal infection.

2. What should you do first?

A. Administer albuterol.
B. Transport to the hospital.
C. Administer epinephrine.
D. Coach the patient to slow his breathing.

3. What possible chemical is being released into this patient's body during this reaction?

A. Histamine
B. Antihistamine
C. Epinephrine
D. Glucose

4. Which medication should be administered first for this patient?

A. Albuterol
B. Epinephrine
C. Acetaminophen (Tylenol)
D. Diphenhydramine (Benadryl)

5. Your partner indicates that he heard wheezes in all lung fields. What did he hear?

A. A high-pitched whistling sound caused by bronchoconstriction
B. A coarse, low-pitched breath sound heard in patients with chronic mucus in the upper airways
C. A high-pitched noise heard primarily on inspiration
D. Crackling, moist breath sounds

6. Your partner notes the presence of a medical alert bracelet around the patient's wrist. What should be done and why?
7. Your partner suggests that, in addition to epinephrine, the two of you should assist the patient in using his albuterol inhaler. How should you respond? Why?
8. Following the administration of epinephrine, the patient reports that his heart is beating "very fast." How should you respond?
9. Besides an allergic reaction, provide an example of another illness or injury you should consider as part of the differential diagnosis.

CHAPTER
21

Toxicology

National EMS Education Standard Competencies

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Toxicology

› Recognition and management of
  - Carbon monoxide poisoning (pp 774–775)
  - Nerve agent poisoning (pp 789–790)

› How and when to contact a poison control center (p 774)

› Anatomy, physiology, pathophysiology, assessment, and management of
  - Inhaled poisons (pp 774–775, 779–781)
  - Ingested poisons (pp 777, 779–782)
  - Injected poisons (pp 777–781)
  - Absorbed poisons (pp 776–777, 779–781)
  - Alcohol intoxication and withdrawal (pp 783–784)

Knowledge Objectives

1. Define toxicology, poison, toxin, and overdose. (p 771)
2. Identify the common signs and symptoms of poisoning or toxic exposure. (p 772)
3. Describe how poisons and toxins can enter the body. (pp 773–778)
4. Describe the assessment and treatment of a patient with a suspected poisoning or toxic exposure. (pp 779–794)
5. Describe the assessment and treatment of a patient with a suspected overdose. (pp 779–791)

6. Discuss scene safety considerations for working at a scene with a potentially hazardous material or violent patient. (p 779)
7. Understand the role of airway management in a patient suffering from poisoning or overdose. (pp 779–793)
8. Explain the use of activated charcoal, including indications, contraindications, and the need to obtain approval from medical control before administration. (pp 780–782)
9. Identify the main types of toxins and poisons and their effects, including alcohol, opiates and opioids, sedative-hypnotic drugs, inhalants, hydrogen sulfide, sympathomimetics, synthetic cathinones, marijuana, hallucinogens, anticholinergic agents, and cholinergic agents. (pp 782–791)
10. Discuss how to manage a patient who has overdosed on an opioid or opiate and who has gone into cardiac or respiratory arrest. (pp 784–785)
11. Describe the assessment and treatment of a patient with suspected food poisoning. (pp 791–793)
12. Describe the assessment and treatment of a patient with suspected plant poisoning. (pp 793–794)

Skills Objectives

1. Demonstrate how to assess and treat a patient with a suspected poisoning. (pp 779–781)
2. Demonstrate how to assess and treat a patient with a suspected overdose. (pp 780–781)
3. Demonstrate how to administer activated charcoal. (pp 781–782)

Introduction

Every day, each of us comes into contact with things that are potentially poisonous. This is not surprising when you consider that almost any substance may be a poison in certain circumstances. Different doses can turn even a remedy into a poison. Consider a common medication such as aspirin. When taken in recommended doses, it is a safe and effective pain reliever (analgesic). Too much aspirin, however, can result in death.

According to the National Poison Data System, acute poisoning affects approximately 2 million people each year. Chronic poisoning—often caused by the long-term abuse of medications, tobacco, and alcohol—is more common. Fortunately, deaths caused by acute poisoning are fairly rare. Rates of death as the result of acute poisoning in children have decreased steadily since the late 1960s, when child-resistant caps were introduced for drug bottles and containers. However, deaths caused by chronic poisoning in adults have risen in the last few years, primarily as the result of drug abuse.

In this chapter, the term *poisoned* includes acute and chronic poisonings. As an EMT, you must recognize that patients with either type of condition may have a variety of symptoms. Although you cannot stop chronic substance abuse in a patient, you may be able to prevent death caused by the acute effects of a poison, simply by providing airway management and symptomatic care during transport.

This chapter discusses how to identify a patient who has been poisoned or exposed to a toxin, and how to gather clues about the substance. Also described are the different ways in which a poison or toxin is introduced into the body. The chapter then discusses the signs, symptoms, and treatment of specific poisons. Hazardous materials exposure, food poisoning, and plant poisoning are also discussed.

Words of Wisdom

Drugs interact with one another. Food, alcohol, vitamins, over-the-counter (OTC) medications, homeopathic agents, and other substances can prevent a drug from working as expected. These interactions can alter the effectiveness of the drug and increase the risk of adverse (harmful) effects.

Identifying the Patient and the Poison

Toxicology is the study of toxic or poisonous substances. A **poison** is any substance whose chemical action can damage body structures or impair body function. A **toxin** is a poisonous substance produced by bacteria, animals, or plants that acts by changing the normal metabolism of cells or by destroying them. Toxins can have acute effects (for example, an injection of heroin may cause respiratory arrest) and chronic effects (for example, years of substance abuse may lead to a weakened immune system). **Substance abuse** is the misuse of any substance to produce a desired effect (for example, heroin intoxication). A common complication of substance abuse is **overdose**, when a patient takes a toxic or lethal dose of a substance.

Your primary responsibility to the patient who has been poisoned is to recognize that a poisoning has occurred. Your own safety plays a key role here as well; pay attention to your surroundings **Figure 21-1**. The where, what, and how of the exposure is important. Keep in mind that very small amounts of some poisons or toxins can cause considerable harm or death. Never let your guard down and allow yourself to become exposed to the same substance. If you have even the slightest suspicion that an **ingestion** (swallowing) or exposure to a toxic substance has occurred, notify medical control and begin emergency treatment immediately. Discussion of issues relating to suicide is covered in Chapter 22, *Psychiatric Emergencies*.

Figure 21-1 Never open a door or approach a scene until you have ascertained that the area is safe to enter. Keep in mind that very small amounts of some poisons or toxins can cause considerable harm or death.

Courtesy of Darin Dowe/Law and Order Magazine/Hedon Media Group.

Symptoms and signs of poisoning or overdose vary according to the specific agent, as shown in Table 21-1. Some poisons cause the pulse to speed up, whereas others cause it to slow down; some poisons cause the pupils to dilate, while others cause the pupils to constrict. If respiration is depressed or difficult, cyanosis may occur. Some chemical compounds will irritate or burn the skin or mucous membranes, resulting in burning or blistering. The presence of such injuries at the patient's mouth strongly suggests the ingestion of a poison, such as lye. If possible, ask the patient the following questions while you obtain the SAMPLE history (Signs and symptoms; Allergies; Medications; Pertinent past medical history; Last oral intake; Events leading up to the injury or illness):

- What substance did you take?
- When did you take it (or become exposed to it)?
- How much did you ingest?
- Did you have anything to eat or drink before or after you took it?
- Has anyone given you an antidote or any substance orally since you ingested it?
- How much do you weigh?

Be extremely careful in dealing with a child who has ingested a poisonous substance. Although such incidents usually do not lead to death, family members may be distraught, and your calm, professional attitude will help to ease the tension. Remember, however, that a single swallow or single pill of some substances can kill a child.

Table 21-1 Typical Signs and Symptoms of Specific Overdoses

Agent	Signs and Symptoms
Opiates (Examples: morphine, codeine) Opioids (Examples: heroin, methadone, oxycodone)	▪ Hypoventilation or respiratory arrest ▪ Pinpoint pupils ▪ Sedation or coma ▪ Hypotension
Sympathomimetics (Examples: epinephrine, albuterol, cocaine, methamphetamine)	▪ Hypertension ▪ Tachycardia ▪ Dilated pupils ▪ Agitation or seizures ▪ Hyperthermia
Sedative-hypnotics (Examples: diazepam, secobarbital, flunitrazepam, midazolam)	▪ Slurred speech ▪ Sedation or coma ▪ Hypoventilation ▪ Hypotension
Anticholinergics (Examples: atropine, diphenhydramine, chlorpheniramine, doxylamine, *Datura stramonium* [jimsonweed])	▪ Tachycardia ▪ Hyperthermia ▪ Hypertension ▪ Dilated pupils ▪ Dry skin and mucous membranes ▪ Sedation, agitation, seizures, coma, or delirium ▪ Decreased bowel sounds

Cholinergics (Examples: organophosphates, pilocarpine, nerve gas)	▪ Airway compromise
	▪ SLUDGEM:
	  ▪ **S** Salivation, sweating
	  ▪ **L** Lacrimation (excessive tearing of the eyes)
	  ▪ **U** Urination
	  ▪ **D** Defecation, drooling, diarrhea
	  ▪ **G** Gastric upset and cramps
	  ▪ **E** Emesis (vomiting)
	  ▪ **M** Muscle twitching/miosis (pinpoint pupils)

Words of Wisdom

Do not judge the patient for becoming exposed to a poisonous substance, especially if the exposure was an incident of self-harm. Always treat the patient with respect and compassion.

Try to determine the nature of the poison. Look around the immediate area for objects that may provide clues: an overturned bottle, a needle or syringe, scattered pills, chemicals, the remains of food or drink items, or even an overturned or damaged plant. Place any suspicious material in a plastic bag and take it with you to the hospital, along with any containers you find.

Drug containers at the scene can provide critical information. In addition to the name and concentration of the drug, a pill bottle label may list specific ingredients, the number of pills that were originally in the bottle, the name of the manufacturer, and the dose that was prescribed. This information can help emergency department physicians determine how much has been ingested and what specific treatment may be required. For certain food poisonings, a food container that lists the name and location of the restaurant or vendor may help save the life of the patient and possibly other customers.

If the patient vomits, examine the contents for pill fragments. Wear proper personal protective equipment (PPE) for this activity. Note and document anything unusual that you see.

How Poisons Enter the Body

Emergency care for a patient who has been poisoned may range from reassuring an anxious parent or caregiver to performing cardiopulmonary resuscitation (CPR). For these patients, definitive treatment can only be provided at the emergency department, so transport promptly whenever poisoning is involved. Often, you will not administer a specific **antidote** (a substance that will counteract the effects of a particular poison) because most poisons do not have one. Depending on local protocols, the antidote most commonly available to EMTs is naloxone (Narcan), which is used to reverse the effects of an opioid overdose. Naloxone is discussed later in the chapter. If you work in a tiered system, advanced life support (ALS) backup may also be appropriate, because these providers can administer additional medications and therapies.

In general, the most important treatment you can perform for a poisoning is to dilute and/or physically remove the poisonous agent. How you do this depends on how the poison entered the patient's body in the first place. The four routes to consider are as follows:

- Inhalation **Figure 21-2A**
- Absorption (surface contact) **Figure 21-2B**
- Ingestion **Figure 21-2C**
- Injection **Figure 21-2D**

YOU are the Provider — PART 1

It is 0220 hours. Your unit is dispatched to a prominent gated community. A security guard meets you and fire department personnel at the gate and escorts you to 1968 Holly Creek Place. Dispatch advises you the patient is female with acute onset of "flulike symptoms." As you arrive, you notice several police cars on scene as well. You and your paramedic partner enter the home and find a 17-year-old girl slouched on the couch. There is a strong odor of vomit on her clothing and she appears sleepy.

The patient's mother is by her side and there is a basin with vomit on the floor beside them. The father reports he was awakened when the teenager and her friends came home from a party and were making a lot of noise. He found his daughter on the front porch and brought her inside.

1. In addition to providing immediate lifesaving treatment, what else should you do when you arrive at this scene?
2. How can knowledge of various signs and symptoms caused by different types of medications improve the care you provide to a patient?

Figure 21-2 There are four routes by which a poison can enter the body. **A.** Inhalation. **B.** Absorption (surface contact). **C.** Ingestion. **D.** Injection.

Words of Wisdom

Poison Centers

The American Association of Poison Control Centers (AAPCC) supports the nation's poison centers in their efforts to prevent and treat poison exposures. The phone number of your regional poison center is typically listed on the inside cover of your local phone book or on the AAPCC website. The telephone number for the Poison Help hotline is 1-800-222-1222 (available 24 hours a day, 7 days a week). Staff members at every center have access to information about virtually all of the commonly used medications, chemicals, and substances that could possibly be poisonous. These experts know the appropriate emergency treatment for each, including the antidote, if there is one.

If you believe a patient has been poisoned, immediately provide the poison center with all relevant information: when the poisoning occurred; evidence found at the scene; a description of the suspected poison, including the amount involved; and the patient's size, weight, and age. If necessary, medical control can contact the regional poison center for you and relay specific instructions back to you. Follow your local protocols.

A medical toxicologist is a physician who specializes in caring for patients who have been poisoned. These specialists work in special facilities called medical toxicology treatment centers, located throughout the United States. At times, your medical control may divert a patient who meets certain poisoning criteria to one of these centers instead of to the closest hospital.

You and your medical control center should know the telephone number of your regional poison center and have it available in the event you encounter an unexpected case of poisoning.

All four routes of poisoning can lead to serious and possibly life-threatening conditions. Take care to treat these patients appropriately and to keep yourself safe from harm. If you are uncertain how to treat a patient who has been poisoned or exposed to a specific substance, find the container if possible, and contact medical control and/or the poison control center before you proceed. Always assess the situation and determine whether the scene is safe before you approach the patient.

Inhaled Poisons

Patients who have inhaled poison—including natural gas, sewer gas, certain pesticides, carbon monoxide, and chlorine—should be moved to fresh air immediately. Depending on how long the patient was exposed, he or she may require supplemental oxygen **Figure 21-3**. During the scene size-up, if you suspect the presence of a toxic gas, call for specialized resources such as the hazardous materials (HazMat) team. Never approach a contaminated patient unless you have specialized HazMat training and are using the appropriate PPE. It will be necessary to use a self-contained breathing apparatus to protect yourself from poisonous fumes. If you are not specifically trained in the use of this apparatus or do not have appropriately fit-tested equipment available, defer to appropriately trained and equipped personnel. Patients may need to be decontaminated by the HazMat team after they are removed from the toxic environment. The patient's clothing should be removed in this process because it may contain trapped gases that can be released, exposing you to the substance. You cannot administer emergency care until this step has been completed and there is no danger of the poison contaminating you.

Some inhaled poisons, such as carbon monoxide, are colorless and odorless and produce severe hypoxia without damaging or even irritating the lungs. Others, such as chlorine, are very irritating to the tissues and cause airway obstruction and pulmonary edema. The patient may have the following signs and symptoms: burning eyes, sore throat, cough, chest pain, hoarseness, wheezing, respiratory distress, dizziness, confusion, headache, or stridor in severe cases. The patient may also have seizures or an altered mental status. Most inhaled toxins can be treated by removing the patient from the exposure and applying oxygen. However, some inhaled agents cause progressive lung damage, even after the patient has been removed from direct exposure; the damage may not be evident for several hours. Meanwhile, it may take 2 or 3 days or more of intensive care to restore normal lung function. For this reason, all patients who have inhaled poison require prompt transport to an emergency department. Be prepared to use supplemental oxygen via a nonrebreathing mask and/or ventilatory support with a bag-valve mask (BVM), if necessary. Remember that pulse oximetry readings may be inaccurate with inhaled poisons. Make sure a suction unit is available in case the patient vomits.

Figure 21-3 Patients who have inhaled poisons may need supplemental oxygen and prompt transport to the emergency department.

Words of Wisdom

According to the Centers for Disease Control and Prevention, during the winter months, the increased use of alternative heating systems in poorly-ventilated spaces can lead to an increase in carbon monoxide poisonings.

As with other poisonings, it is helpful to take the containers, bottles, and labels with you when you transport the patient to the hospital. Some patients use inhaled poisons to commit suicide. A common method is for the patient to sit inside a vehicle with the engine running in an enclosed garage. The exhaust fumes from the vehicle contain high levels of carbon monoxide that will cause the patient to become unconscious and eventually stop breathing. A variation of this method is chemical or detergent suicide, which involves using a tightly sealed vehicle as a type of gas chamber. These people mix household chemicals inside the vehicle to produce hydrogen sulfide gas, which is quickly fatal. When you approach the vehicle and open the door, you may be overcome by the gas as well. If you suspect this type of scenario has taken place, contact HazMat responders and have them remove the victim. Hydrogen sulfide is discussed in more detail later in the chapter.

Words of Wisdom

Any time there is more than one patient and no evidence of the mechanism of injury (MOI) or nature of illness (NOI), be suspicious. This is especially true when you encounter patients with changes in level of consciousness, especially at an industrial site or in an enclosed space. Toxic fumes may be odorless and colorless or may seem harmless, such as in the case of sewer gas. If the substance is in the atmosphere, it will affect the emergency providers as well as the patients. An EMT who is incapacitated is no help to anyone.

Absorbed and Surface Contact Poisons

Poisons that come in contact with the surface of the body can affect the patient in many ways. Many corrosive substances will damage the skin, mucous membranes, or eyes, causing chemical burns, rashes, or lesions. Acids, alkalis, and some petroleum (hydrocarbon) products are very destructive. Other substances are absorbed into the bloodstream through the skin and have systemic effects, just like medications or drugs taken via the oral or injectable routes. Other substances, such as poison ivy or poison oak, may cause an itchy rash without being dangerous to the patient's health. It is important, therefore, to distinguish between contact burns and contact absorption.

Words of Wisdom

Absorption of toxic substances through the skin is a common problem in the agriculture and manufacturing industries. Most solvents, insecticides, herbicides, and pesticides are toxic and can be readily absorbed through the skin.

Signs and symptoms of absorbed poisons include a history of exposure, liquid or powder on a patient's skin, burns, itching, irritation, redness of the skin in light-skinned people, or typical odors of the substance.

Emergency treatment for a typical contact poisoning includes the following two steps:

1. Avoid contaminating yourself or others.
2. While protecting yourself from exposure, remove the irritating or corrosive substance from the patient as rapidly as possible.

Remove all clothing that has been contaminated with poisons or irritating substances. If a dry powder has been spilled, thoroughly brush off the chemical (avoid creating a dust cloud), flush the skin with clean water for 15 to 20 minutes, and then wash the skin with soap and water. If liquid material has been spilled on a patient, flood the affected part for 15 to 20 minutes. If the patient has a chemical agent in the eyes, irrigate them quickly and thoroughly. To avoid contaminating the other eye as you irrigate the affected eye, make sure the fluid runs from the bridge of the nose outward **Figure 21-4**. Initiate this action on the scene and continue it during transport. Keep in mind that you may have to help the patient keep his or her eyes open.

Many chemical burns occur in industrial settings, where safety showers and specific protocols for handling surface burns are available. If you are called to such a scene, a HazMat team should be available to assist you. Always ensure you, your team members, and the exposed patient are thoroughly decontaminated prior to transport. Failure to do so will result in the risk of contaminating the entire emergency department and staff. After effective decontamination has occurred, promptly transport to the emergency department for definitive care. Obtain a **material safety data sheet (MSDS)** (or safety data sheet [SDS]) from industrial sites and transport it with the patient. If it is not immediately available, ask the company to fax it to the receiving hospital while you are en route. This will help to identify and quickly make available specific interventions and potential antidotes. Chapter 39, *Incident Management*, discusses hazardous materials and decontamination in detail.

YOU are the Provider — PART 2

You approach the patient and the mother tells you she vomited up some pills. You glance down at the basin of vomit on the floor and note several different colors of pill fragments. You also notice a vomit stain on the patient's shirt is speckled with different colors. As you begin your assessment of the patient, you note her respirations are very slow.

Recording Time: 0 Minutes	
Appearance	Slouched into the couch with her head down, motionless
Level of consciousness	Sleepy and not responding without stimulation
Airway	Oral secretions; snoring respirations
Breathing	Slow rate; shallow depth; breath sounds diminished to absent
Circulation	Radial pulses, rapid and weak; skin is cool, pale, and wet; no gross bleeding

3. On the basis of your initial assessment, what is the most appropriate treatment for this patient?
4. On the basis of the patient's initial presentation, what type of drug should you suspect she overdosed on?

Figure 21-4 If chemical agents are in the patient's eyes, irrigate the eyes quickly and thoroughly, ensuring that the irrigation fluid runs from the bridge of the nose outward. (Use of a nasal cannula is pictured.)

Ingested Poisons

According to the AAPCC, approximately 80% of all poisoning is by mouth (ingestion). Ingested poisons include liquids, household cleaners, contaminated food, plants, and, in most cases, drugs. Ingested poisoning is usually accidental in children and, except for contaminated food, deliberate in adults. Plant poisonings are common among children, who like to explore and often bite the leaves of various bushes or shrubs.

The signs and symptoms of ingested poisons vary greatly with the type of poison, the age of the patient, and the time that has passed since the ingestion. Small children may respond by crying if the poison is an acid or alkaline, and these types of poisons often cause burns around the mouth. Gastrointestinal pain may be present in some cases, and patients may vomit before or after your arrival. If the patient has an altered mental status, it is critical that you protect the patient from aspirating if he or she vomits. Other signs and symptoms depend on the substance involved; for example, some poisons may cause cardiac dysrhythmias whereas others may cause seizures. It is important to treat these signs and symptoms and notify the poison center and medical control of the patient's condition. Consider whether there is unabsorbed poison remaining in the gastrointestinal tract and whether you can safely and effectively prevent its absorption.

Words of Wisdom

Be aware that some chemicals react with water. Although small amounts can usually be flushed safely with large quantities of water, larger amounts of such chemicals can give off toxic fumes or explode when wet. Be sure to check the relevant warnings and placards, and avoid potential injury to your patient and yourself by calling for additional resources (HazMat team) when in doubt.

When the patient has ingested a toxin, some EMS systems allow EMTs to administer activated charcoal by mouth.

Activated charcoal is discussed later in the chapter.

Although every poison will result in a specific set of symptoms and signs, always immediately assess the airway, breathing, and circulation (ABCs) of every patient who has been poisoned. Many patients have died as a result of conditions related to the ABCs that might have been managed easily. Be prepared to provide aggressive ventilatory support and CPR, if necessary, to a patient who has ingested an opioid, a sedative, or a barbiturate, each of which can cause depression of the central nervous system (CNS) and slow breathing.

Injected Poisons

Exposure by injection includes intravenous drug abuse and envenomation by insects, arachnids, and reptiles (these injuries are covered in Chapter 20, *Immunologic Emergencies* and Chapter 32, *Environmental Emergencies*). Injected poisons cannot be diluted or removed from the body in the field because they are usually absorbed quickly into the body or cause intense local tissue destruction. When people become ill from an injected poison, their condition can be life threatening and you must act quickly **Figure 21-5**.

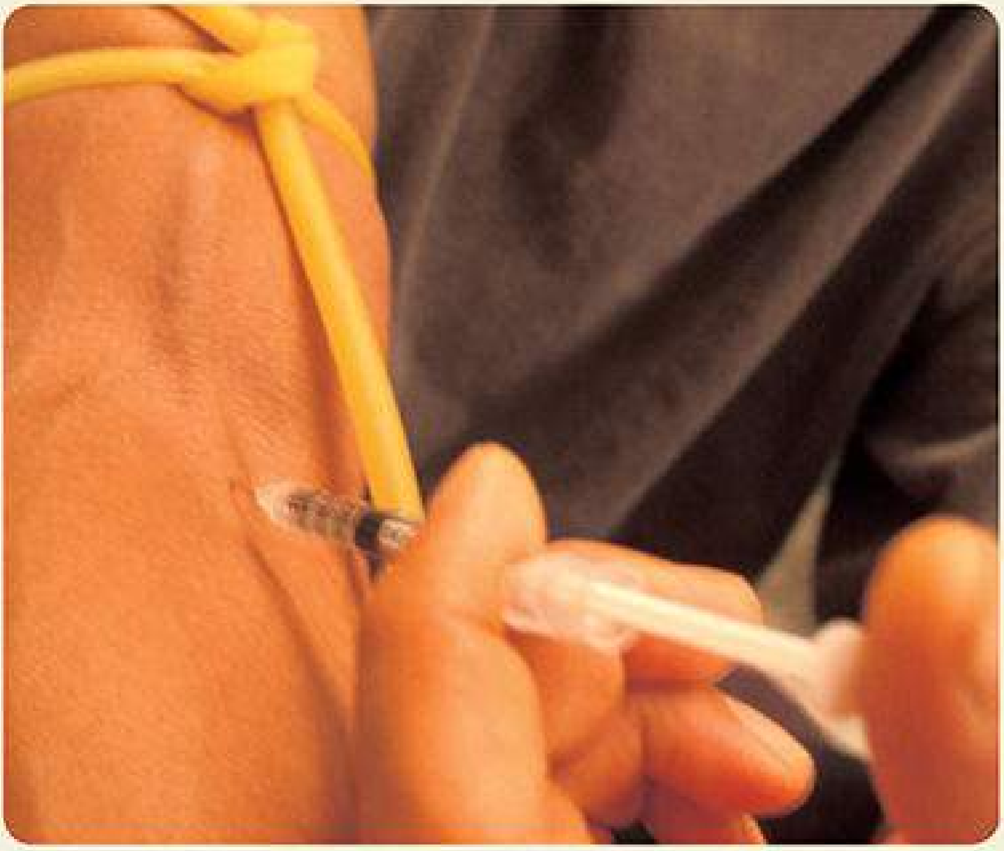

Figure 21-5 Injected poisons are impossible to dilute or remove from the body in the field; therefore, prompt transport to the emergency department is critical.

Words of Wisdom

Take time at the scene to make thorough notes about the nature of the poisoning. You can then use this information to state the type and amount of substance and the time and route of exposure in your radio, verbal, and written reports. The busy emergency department staff will also appreciate clear notes that can quickly be handed over on arrival.

Signs and symptoms of poisoning by injection include weakness, dizziness, fever, chills, and unresponsiveness, or the patient may be easily excited.

If you suspect that rapid absorption has occurred, monitor the patient's airway, provide high-flow oxygen for any patient with respiratory distress or signs of hypoxia (Spo_2 level is less than 94%, cyanosis), and be alert for nausea and vomiting. Remove rings, watches, and bracelets from areas around the injection site if swelling occurs. Prompt transport to the emergency department is essential. Take all containers, bottles, and labels with the patient to the hospital.

YOU are the Provider — PART 3

The patient's respirations continue to slow and then stop completely. You, your partner, and the fire crew begin to manage the patient. She is placed on the floor supine. One of the firefighters begins ventilation with a BVM and oxygen. You set up an IV line and your partner initiates IV access.

Recording Time: 6 Minutes	
Respirations	Apneic; assisted ventilations
Pulse	116 beats/min; weak and regular
Skin	Cool, pale, and wet
Blood pressure	96/50 mm Hg
Oxygen saturation (Spo_2)	91% (on oxygen)

As you treat the patient, a law enforcement officer brings inside one of the friends that brought the patient home. He reports they went to a "skittle party" earlier that night. He explains the teenagers took prescription pills from their parents' medicine cabinets, mixed them up in a bowl, and then took turns selecting pills to get high. They were also drinking beer and liquor.

While your partner establishes the IV line, you check the patient's pupils. You and your partner agree they are pinpoint. As the IV line is secured, your partner asks you to prepare a preloaded syringe of naloxone to be administered to the patient. You hand the syringe to your partner, then check the patient's blood glucose level. The glucometer registers a fingerstick glucose level of 112 mg/dL.

5. Would activated charcoal benefit this patient? Why or why not?
6. Why is naloxone being given to this patient?

Patient Assessment

Scene Size-up

When you have a situation that involves a toxicologic emergency, a well-trained dispatcher can obtain important information pertaining to a poisoning call that will help you anticipate the proper protection needed to ensure your safety. The dispatcher may be able to obtain information pertaining to the MOI/NOI, the number of patients involved, whether additional resources are needed, and whether trauma is involved. If this information has been obtained before your arrival, you must assess the scene nevertheless to ensure your safety and to determine the accuracy of the dispatcher's information.

Because of the risk of possible cross-contamination by poisons that can be inhaled, absorbed, ingested, and injected, you must take appropriate standard precautions. As you approach the scene, think like a detective and look for clues that might indicate the substance involved. Ask yourself the following questions:

- Is there an unpleasant or odd odor in the room? If so, is the scene safe? (This could indicate an inhaled poison.)
- Are there medication bottles near the patient or at the scene? If so, is there medication missing that might indicate an overdose?
- Are there alcoholic beverage containers present?
- Are there syringes or other drug paraphernalia on the scene?
- Is there a suspicious odor and/or drug paraphernalia present that may indicate the presence of an illegal drug laboratory? Drug laboratories can be volatile, so ensure scene safety **Figure 21-6**.

The location of the patient may help contribute to identifying a suspected poisoning, and other clues such as empty pill bottles or open bottles of household cleaners near the patient may provide further information to help you determine what happened. Keep a constant eye on the surroundings, and keep an open mind when questioning the patient or bystanders to avoid mistaken conclusions.

Figure 21-6 An illegal laboratory capable of producing large quantities of methamphetamine.

Courtesy of DEA.

Primary Assessment

To best determine the severity of the patient's condition, first obtain a general impression of the patient, assess his or her level of consciousness, and determine any life threats. With substance abuse and poisonings, do not assume a conscious, alert, and oriented patient is in stable condition and has no apparent life threats. The patient may have a harmful or even lethal amount of poison in his or her system that has not had time to produce systemic reactions. A primary assessment that reveals a patient with signs of distress and/or altered mental status gives you early confirmation that the poisonous substance is causing systemic reactions.

Quickly ensure that the patient has an open airway and adequate ventilation. If the patient has any difficulty breathing, begin oxygen therapy. In situations where a patient may have an inhalation injury (typically carbon monoxide and/or cyanide poisoning), place the patient on high-flow oxygen regardless of the pulse oximetry reading. If the patient is unresponsive to painful stimuli, consider inserting an airway adjunct to ensure an open airway. Have suction available; these patients are susceptible to vomiting. You may also have to assist a patient's ventilations with a BVM because some substances act as depressants on the body's systems.

Once the airway and breathing have been assessed and appropriate interventions performed, assess the patient's circulatory status. You will find variations in a patient's circulatory status depending on the substance involved. Assess the pulse and skin condition. Some poisons are stimulants, and others are depressants. Some poisons will cause vasoconstriction and others vasodilation. Although bleeding may not be obvious, alterations in consciousness may have contributed to trauma and bleeding.

Consider prompt transport for patients with obvious alterations in the ABCs or for patients you have determined have a poor general impression. Some industrial settings may have specific decontamination stations and antidotes available at the site. Remember, everyone who is exposed to the hazardous material must be thoroughly decontaminated by the HazMat team before leaving the scene.

History Taking

After you have managed the life threats during the primary assessment, investigate the chief complaint or history of present illness. Obtain the patient's medical history. In many situations, you can perform this in the ambulance en route to the hospital. If your patient is responsive and can answer questions, begin with an evaluation of the exposure and the SAMPLE history. If the patient is unresponsive, attempt to obtain the history from coworkers, bystanders, friends, or family members. Medical identification jewelry and wallet cards may also provide information about the patient's medical history.

In these situations, the SAMPLE history guides you in what to focus on as you continue to assess the patient's complaints, and the physical examination and vital signs tell you what is happening to the patient's body. These three assessments give you direction in the interventions your patient might need.

In addition to the SAMPLE history, ask the following questions:

- **What is the substance involved?** If you know the substance involved, you will be better able to access the appropriate resource, such as the poison center, to determine lethal doses, time before adverse effects begin, effects of the substance at toxic levels, and appropriate interventions.
- **When did the patient ingest or become exposed to the substance?** This will let you know if and when the adverse effects will begin. This will also let the emergency physician know what adverse effects can be reversed and which ones cannot because of the length of time the patient has been exposed to the substance.
- **How much did the patient ingest or what was the level of exposure?** With this information, the poison center will be able to inform you whether the patient has had a harmful or lethal dose.
- **Over what period did the patient take or was the patient exposed to the substance?** Did the exposure occur all at once or over minutes or hours?
- **Has the patient or a bystander performed any intervention on the patient? Has the intervention helped?** The patient's or bystander's intervention may cause complications. The emergency physician will need to know this information to be able to adjust interventions accordingly.
- **How much does the patient weigh?** If activated charcoal is indicated and permitted by local protocols, you will need to determine the dose based on the patient's weight. The antidote or neutralizing agent given by the emergency physician may be based on the patient's weight as well.

Secondary Assessment

In some instances, such as a critically ill patient or a short transport time, you may not have time to conduct a secondary assessment.

Your physical examination should focus on the area of the body involved with the route of exposure and the particular drug or chemical the patient was exposed to. For example, if you suspect a person has ingested a poison, inspect the mouth for indications of poisoning. Are there burns from caustic chemicals? Are there plant or pill fragments? If the person's skin came in contact with a poison, is there a rash or burns? How large an area is involved? If a respiratory exposure occurred, auscultate the lungs. Is there good air movement in and out of the lungs? Do you hear any wheezing or crackles? Learn about the effects of general classes of drugs and chemicals so that you will become familiar with specific and common poisons.

Your priority is to manage the ABCs during the primary assessment. These interventions take precedence over a thorough physical examination. However, once the ABCs have been addressed and managed, conducting a thorough physical examination will often provide additional information on the exposure the patient experienced. A general review of all body systems may help to identify systemic problems. Perform this review, at a minimum, on patients with extensive chemical burns or other significant trauma and on patients who are unresponsive.

A complete set of baseline vital signs is important. Many poisons have no outward indications of the seriousness of the exposure. Alterations in the level of consciousness, pulse, respirations, blood pressure, and skin are more sensitive indicators that something serious is wrong.

Reassessment

The condition of patients exposed to poisons may change suddenly and without warning. Continually reassess the adequacy of the patient's ABCs. Repeat the vital signs, and compare them with the baseline set obtained earlier in your assessment. Evaluate the effectiveness of interventions you have provided. If your assessment has provided necessary information about the poisonous substance, you may be able to anticipate changes in the patient's condition. If the patient has consumed a harmful or lethal dose of a poisonous substance, reassess the vital signs at least every 5 minutes. If the patient is in stable condition and there are no life threats, reassess every 15 minutes. If the poison or the level of exposure (eg, the number and type of pills taken) is unknown, careful and frequent reassessment is mandatory.

The treatment you provide for poisoned patients depends a great deal on what they were exposed to, how they were exposed, and other signs and symptoms found in your assessment. Remember, supporting the ABCs is your most important task. Contact your medical control or a poison center to discuss treatment options for particular poisonings. Dilute airborne exposures with oxygen, remove contact exposures with large amounts of water unless contraindicated, and consider activated charcoal for ingested poisons (if permitted by local protocol).

Once you have completed your primary assessment, history taking, and secondary assessment, contact medical control to request necessary interventions. Report to the hospital as much information as you have about the poison or chemical that the patient was exposed to. If a material safety data sheet is immediately available in a work setting, take it with you to the hospital.

Emergency Medical Care

First, ensure scene safety by following standard precautions and performing external decontamination. Remove tablets or pill fragments from the patient's mouth, and wash or brush dry poison from the patient's skin. Treatment focuses on support. Assess and maintain the patient's ABCs. If the patient has difficulty breathing, provide oxygen to the patient, and perform assisted ventilations if necessary. Keep the patient warm, treat for shock as necessary, and transport promptly to the nearest appropriate hospital.

In certain cases, some EMS systems allow EMTs to give activated charcoal by mouth. As discussed in Chapter 11, *Pharmacology,* activated charcoal binds to specific toxins—for example, pills that have been ingested—and prevents their absorption by the body. The toxins are then carried out of the body in the stool.

Activated charcoal is not indicated, nor will it be effective, for patients who have ingested alkali poisons, cyanide, ethanol, iron, lithium, methanol, mineral acids, or organic solvents. If the patient has a decreased level of consciousness and cannot protect his or her airway, do not give activated charcoal.

If local protocol permits, your ambulance will likely carry plastic bottles of premixed suspension, each containing up to 50 g of activated charcoal **Figure 21-7**. Some common trade names for the suspension form are InstaChar, Actidose, and LiquiChar. The usual dose for an adult or child is 1 g of activated charcoal per kilogram of body weight (more if food is present). The usual adult dose is 30 to 100 g, and the usual pediatric dose is 15 to 30 g for children younger than age 13.

Figure 21-7 Activated charcoal comes as a pre-mixed suspension.

© Chuck Stewart, MD.

Before you give a patient charcoal, obtain approval from medical control. Consider the amount of the toxin and the patient's condition. In most cases, the activated charcoal should be used within 1 hour of ingestion. Next, shake the bottle vigorously to mix the suspension. The medication looks like mud, so it is best to cover the outside of the container so that the fluid is not visible and ask the patient to drink it with a straw. Some patients may not tolerate the medication due to its gritty texture. You might need to convince the patient why this intervention is important, particularly if the patient is a child, but never force him or her. If the patient takes a long time to drink the mixture, you will have to shake the container frequently to keep the medication mixed. Once the patient has finished, discard the container from which the charcoal was administered. Be sure to record the time when you administered the activated charcoal. If the patient refuses the activated charcoal, document the refusal and your attempts to counsel the patient, and transport the patient for further evaluation.

The adverse effects of ingesting activated charcoal include constipation and black stools. If the patient has ingested a poison that causes nausea, he or she may vomit after taking activated charcoal, and the dose will have to be repeated. As you reassess the patient, be prepared for vomiting, nausea, and possible airway conditions.

Words of Wisdom

While one EMT explains the activated charcoal treatment to the patient, the other EMT can prepare a large plastic garbage bag to hang on the patient as a bib. This will help contain the charcoal suspension if the patient vomits.

Specific Poisons

Over time, a person who routinely misuses a substance may need increasing amounts of it to achieve the same result. This is called developing a **tolerance** to the substance. A person with an **addiction** has an overwhelming desire or need to continue using the substance, at whatever cost, with a tendency to increase the dose. This does not happen only with the classic drugs of abuse, such as cocaine or heroin. Almost any substance can be abused, including laxatives, nasal decongestants, vitamins, and food.

The importance of safety awareness when caring for drug users cannot be overemphasized. Known drug users have a fairly high incidence of serious and undiagnosed infections, including human immunodeficiency virus and hepatitis. These patients, when intoxicated, may bite, spit, hit, or otherwise injure you, causing you to come into contact with their blood and other body fluids. Always wear appropriate PPE. A calm, professional approach can defuse frightening situations, but keep your safety and that of your team uppermost in mind. Expect the unexpected and remember: The drug user, not the drug, can pose the greatest threat.

YOU are the Provider — PART 4

Your partner administers the naloxone slowly, titrating the dose until the patient begins to breathe on her own. After about 30 seconds, the patient starts moving and pushing the BVM away from her face. You apply a nonrebreathing mask at 15 L/min, which the patient tolerates. You reassess her condition and vital signs and prepare for transport.

Recording Time: 11 Minutes	
Level of consciousness	Conscious, but sleepy
Respirations	12 breaths/min; adequate depth
Pulse	84 beats/min; regular and stronger
Skin	Cool; color is improving
Blood pressure	108/52 mm Hg
Spo_2	96% (on oxygen)

7. What other issues about this patient should concern you?
8. How would this patient's presentation have differed had she overdosed on a sympathomimetic?

Alcohol

As a new EMT, you will notice that many calls for service have a connection to alcohol use. Alcohol can damage the liver, whether thorough chronic overuse or occasional heavy use (binge drinking). According to the Centers for Disease Control and Prevention, 1 in 10 deaths among working-age adults in the United States can be attributed to excessive alcohol use. Many people dismiss the dangers of drinking and do not understand that binge use can be more damaging than chronic use, depending on the frequency of the binging and the surrounding circumstances. According to the Institute for Health Metrics and Evaluation, binge use has increased more than 17% since 2005.

Alcohol is a powerful CNS depressant. It is a **sedative**, a substance that decreases activity and excitement, and a **hypnotic**, meaning that it induces sleep. In general, alcohol dulls the sense of awareness, slows reflexes, and reduces reaction time **Figure 21-8**. It may also cause aggressive and inappropriate behavior and lack of coordination. However, a person who appears intoxicated may have other medical conditions as well. Look for signs of head trauma, mental illness, toxic reactions, or uncontrolled diabetes. Severe acute alcohol ingestion may cause hypoglycemia, which may contribute to the symptoms. You should assume that all intoxicated patients are experiencing a drug overdose and require a thorough examination by a physician. In most states, patients who are impaired in any way—whether by mental illness, medical condition, or intoxication—cannot legally refuse transport. Always consult with your supervisor, law enforcement, or medical control in these situations. Chapter 22, *Psychiatric Emergencies*, covers this topic in more detail.

Figure 21-8 Alcohol intoxication causes altered mental status, slowed reflexes, and impaired reaction time.

Alcohol increases the effects of many drugs and is commonly taken with other substances. OTC drugs, including antihistamines and diet medications, can cause serious complications when combined with alcohol.

If a patient exhibits signs of serious CNS depression, provide respiratory support. This may be difficult, however, because depression of the respiratory system can also cause **emesis**, or vomiting. The vomiting may be forceful or even bloody (**hematemesis**) because large amounts of alcohol irritate the stomach. Internal bleeding should also be considered if the patient appears to be in shock (hypoperfusion) because blood might not clot effectively in a patient who has a prolonged history of alcohol abuse.

Special Populations

Drug and alcohol abuse among teenagers is one of the most common issues in society today. Most teenagers are encouraged to experiment with drugs through peer pressure. Often, older teenagers will encourage younger teenagers to try combinations of drugs. In other cases, an older teenager who has developed a tolerance will give too large of a dose of a drug to a first-time user, resulting in an overdose. Many teenagers will do things they know are not safe just to gain acceptance from their peers. Often teenagers will lie about taking drugs out of fear of being arrested. Reassure them that your intent is only to give them the best treatment possible.

Also be aware that some teenagers use drugs to attempt suicide. According to the American Psychological Association, teen suicide is a growing health concern and the third-leading cause of death for young people ages 15 to 24. Do not be judgmental with these teenagers and treat them as you would any other patient, with empathy and patience.

A patient in alcohol withdrawal may experience frightening hallucinations, or **delirium tremens (DTs)**. About 1 to 7 days after a person stops drinking or when alcohol consumption levels are decreased suddenly, DTs may develop. Alcoholic hallucinations come and go. A patient with an otherwise clear mental state may see fantastic shapes or figures or hear odd voices. Such auditory and visual hallucinations often precede DTs, which are a more severe complication.

Patients may experience one or more of the following signs and symptoms:

- Agitation and restlessness
- Fever
- Sweating
- Tremors
- Confusion and/or disorientation
- Delusions and/or hallucinations
- Seizures

Provide prompt transport after you have completed your assessment and given necessary care. A person who is experiencing hallucinations or DTs is extremely ill. Should seizures develop, treat them as you would any other seizure. Do not restrain the patient, although you must protect him or her from self-injury. If the patient has difficulty breathing, provide supplemental oxygen and watch carefully for vomiting; have suction ready. Hypovolemia may develop because of sweating, fluid loss, insufficient fluid intake, or vomiting associated with DTs. If you see signs of hypovolemic shock, clear the airway, and turn the patient's head to one side to minimize the chance of aspiration during transport. These patients may not respond appropriately to suggestions or conversation; they are often confused and frightened. Therefore, use a calm and relaxed approach. Reassure the patient, and provide emotional support.

Safety Tips

In situations that involve toxic substances, your safety is paramount. Always be aware of the environment. When dealing with patients who have taken illegal drugs, be cautious and be prepared for unexpected violence. Do not hesitate to call for law enforcement support.

Opiates and Opioids

A **narcotic** is a drug that produces sleep or altered mental consciousness. An **opioid** is a type of narcotic medication used to relieve pain. An **opiate** is a subset of the opioid family, and refers to natural, non-synthetic opioids. Opioids are named for the opium in poppy seeds, from which the opiates codeine and morphine are derived. According to the National Institute on Drug Abuse (NIDA), prescription opioid drugs are among the most commonly abused drugs in the United States. Some people become physically dependent on opioids after taking an appropriate medical prescription. These drugs include a number of synthetic (laboratory-manufactured) opioids, such as meperidine, hydromorphone, oxycodone, hydrocodone, and methadone Table 21-2. In addition, according to the National Center for Health Statistics, the death rate from heroin overdoses (which is illegal in any amount or form) tripled between 2010 and 2013, for a total of nearly 44,000 deaths.

These agents are CNS depressants and can cause severe respiratory depression. When administered intravenously, however, they produce a characteristic "high" or "kick." Tolerance develops rapidly, so some users may require massive doses to experience the same high. In general, emergency medical conditions related to opioids are caused by respiratory depression, including a decreased volume of inspired air and decreased respirations. This can lead to respiratory and then cardiac arrest if not treated promptly. These drugs often cause nausea and vomiting and may lead to hypotension. Although seizures are uncommon, they can occur and an overdose can result in the patient entering a comatose condition. Patients typically appear sedated or unconscious and exhibit cyanosis with pinpoint pupils. Whereas all of these signs and symptoms may be present with other drugs, the pinpoint pupils are the most commonly accepted sign of opiate abuse.

Table 21-2 Common Opioids and Opiates

Butorphanol (Stadol)
Codeine
Fentanyl (Sublimaze)
Heroin
Hydrocodone (Vicodin)
Hydromorphone (Dilaudid)
Morphine
Methadone (Dolophine)
Oxycodone hydrochloride (OxyContin)
Oxymorphone (Opana)

Words of Wisdom

Some patients who abuse opioids or opiates may inject the substance intravenously and are at high risk for hepatitis C and human immunodeficiency virus. Be aware of your surroundings and practice bloodborne precautions. Be alert for improperly disposed needles.

Naloxone (Narcan) is an antidote that reverses the effects of opiate or opioid overdose. This medication can be given intravenously, intramuscularly, or intranasally. Ideally, naloxone is administered intravenously. In many instances, however, IV access is difficult to obtain in the chronic user of illicit intravenous drugs such as heroin. These patients have venous scarring, called track marks, from repeated use of needles on peripheral veins. Therefore, the intranasal route is becoming a preferred alternative route for the administration of naloxone. It is safer than giving an IM injection because a needle is not required to administer the medication.

Some EMS systems allow EMTs to administer naloxone by the intranasal route, in which the antidote is atomized through the nares into the nasal mucosa. Be aware that this drug can cause harm. This medication should only be used when the patient has agonal respirations or apnea. Place an oropharyngeal (oral) or nasopharyngeal (nasal) airway and ventilate the patient using a BVM prior to administering naloxone. Adequate ventilation while you prepare to administer naloxone decreases the risk of permanent brain damage related to hypoxia. Watch the patient closely; as the level of consciousness rises, the patient will no longer tolerate the oropharyngeal airway and you will have to remove it to prevent aspiration.

In some areas, lay people are permitted to administer naloxone. Be aware that it may have been administered prior to your arrival. Find out from bystanders what has occurred and who was given naloxone.

When a patient goes into cardiac arrest, follow the algorithm shown in Figure 21-9, including administration of naloxone if it is available. However, providing BVM ventilations is a critical treatment for these patients as well. Whether or not naloxone is available, provide ventilations and rapid transport.

Sedative-Hypnotic Drugs

Barbiturates and benzodiazepines have been a part of legitimate medicine for a long time. They are easy to obtain and relatively cheap. People sometimes solicit prescriptions from several physicians for the same hypnotics or a variety of sedative-hypnotics Table 21-3. These drugs are CNS depressants and alter the level of consciousness, with effects similar to those of alcohol so that the patient may appear drowsy, peaceful, or intoxicated. By themselves, these drugs do not relieve pain, nor do they produce a specific high, although users often take alcohol or an opioid at the same time to boost their effects.

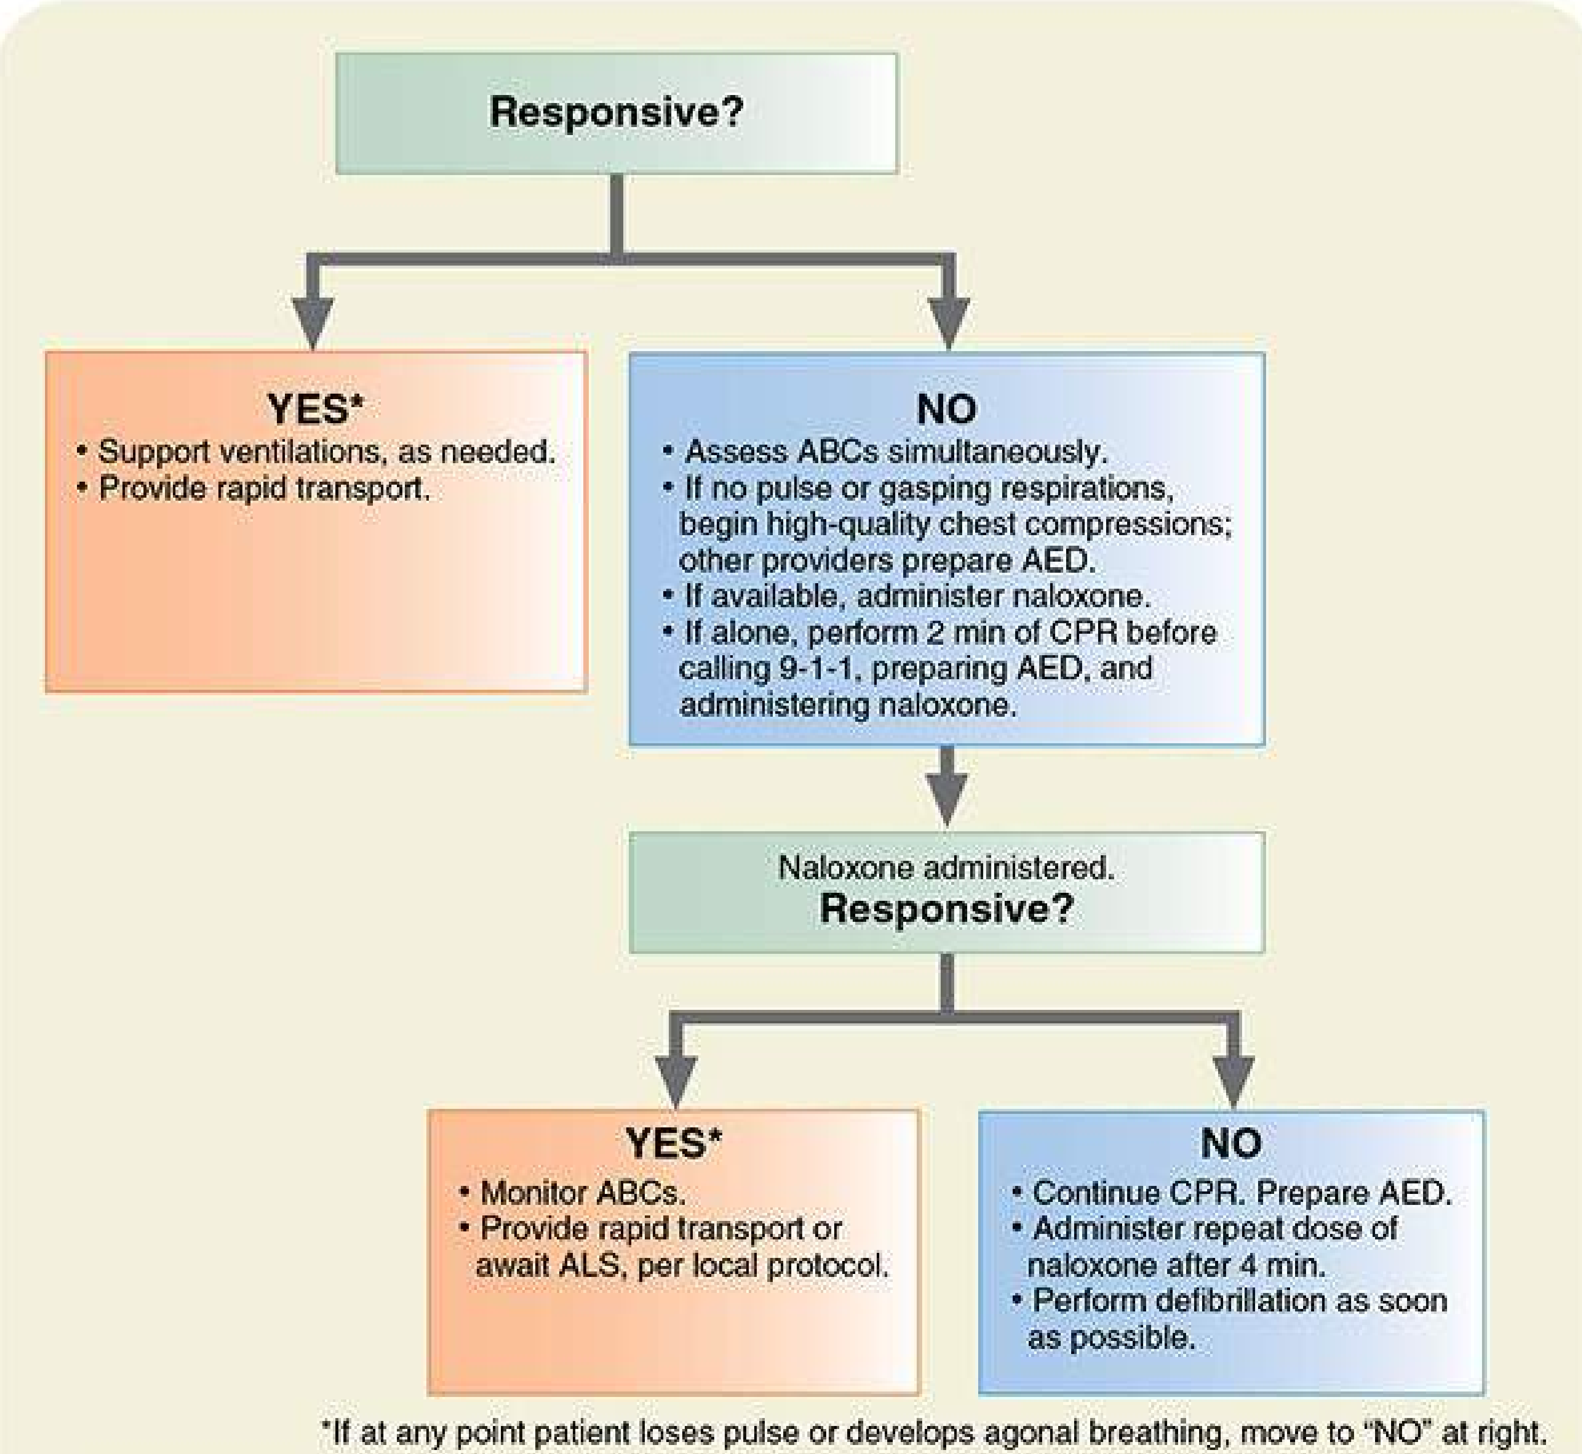

Figure 21-9 Opioid life-threatening overdose algorithm.

In general, these agents are taken by mouth. Occasionally, however, contents of capsules are suspended or dissolved in water and injected to produce a sudden state of ease and contentment. Use of IV sedative-hypnotic drugs quickly induces tolerance, so the person requires increasingly larger doses. You are less likely to be called on to treat an acute overdose in someone who chronically abuses these drugs; however, you may be called to a scene of an attempted suicide in which the patient has taken large quantities of these drugs. In these situations, patients will often have marked respiratory depression and may be in a coma.

Sedative-hypnotic drugs such as chloral hydrate may also be given to people as a "knock-out" drink, or "Mickey Finn," to incapacitate them without their knowledge. Date rape or club drugs such as flunitrazepam (Rohypnol or "roofies") and ketamine (Ketalar or "Special K") are often colorless, tasteless, and odorless. They cause an unwary person to become sedated and even unconscious, which may facilitate sexual assault or rape. The person later awakens, confused and unable to remember what happened. Chapter 23, *Gynecological Emergencies*, discusses this topic in more detail.

Table 21-3 Examples of Sedative-Hypnotic Drugs

Barbiturates	Benzodiazepines	Others
Amobarbital (Amytal)	Alprazolam (Xanax)	Carisoprodol (Soma)
Butabarbital (Butisol)	Chlordiazepoxide (Librium)	Chloral hydrate ("Mickey Finn"), eszopiclone (Lunesta)
Pentobarbital (Nembutal)	Diazepam (Valium)	Cyclobenzaprine (Flexeril)
Phenobarbital (Luminal)	Flunitrazepam (Rohypnol)	Ethchlorvynol (Placidyl)
Secobarbital (Seconal)	Lorazepam (Ativan)	Ethyl alcohol (drinking alcohol)
	Oxazepam (Serax)	Ketamine (ketalar)
	Temazepam (Restoril)	Isopropyl alcohol (rubbing alcohol)
		Meprobamate (Equagesic)

In general, your treatment of patients who have overdosed with sedative-hypnotics and have respiratory depression is to ensure the airway is patent, assist ventilations, and provide prompt transport. Give supplemental oxygen when appropriate and closely monitor the patient's mental status. You may attempt to stimulate the person by speaking loudly or gently shaking him or her; remember to watch for vomiting.

As multidrug use becomes more common, you may find it increasingly difficult to determine what agents patients have taken. Your best approach is to treat any obvious injuries or illnesses, keeping in mind that drug use may complicate the picture and make full life support necessary. Focus on the ABCs, especially the possibility of airway problems (relaxation of the tongue, causing obstruction), vomiting, respiratory depression, and, in severe cases, cardiac arrest.

Abused Inhalants

Many abused inhalants produce several of the same CNS effects as do other sedative-hypnotics, but these agents are inhaled instead of ingested or injected. This method of abuse is known as huffing. Some of the more common agents include acetone, toluene, xylene, and hexane, which are found in glues, cleaning compounds, paint thinners, and lacquers. Similarly, gasoline and various halogenated hydrocarbons, such as Freon, used as propellants in aerosol sprays, are also abused as inhalants. None of these inhalants are medications; rather, these substances briefly displace oxygen in the brain and cause a rush of euphoria. Because these are inexpensive products that can be bought in hardware stores, they are commonly abused by teenagers and curious adults seeking an alcohol-like high. The effective dose and the lethal dose are very close, making these extremely dangerous drugs. Long-term abuse can lead to permanent brain damage.

Take special care in dealing with a patient who may have used inhalants. Effects of inhalants range from mild drowsiness to coma, but unlike most other sedative-hypnotics, these agents may often cause seizures. The lack of oxygen to the brain may cause a loss of brain function. Also, halogenated hydrocarbon solvents can make the heart hypersensitive to the patient's own adrenaline, putting the patient at high risk for sudden cardiac death because of ventricular fibrillation; even the action of walking may release enough adrenaline to cause a fatal ventricular dysrhythmia. You must try to keep such patients from struggling with you or exerting themselves. Give supplemental oxygen for patients with respiratory distress or signs of hypoxia, and use a stretcher to move the patient. Prompt transport to the hospital is essential; monitor vital signs en route.

Hydrogen Sulfide

Hydrogen sulfide is a highly toxic, colorless, and flammable gas with a distinctive rotten-egg odor. Poisoning by hydrogen sulfide usually occurs by inhalation. Hydrogen sulfide affects all organs, but it has the most impact on the lungs and CNS.

Hydrogen sulfide occurs naturally in sewers, swamps, volcanoes, and crude petroleum. As discussed earlier, hydrogen sulfide poisoning is also a method used to commit suicide, referred to as chemical or detergent suicide. According to the Chemical Hazards Emergency Medical Management database, this method of self-inflicted exposure to toxic gas originated in Japan and has reached the United States via the Internet. The patient may obtain a warning sign to place near the area of the suicide, such as an enclosed vehicle, to warn responders of the deadly gas. If you approach an enclosed vehicle with an unconscious patient inside, be alert for warning signs, as well as containers, buckets, or pots. Remember, do not enter a scene where a toxic gas may be present. Be aware of your surroundings as you approach, and if you suspect the presence of a toxic gas, wait for a HazMat team to tell you the scene is safe.

Workers in industrial settings may experience low-level exposure to hydrogen sulfide over a long period of time, leading to eye, nose, and throat irritation, as well as headaches and bronchitis. Chronic exposure to this gas may cause an inability to smell the gas. When patients are exposed to high concentrations of the gas, they will experience nausea and vomiting, confusion, dyspnea, and a loss of consciousness. Seizures, shock, coma, and cardiopulmonary arrest may also result.

There is no antidote for hydrogen sulfide poisoning. Therefore, a HazMat team must quickly remove the patient from the contaminated area. Once the patient has been decontaminated, management is largely supportive. Monitor and assist the patient's respiratory and cardiovascular functions and provide rapid transport.

Sympathomimetics

Sympathomimetics are CNS stimulants that mimic the effects of the sympathetic (fight-or-flight) nervous system. These stimulants frequently cause hypertension, tachycardia, and dilated pupils. A **stimulant** is an agent that produces an excited state. Examples include amphetamine and methamphetamine (also called meth or ice), which are commonly taken by mouth. They are also injected by drug abusers in many cases. Sympathomimetic drugs are typically taken to make the user "feel good," improve task performance, suppress appetite, or prevent sleepiness. They may also produce irritability, anxiety, fear, lack of concentration, or seizures. Paranoia and delusions are common symptoms of sympathomimetic abuse. Other common examples include phentermine hydrochloride, an appetite suppressant, and amphetamine sulfate (Benzedrine), taken for weight control, narcolepsy, and chronic fatigue syndrome. Caffeine and phenylpropanolamine (a nasal decongestant) are mild sympathomimetics. So-called designer drugs such as 3,4-methylenedi-oxymethamphetamine (MDMA, known as ecstasy or Molly) are also frequently abused in the United States.

Sympathomimetic drugs are known by various street names that change often Table 21-4.

Cocaine, also called crystal, snow, freebase, rock, gold dust, blow, and lady, is one of the most addictive substances known. It may be taken in a number of different ways. Classically, it is inhaled into the nose and absorbed through the nasal mucosa, damaging tissue, causing nosebleeds, and ultimately destroying the nasal septum. It can also be injected intravenously or subcutaneously (skin popping). Cocaine can be absorbed through all mucous membranes and even across the skin. In any form, the immediate effects of a given dose, including excitement and euphoria, last less than an hour.

Table 21-4 Examples of Street Names for Sympathomimetics

Street Name	Drug Name
Adam	3,4-Methylenedioxy-methamphetamine (MDMA)
Angel Dust	Phencyclidine (PCP)
Bennies	Amphetamines
Coke	Cocaine
Crank	Crack cocaine, heroin, amphetamine, methamphetamine, methcathinone
DOM	4-Methyl-2,5-dimethoxyamphetamine
Ecstasy	MDMA
Eve	MDMA
Golden eagle	4-Methylthioamphetamine
Ice	Cocaine, crack cocaine, smokable methamphetamine, methamphetamine, MDMA, phencyclidine (PCP)
MDA	Methaqualone
Meth	Methamphetamine
Molly	MDMA
Speed	Crack cocaine, amphetamine, methamphetamine
Uppers	Amphetamines

Another method of abusing cocaine is by smoking it. Crack is pure cocaine. It melts at 93°F (33.9°C) and vaporizes at a slightly higher temperature. Therefore, crack is easily smoked. In this form, it reaches the capillary network of the lungs and can be absorbed into the body in seconds. The immediate outflow of blood from the heart speeds the drug to the brain, so its effect is felt at once. Smoked crack produces the most rapid means of absorption and, therefore, the most potent effect.

Acute cocaine overdose is a genuine emergency because patients are at high risk for seizures, cardiac dysrhythmias, and stroke. You may see blood pressure measurements as high as 250/150 mm Hg. Chronic cocaine abuse may cause hallucinations; patients with "cocaine bugs" think that bugs are crawling out of their skin.

Be aware patients who have been poisoned by a sympathomimetic may be paranoid, putting you and other health care providers in danger. Law enforcement officers should be at the scene to restrain the patient, if necessary. Do not leave the patient unattended and unmonitored during transport.

All of these patients need prompt transport to the emergency department. Give supplemental oxygen if necessary and be ready to provide suctioning. If the patient is already having a seizure, protect him or her against self-injury.

Synthetic Cathinones (Bath Salts)

Bath salts, or synthetic cathinones, refer to an emerging class of drugs similar to MDMA. The drug commonly includes the chemical methylenedioxypyrovalerone (MDPV). Bath salts should not be confused with products such as Epsom salt (magnesium sulfate), although selling it under this umbrella label has allowed its manufacturers and users to escape the legal restrictions imposed on illicit drugs. Brand names include Ivory Wave and Cloud Nine. Many states are working to make it illegal to manufacture or possess this drug.

Bath salts produce euphoria, increased mental clarity, and sexual arousal. Most users of this drug snort or insufflate the powder nasally. The effects reportedly last as long as 48 hours. Adverse effects include teeth grinding, appetite loss, muscle twitching, lip-smacking, confusion, gastrointestinal conditions, paranoia, headache, elevated heart rate, and hallucinations.

Keep the patient calm and transport. Consider ALS assistance; some of these patients may require chemical restraint to facilitate safe transport.

Marijuana

The flowering hemp plant, *Cannabis sativa*, called marijuana, is abused throughout the world. According to the Pew Research Center, nearly half (49%) of Americans say they have tried marijuana. Tetrahydrocannabinol, or THC, is the chemical in the marijuana plant that produces its high. Inhaling marijuana smoke from a cigarette or pipe produces euphoria, relaxation, and drowsiness. It also impairs short-term memory and the capacity to do complex thinking and work. In some people, the euphoria progresses to depression and confusion. An altered perception of time is common, and anxiety and panic can occur. With very high doses, some patients may experience hallucinations or become very anxious or paranoid. In these cases, keep the patient calm and provide transport. However, be aware that marijuana is often used as a vehicle to get other drugs into the body. For example, it may be laced with crack or PCP.

Several states have legalized the recreational use of marijuana, and many others allow for the medical use of marijuana and products that contain THC. As the move toward legalization continues and as people become more aware of the health risks associated with smoking, delivery methods have evolved. Many medical users opt against smoking marijuana and instead obtain THC in the form of "edibles" or baked goods, candies, and other food additives that have been infused with marijuana. However, the ingestion of marijuana can lead to *cannabinoid hyperemesis syndrome*, characterized by chronic marijuana use and extreme nausea and vomiting that is relieved only by a hot shower or bath. Bathing can become compulsive in these patients. The definitive treatment for this condition is to stop using marijuana; however, these users often believe that more marijuana will help the nausea and continue to consume it.

Synthetic marijuana or "Spice" refers to a variety of herbal incense or smoking blends that resemble THC and produce a similar high. Synthetic marijuana is often marketed as a "safe" alternative to that drug under brand names such as K2 and Skunk. However, according to NIDA, the chemicals commonly found in Spice products have no medical benefit and have a high potential for abuse. Therefore, powerful and unpredictable effects may result, ranging from simple euphoria to complete loss of consciousness.

Hallucinogens

Hallucinogens alter a person's sensory perceptions Table 21-5. The classic hallucinogen is lysergic acid diethylamide (LSD). Abuse of another hallucinogen, phencyclidine (PCP, or angel dust), is relatively uncommon among young adults. PCP is a dissociative anesthetic that is easily synthesized and highly potent. Its effectiveness by oral, nasal, pulmonary, and intravenous routes makes it easy to add to other street drugs. It is dangerous because it causes severe behavioral changes in which people often inflict injury on themselves.

All these agents cause visual hallucinations, intensify vision and hearing, and generally separate the user from reality. The user, of course, expects that the altered sensory state will be pleasurable. Often, however, it can be terrifying. At some point, you are bound to encounter patients who are having a "bad trip." They will usually have hypertension, tachycardia, anxiety, and paranoia.

Many hallucinogens have sympathomimetic properties. Your care for a patient who is having a bad reaction to a hallucinogenic agent is the same as that for a patient who has taken a sympathomimetic. Use a calm, professional manner, and provide emotional support. Do not use restraints unless you or the patient is in danger of injury. Follow the guidelines specified by local authorities. These patients may suddenly experience hallucinations or odd perceptions, so watch them carefully throughout transport. Never leave a patient who has taken a hallucinogen unattended and unmonitored. Request ALS assistance when appropriate.

Table 21-5 Commonly Abused Hallucinogens

Bufotenine (toad skin)
Dextromethorphan (DXM)
Dimethyltryptamine (DMT)
Hashish
Datura stramonium (jimsonweed)
LSD
Marijuana
Mescaline (peyote)
Morning glory
Nutmeg
PCP
Psilocybin (mushrooms)

▶ Anticholinergic Agents

Anticholinergic agents are medications that block the parasympathetic nerves. The classic picture of a person who has taken too much of an anticholinergic medication is "hot as a hare, blind as a bat, dry as a bone, red as a beet, and mad as a hatter." In other words, the patient will exhibit hypothermia, dilated pupils, dry skin and mucous membranes, reddened skin, and agitation or delirium. Common drugs with a significant anticholinergic effect include atropine, antihistamines such as diphenhydramine (Benadryl), *Datura stramonium* (jimsonweed), and certain tricyclic antidepressants such as amitriptyline (Elavil). With the exception of jimsonweed, these medications usually are not abused drugs but may be taken as an intentional overdose. It is often difficult to distinguish between an anticholinergic overdose and a sympathomimetic overdose. Both groups of patients may be agitated and have tachycardia and dilated pupils.

As newer, safer antidepressants are added to the market, you can expect to see fewer overdoses of tricyclic antidepressants. In addition to its anticholinergic effects, a tricyclic antidepressant overdose may cause more serious and life-threatening effects because the medication may block the electrical conduction system in the heart, leading to lethal cardiac dysrhythmias. Patients with acute tricyclic antidepressant overdose must be transported immediately to the emergency department; they may appear "normal," but seizure and death can occur within 30 minutes. The seizures and cardiac dysrhythmias caused by a severe tricyclic antidepressant overdose are best treated in the hospital. If you work in a tiered system, consider calling for ALS backup when you are en route to the scene.

▶ Cholinergic Agents

Cholinergic agents are medications that overstimulate the normal body functions controlled by the parasympathetic nervous system. These agents have been used for chemical warfare, such as during the sarin gas attack on the Tokyo subway system in 1995. These agents also occur in organophosphate insecticides, which are commonly used for lawn and garden care. A patient who has been poisoned by a cholinergic agent will exhibit excessive salivation or drooling; mucous membrane oversecretion, resulting in a runny nose (rhinorrhea); excessive urination; excessive tearing of the eyes; uncontrolled diarrhea; and an abnormal heart rate. The signs and symptoms of cholinergic drug poisoning are easy to remember using the mnemonic DUMBELS:

D Diarrhea

U Urination

M Miosis (constriction of the pupils), muscle weakness

B Bradycardia, bronchospasm, bronchorrhea (discharge of mucus from the lungs)

E Emesis (vomiting)

L Lacrimation (excessive tearing)

S Seizures, salivation, sweating

Alternatively, you can use the mnemonic SLUDGEM:

S Salivation, sweating

L Lacrimation (excessive tearing)

U Urination

D Defecation, drooling, diarrhea

G Gastric upset and cramps

E Emesis (vomiting)

M Muscle twitching/miosis (pinpoint pupils)

Patients who have been poisoned will have excessive body secretions. In addition, patients may have bradycardia.

The most important consideration in caring for a patient who has been exposed to a cholinergic agent is to avoid exposure yourself. Because these agents may cling to a patient's clothing and skin, decontamination will take priority over prompt transport to the emergency department. In many jurisdictions, the HazMat team will provide decontamination and contain the exposure chemical.

To care for the exposed patient, hospital staff or paramedics can use the anticholinergic drug atropine to dry up the patient's secretions, followed by the use of pralidoxime to reverse the nerve agent's effect on the patient's nervous system. In the meantime, your priorities after decontamination are to decrease the secretions in the mouth and trachea that threaten to suffocate the patient and provide airway support.

The military has developed antidotes to nerve gas agents that responders can self-administer if the agents are available. In some areas across the country, these kits are issued to emergency medical providers depending on local protocols. The most common kit is the DuoDote Auto-Injector. The Antidote Treatment Nerve Agent Auto-Injector (ATNAA) is the military form of the DuoDote Auto-Injector.

The DuoDote Auto-Injector is a single auto-injector containing 2 mg of atropine and 600 mg of pralidoxime. If a known exposure to nerve agents or organophosphates with manifestation of signs and symptoms has occurred, use the antidote kit only on yourself. If your service carries these antidote kits, you should receive training on their proper use prior to administering them.

Miscellaneous Drugs

Accidental or intentional overdose with cardiac medications has become common because there are so many patients who have these medications prescribed for them. For example, children may ingest these medications at their grandparent's house, thinking they are candy. Another common scenario is older patients who have forgotten they have already taken their medication and take a second dose. Occasionally people wanting to commit suicide will take an overdose of cardiac medications if that is all they have available. The signs and symptoms of cardiac medication overdose depend on the medication ingested. These drugs may cause bleeding, cardiac dysrhythmias, unconsciousness, and even cardiac arrest. Most of these medications are powerful, so contact the poison center as soon as possible. Depending on local protocol, you may be ordered to administer activated charcoal, but check with the poison center first.

Aspirin poisoning is a potentially lethal condition. Ingesting too many aspirin tablets, acutely or chronically, is an emergency that may result in nausea, vomiting, hyperventilation, and ringing in the ears. Patients with this condition frequently have anxiety, confusion, tachypnea, and hyperthermia, and are in danger of having seizures. Rapidly transport these patients to the hospital.

When consumed in excess, acetaminophen becomes toxic. Overdosing with acetaminophen and combination medications containing acetaminophen is also common. According to the US Food and Drug Administration, acetaminophen is among the top 25 substances with the largest number of fatalities due to poisoning.

It is essential to determine what medications the patient takes or has taken, including OTC medications. Acetaminophen overdose, unintentional or intentional, must be treated promptly and aggressively.

Accidental acetaminophen overdose is as serious as intentional overdose. In fact, its effects can be worse because the patient is unaware of the continuous exposure to the toxin. For example, massive liver failure may not be apparent for a full week. In addition, patients may not provide the information necessary for a correct diagnosis. For this reason, gathering information at the scene is very important. By finding an empty acetaminophen bottle, you may save a patient's life. If a specific antidote is given early enough (before liver failure occurs), liver damage may be prevented.

Some alcohols, including methyl alcohol and ethylene glycol, are even more toxic than ethyl alcohol (drinking alcohol). Methyl alcohol is found in dry gas products and stove kits (Sterno); ethylene glycol is found in some antifreeze products. Both cause a feeling of intoxication. Left untreated, both will also cause severe tachypnea, blindness (methyl alcohol), renal failure (ethylene glycol), and eventually death. Even ethyl alcohol can stop a patient's breathing if taken in too high a dose or too fast, particularly in children. Although methyl alcohol or ethylene glycol may be used as a substitute by a chronic alcoholic who is unable to obtain ethyl alcohol, they are more often taken by someone attempting suicide. In either case, prompt transport to the emergency department is essential. Table 21-6 lists the most common fatally ingested poisons.

Food Poisoning

The term *ptomaine poisoning* was coined in 1870 to indicate poisoning by a class of chemicals found in rotting food. It is still used today in many news accounts of food poisoning. Food poisoning is almost always caused by eating food that is contaminated by bacteria. The food may appear normal, with little or no decay or odor to suggest danger.

There are two main types of food poisoning. In one, the organism itself causes disease; in the other, the organism produces toxins that cause disease Table 21-7.

One organism that produces direct effects of food poisoning is the *Salmonella* bacterium. Salmonellosis is a condition characterized by severe gastrointestinal symptoms within 72 hours of ingestion, including nausea, vomiting, abdominal pain, and diarrhea. In addition, patients with salmonellosis may be systemically ill with fever and generalized weakness. Some people are carriers of certain bacteria; although they may not become ill themselves, they may transmit diseases, particularly if they work in the food services industry. Usually, proper cooking kills bacteria, and proper cleanliness in the kitchen prevents the contamination of uncooked foods.

Table 21-6 Examples of Fatally Ingested Poisons

Benzocaine
Calcium channel blockers (verapamil, nifedipine, diltiazem)
Camphor
Chloroquine
Hydrocarbon solvents
Diphenoxylate-atropine (Lomotil)
Methanol and ethylene glycol
Methylsalicylate (oil of wintergreen)
Phenothiazines (eg, Thorazine)
Quinine
Theophylline
Tricyclic antidepressants (amitriptyline [Elavil], imipramine [Tofranil], nortriptyline [Pamelor])

Data From: Olson, Kent R. *Poisoning & Drug Overdose*. 6th ed. New York: McGraw-Hill Medical, 2011.

YOU are the Provider PART 5

You begin transport to the hospital, which is located a short distance away. You and your partner watch the patient closely because she has been retching and her airway may become an issue if she vomits. You reassess the patient. Her IV line continues to flow and is patent, she is on the cardiac monitor, and her vital signs remain normal. You call in your radio report to the hospital. The estimated time of arrival is 6 minutes.

Recording Time: 17 Minutes	
Level of consciousness	Conscious, but sleepy
Respirations	14 breaths/min; adequate depth
Pulse	72 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	108/60 mm Hg
Spo_2	**97% (on oxygen)**

9. What additional treatment is required for this patient?
10. What information should you relay to the hospital staff during your verbal report?

Table 21-7 Common Causes of Food Poisoning
Campylobacter
Clostridium botulinum toxin
Clostridium perfringens
Cryptosporidium
Cyclospora
Escherichia coli
Giardia lamblia
Listeria monocytogenes
Norovirus
Rotavirus
Salmonella
Shigella
Staphylococcus toxin
Vibrio parahaemolyticus
Yersinia enterocolitica

The more common cause of food poisoning is the ingestion of powerful toxins produced by bacteria, often in leftovers. The bacterium *Staphylococcus*, a common culprit, is quick to grow and produce toxins in foods that have been prepared in advance and kept too long, even in the refrigerator. Foods left unrefrigerated are a common vehicle for the development of staphylococcal toxins. Usually, staphylococcal food poisoning results in sudden gastrointestinal symptoms, including nausea, vomiting, and diarrhea. Although time frames may vary from person to person, these symptoms usually start within 2 to 3 hours after ingestion or as long as 8 to 12 hours after ingestion.

The most severe form of toxin ingestion is botulism. This often-fatal disease usually results from eating improperly canned food, in which the spores of *Clostridium* bacteria have grown and produced a toxin. The symptoms of botulism are neurologic: blurring of vision, weakness, and difficulty in speaking and breathing. Botulism can also cause muscle paralysis and is typically fatal when it reaches the muscles of respiration. Symptoms of botulism may develop as long as 4 days after ingestion or as early as the first 24 hours.

In general, do not try to determine the specific cause of acute gastrointestinal conditions. After all, severe vomiting may be a sign of food poisoning, a bowel obstruction requiring surgery, or poisoning by substances such as copper, arsenic, zinc, cadmium, scombrotoxin (fish poison), or *Clitocybe* or *Inocybe* mushrooms. Instead, gather as much history as possible from the patient and transport him or her promptly to the hospital. When two or more people in one group have the same illness, take along some of the suspected food to the hospital. In advanced cases of botulism, you may have to assist ventilation and give basic life support.

Special Populations

Geriatric patients are susceptible to toxicity for a number of reasons. Consider the case of an accidental overdose or poisoning. The older patient may have forgotten that the medication had been taken and take repeated doses. Alcohol abuse can make a patient more likely to make medication mistakes. Many older patients take multiple prescriptions that may negatively interfere with each other, resulting in increased effects or unwanted drug interactions. The aging process may also impair the older patient's ability to metabolize or excrete the poison. The drug could quickly accumulate to toxic levels and become fatal in lesser doses than in a younger person. Chapter 35, Geriatric Emergencies, discusses these risk factors in more detail.

If an older person inhales a poison, even in tiny quantities, lung damage can be severe. Consider the decreased lung capacity and ability to exchange oxygen and carbon dioxide in an older patient's lungs. Pulmonary function could be worsened to potentially fatal levels with the inhalation of minute amounts of poison. For poisons that are absorbed by or injected into the skin, reduced circulation to the skin can decrease or delay absorption into the body. Watch for an increased reaction or irritation at the skin site.

A geriatric patient may also intentionally overdose in an attempt to commit suicide. Be alert for any indication of an intentional overdose or poisoning, even though the patient might deny an attempted suicide.

Special Populations

Small children or toddlers may experience accidental poisoning due to their natural curiosity. Children at this age commonly put objects in their mouth as a means to learn about them. When they gain access to toxic substances, they will almost always ingest them. Most parents and caregivers are aware of these dangers and properly secure cabinets or store substances out of reach, but often grandparents or older adults without children will store household chemicals in easy-to-reach, lower cabinets without locks. This creates a serious hazard when young children visit. It is fortunate that most accidental poisonings of children are not fatal. Avoid blaming the adults and focus instead on treating the child in the most appropriate manner.

Plant Poisoning

According to the National Poison Data System, tens of thousands of cases of poisoning from plants occur each year, some severe. Many household plants are poisonous if ingested; children have been known to nibble on the leaves **Table 21-8**. Some poisonous plants cause local irritation of the skin; others can affect the circulatory system, the gastrointestinal tract, or the CNS. It is impossible for you to memorize every plant and poison, let alone their effects **Figure 21-10**. You can and should do the following:

1. Assess the patient's airway and vital signs.
2. Notify the regional poison center for assistance in identifying the plant.
3. Take the plant to the emergency department.
4. Provide prompt transport.

Irritation of the skin and/or mucous membranes is a problem with the common houseplant called dieffenbachia, which resembles elephant ears. When chewed, a single leaf may irritate the lining of the upper airway enough to cause difficulty swallowing, breathing, and speaking. For this reason, dieffenbachia has been called Dumb Cane. In rare circumstances, the airway may be completely obstructed. Emergency medical treatment of dieffenbachia poisoning includes maintaining an open airway, giving oxygen when necessary, and transporting the patient promptly to the hospital for respiratory support. Assess the patient for airway difficulties throughout transport. If necessary, provide positive-pressure ventilation.

Table 21-8 Common Toxic Plants

Scientific Name	Common Name
Abrus precatorius	Jequirity bean/rosary pea
Cicuta species	Water hemlock/wild carrot
Colchicum autumnalel	Autumn crocus
Conium maculatum	Poison hemlock
Convallaria majalis	Lily of the valley
Datura species	Jimsonweed/stinkweed
Dieffenbachia	Dumbcane
Digitalis purpurea	Foxglove
Nerium oleander	Oleander or rose laurel
Nicotiana glauca	Tree tobacco
Phoradendron	Mistletoe
Phytolacca americana	Pokeweed
Rhododendron	Rhododendron or azalea
Ricinus communis	Castor bean
Solarium nigrum	Nightshade
Zygadenus species	Death camas

1. In addition to providing immediate lifesaving treatment, what else should you do when you arrive at this scene?

Never make assumptions about the scene. Although the home is located in an affluent neighborhood with law enforcement officers available at the scene, always remember that your safety is of the utmost importance. If possible, obtain information from family members or bystanders at the scene. This information is essential to the proper treatment of your patient. In this case, the father reported that he was awakened when the patient and her friends came home from a party and were making a lot of noise. A full secondary assessment may reveal other injuries that are not apparent. Since both parents are available, obtain a full SAMPLE history.

2. How can knowledge of various signs and symptoms caused by different types of medications improve the care you provide to a patient?

When you assess a patient who has overdosed on a medication or other substance, a careful assessment may help you identify a series of signs and symptoms that indicate a particular type of toxic exposure—thereby allowing you to direct your treatment accordingly.

3. On the basis of your initial assessment, what is the most appropriate treatment for this patient?

Your patient is sleepy and not responding without stimulation she has vomited but her airway is currently patent. Her ventilation status is inadequate and requires immediate attention.

With the help of your partner and the members of the fire crew, position the patient supine. Ensure the patient and other providers are not injured in the process. You have assigned a firefighter to manage her airway with a BVM and an airway adjunct as she does not have a gag reflex. An IV line will need to be established and a blood glucose level determined. This patient requires aggressive treatment and monitoring.

4. On the basis of the patient's initial presentation, what type of drug should you suspect that she overdosed on?

On the basis of the patient's initial presentation—unconsciousness, hypoventilation, and pinpoint pupils—you should suspect that she has overdosed on an opiate or opioid. As an EMT, your job is to recognize the signs and symptoms that are associated with these types of drugs, begin immediate treatment to support the ABCs, and transport the patient to the hospital without delay.

5. Would activated charcoal benefit this patient? Why or why not?

There are several reasons why activated charcoal is not indicated for this patient. First, the patient is unconscious, is unable to protect her own airway, and clearly cannot swallow. Pouring anything into her mouth would lead to aspiration, thus substantially increasing her chance of death.

On the basis of the patient's clinical presentation, it is clear that at least some of the medications she ingested are no longer in her stomach. She is now experiencing systemic effects that are causing compromise of her breathing and circulatory status.

6. Why is naloxone being given to this patient?

Naloxone blocks opiate receptors in the body and reverses the effects of an opioid overdose. The patient's presentation indicates that one (or many) of the unknown medications she ingested is a narcotic; therefore, naloxone is indicated.

7. What other issues about this patient should concern you?

Although the patient's condition has improved following the administration of naloxone, the fact remains that she also ingested an unknown quantity of unknown medications. By no means is she out of danger.

8. How would this patient's presentation have differed had she overdosed on a sympathomimetic?

Unlike CNS depressants, sympathomimetics are CNS stimulants. A sympathomimetic is any substance that mimics the effects of the sympathetic (fight or flight) nervous system. When the sympathetic nervous system is stimulated, it releases epinephrine and norepinephrine, resulting in hypertension, tachycardia, and restlessness or agitation.

Had the patient overdosed on a sympathomimetic, her clinical presentation would have been the exact opposite. Her vital functions, such as breathing, heart rate, and blood pressure, would have significantly increased. Furthermore, she would likely have experienced paranoia, delusions, and disorganized behavior.

9. What additional treatment is required for this patient?

Further treatment for this patient is mainly supportive; closely monitor her ABCs and be alert for the recurrence of CNS depression (eg, decreased level of consciousness, hypoventilation, hypotension). Monitor her vital signs at regular intervals.

Naloxone is a short-acting reversal agent when compared with most opiate/narcotics. Assisted ventilation and additional naloxone may be required if the patient lapses back into CNS depression. The paramedic who is monitoring the patient's cardiac rhythm may need to give additional medications if the patient develops a cardiac dysrhythmia.

10. What information should you relay to the hospital staff during your verbal report?

Your verbal (hand-off) report at the hospital should be more in-depth than what was provided over the radio. Advise the receiving nurse or physician of how you found the patient, what you initially did to treat her, and how she responded to your treatment.

Inform the hospital staff of the patient's condition en route to the hospital, and advise them of any changes—good or bad—that may have occurred after you gave your radio report.

EMS Patient Care Report (PCR)

Date: 12-04-16	**Incident No.:** 03188	**Nature of Call:** "Flulike symptoms"		**Location:** 1968 Holly Creek Place	
Dispatched: 0220	**En Route:** 0222	**At Scene:** 0226	**Transport:** 0240	**At Hospital:** 0249	**In Service:** 0301

Patient Information

Age: 17 **Sex:** F **Weight (in kg [lb]):** 49 kg (108 lb)	**Allergies:** No known drug allergies **Medications:** None **Past Medical History:** None **Chief Complaint:** Patient unconscious; mother reports one episode of vomiting

Vital Signs

Time: 0232	**BP:** 96/50	**Pulse:** 116	**Respirations:** 0	**Spo_2:** 91%
Time: 0237	**BP:** 108/52	**Pulse:** 84	**Respirations:** 12	**Spo_2:** 96%
Time: 0243	**BP:** 108/60	**Pulse:** 72	**Respirations:** 14	**Spo_2:** 97%

Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** IV therapy, 2 mg Narcan cardiac monitoring, blood glucose assessment

Narrative

Medic 504 dispatched to a single-family home for "flulike symptoms." Accessed community through security gate and was escorted to scene with Engine 11 by community security guard. Law enforcement was also on scene. Found the patient, a 17-year-old girl, sitting slouched on a couch with her mother. Her mother reported the patient was "sleepy" and had vomited once. Vomit contained colored pill fragments. Assessment of the patient revealed she was unresponsive; her airway was clear of emesis. She had snoring respirations as we entered the home. Subsequently, all respirations ceased. Patient was moved to floor, her airway was secured manually, and an oral airway was inserted. Ventilation was provided via BVM and high-flow oxygen. Patient's pulse was weak and slow but increased as ventilations were assisted.

Obtained vital signs as partner established IV access. A bystander stated he and the patient went to a "skittle party," where the teenagers brought an assortment of pills from home and took as many as they wanted to get high. Bystander also stated they were drinking beer and liquor. Secondary assessment revealed pinpoint pupils, but was otherwise unremarkable. No medical alert bracelets were found on the patient. Blood glucose level was assessed and was noted to read 112 mg/dL.

After IV access was established, the paramedic administered naloxone by titration in 0.4 mg amounts until respirations were achieved. The total amount of naloxone given was 2 mg.

Reassessment of patient revealed that her level of consciousness, heart rate, blood pressure, and oxygen saturation had improved. She no longer tolerated the oral airway or BVM-assisted ventilation. The patient was placed on high-flow oxygen via nonrebreathing mask. Cardiac rhythm was monitored by the paramedic.

Patient was loaded into the ambulance. Departed the scene and continued treatment en route. Reassessment revealed the patient remained conscious but sleepy. Her airway was patent and her breathing and pulse were adequate. We continued oxygen therapy and monitored patient's vital signs for the duration of the transport. Patient was delivered to the emergency department staff without incident; her condition was improving. Gave verbal report to charge nurse. Medic 504 cleared the hospital and returned to service at 0301.**End of report**

Prep Kit

Ready for Review

- Poisons act acutely or chronically to destroy or impair body cells.
- If you believe a patient may have taken a poisonous substance, support the ABCs and notify medical control.
- Management of the patient also entails collecting any evidence of the type of poison that was used and taking it to the hospital; diluting and physically removing the poisonous agent; providing respiratory support; and transporting the patient promptly to the hospital.
- Emergency treatment may include administration of an antidote, usually at the hospital, if an antidote exists.
- A poison can be introduced into the body in one of four ways:
  - Inhalation
  - Absorption (surface contact)
  - Ingestion
  - Injection
- It is impossible to remove or dilute injected poisons from the body, a fact that makes these cases especially urgent.
- Always consult medical control before you proceed with the treatment of a patient who has been poisoned.
- Move patients who have inhaled poison to fresh air; be prepared to use supplemental oxygen via a nonrebreathing mask and/or ventilatory support via a BVM if necessary.
- With absorbed or surface contact poisons, be sure to avoid contaminating yourself. Remove all contaminated substances and clothing from the patient, and flood the affected part.
- Approximately 80% of all poisonings are by ingestion, including plants, contaminated food, and most drugs. If permitted by local protocol, give activated charcoal to these patients.
- People who abuse a substance can develop a tolerance to it or can develop an addiction.
- One of the most commonly abused drugs in the United States is alcohol. It can depress the CNS and can cause respiratory depression. You must support the airway in such cases, and be prepared for the patient to vomit.
- Opioids, opiates, sedative-hypnotic drugs, and abused inhalants can also depress the CNS and can cause respiratory depression.
- Naloxone is an antidote that reverses the effects of opiate or opioid overdose. Indications for this drug include agonal respirations or apnea. Ventilate the patient prior to administration to minimize hypoxia.
- Take special care with patients who have used inhalants because the drugs may cause seizures or sudden death.
- Sympathomimetics, including cocaine, stimulate the CNS, causing hypertension, tachycardia, seizures, and dilated pupils. Patients who have taken these drugs may be paranoid, as may patients who have taken hallucinogens.
- Anticholinergic medications, often taken in suicide attempts, can cause a person to become hot, dry, blind, red-faced, and mentally unbalanced. An overdose of tricyclic antidepressants can lead to cardiac dysrhythmias.
- The symptoms of cholinergic medications, which include organophosphate insecticides, can be remembered by the mnemonic DUMBELS, for excessive Diarrhea, Urination, Miosis/muscle weakness, Bradycardia/bronchospasm/bronchorrhea, Emesis, Lacrimation, and Seizures/salivation/sweating; or SLUDGEM, for Salivation/sweating, Lacrimation, Urination, Defecation/drooling/diarrhea, Gastric upset and cramps, Emesis, and Muscle twitching/ miosis.
- Two main types of food poisoning cause gastrointestinal symptoms.
  - In one type, bacteria in the food directly cause disease, such as salmonellosis; in the other, bacteria such as *Staphylococcus* produce powerful toxins, often in leftover food.
  - The most severe form of toxin ingestion is botulism; the first neurologic symptoms may appear as late as 4 days after ingestion.
- Plant poisoning can affect the circulatory system, the gastrointestinal system, and the CNS. Some plants, such as the dieffenbachia, irritate the skin or mucous membranes and may cause obstruction of the airway.
- Always remember the importance of scene safety.

Vital Vocabulary

addiction A state of overwhelming obsession or physical need to continue the use of a substance.

antidote A substance that is used to neutralize or counteract a poison.

delirium tremens (DTs) A severe withdrawal syndrome seen in alcoholics who are deprived of ethyl alcohol; characterized by restlessness, fever, sweating, disorientation, agitation, and seizures; can be fatal if untreated.

emesis Vomiting.

hallucinogen An agent that produce false perceptions in any one of the five senses.

hematemesis Vomiting blood.

hypnotic A sleep-inducing effect or agent.

ingestion Swallowing; taking a substance by mouth.

material safety data sheet (MSDS) A form, provided by manufacturers and compounders (blenders) of chemicals, containing information about chemical composition, physical and chemical properties, health and safety hazards, emergency response, and waste disposal of a specific material; also known as a safety data sheet (SDS).

narcotic A drug that produces sleep or altered mental consciousness.

opiate A subset of the opioid family, referring to natural, non-synthetic opioids.

opioid A synthetically-produced narcotic medication, drug, or agent similar to the opiate morphine, but not derived from opium; used to relieve pain.

overdose An excessive quantity of a drug that, when taken or administered, can have toxic or lethal consequences.

poison A substance whose chemical action could damage structures or impair function when introduced into the body.

sedative A substance that decreases activity and excitement.

stimulant An agent that produces an excited state.

substance abuse The misuse of any substance to produce a desired effect.

tolerance The need for increasing amounts of a drug to obtain the same effect.

toxicology The study of toxic or poisonous substances.

toxin A poison or harmful substance produced by bacteria, animals, or plants.

Assessment *in Action*

© Jones & Bartlett Learning. Courtesy of MIEMSS.

It is midmorning on a bright and sunny autumn day and your unit is dispatched to a park on East 14^{th} Street for an unknown medical emergency. As you arrive, you see three middle-aged men sitting on a park bench. A police officer is on scene and tells you it is safe to approach. You notice one of the men appears to be looking straight up. The man next to him grabs his head and repositions it so he is facing forward. You can see the man is not moving or breathing. While your partner opens the airway bag, you and the police officer move the patient from the park bench onto the ambulance cot. Once the patient is positioned, your partner begins assisting the man's respirations.

1. As you load the patient into the ambulance, what should you do to assist your partner?

   A. Prepare an IV setup.
   B. Place the patient on the cardiac monitor.
   C. Begin a detailed assessment.
   D. Take vital signs.

2. As you assess the patient, you notice he has pinpoint pupils. You suspect a drug overdose. What drug is the likely cause of this phenomenon?

   A. Cocaine
   B. Methamphetamine
   C. Heroin
   D. Alcohol

3. What is another sign of substance abuse that will make it difficult for your partner to establish IV access in this patient?

   A. Tachycardia
   B. Nausea and/or vomiting
   C. Venous scarring (track marks)
   D. Hypotension

4. What is the duration of action of naloxone?

   A. 30 minutes to 9 hours
   B. 30 minutes to 7 hours
   C. 30 minutes to 5 hours
   D. 30 minutes to 1 hours

5. You are dispatched to an address known for being a place where illicit drugs are purchased. You arrive at the scene prior to fire or police personnel and see several people outside the building. They are yelling and directing you and your partner inside, where the patient is located. What is the best course of action?

   A. Enter the building, find the patient, and begin assessment.
   B. Park the ambulance in front of the building and remain inside the vehicle.
   C. Stage around the corner and wait for police to declare the scene safe.
   D. Investigate the scene to determine whether it is safe.

6. Imagine a patient has taken 10 tablets of diazepam. He is sleepy and having trouble managing his airway while sitting up. You secure his airway by laying him down on your ambulance cot in a sniffing position with a nonrebreathing mask. Will the antidote naloxone work for this overdose?

   A. Yes
   B. No

7. Explain delirium tremens, including common symptoms and how to monitor the patient during transport.
8. Describe the four routes by which poisons can enter the body and provide examples of poisons for each route.
9. List and discuss two commonly abused hallucinogens.
10. Describe the safest method to administer naloxone to a patient who has overdosed on an injectable opioid drug and has no recognizable sites for IV access.

CHAPTER

22

Psychiatric Emergencies

National EMS Education Standard Competencies

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Psychiatric

Recognition of

› Behaviors that pose a risk to the EMT, patient, or others (pp 804, 810–811, 815–818)
› Basic principles of the mental health system (p 804)
› Assessment and management of
  - Acute psychosis (pp 806–811)
  - Suicidal/risk (pp 806–810, 816–818)
  - Agitated delirium (pp 806–811)

Knowledge Objectives

1. Discuss the myths and realities concerning psychiatric emergencies. (p 803)
2. Discuss general factors that can cause alteration in a patient's behavior. (p 804)
3. Define a behavioral crisis. (p 804)
4. Recognize the magnitude of mental health disorders in society. (p 804)
5. Know the main principles of how the mental health care system functions. (p 804)
6. Know the two basic categories of diagnosis that a mental health professional will use. (p 805)
7. Explain special considerations for assessing and managing a behavioral crisis or psychiatric emergency. (pp 806–810)
8. Define acute psychosis. (p 810)
9. Define schizophrenia. (p 810)
10. Explain the care for a psychotic patient. (pp 810–811)

11. Define excited delirium or agitated delirium. (p 811)
12. Explain the care for a patient with excited delirium. (p 811)
13. Describe methods used to restrain patients. (pp 811–815)
14. Know the main principles of care for the agitated, violent, or uncooperative patient. (pp 815–816)
15. Explain how to recognize the behavior of a patient at risk of suicide, including the management of such a patient. (pp 816–818)
16. Recognize issues specific to posttraumatic stress disorder (PTSD) and the returning combat veteran. (pp 818–820)
17. Discuss the medical and legal aspects of managing a psychiatric emergency. (pp 820–821)

Skills Objective

1. Demonstrate the techniques used to mechanically restrain a patient. (pp 814–815, Skill Drill 22-1)

Introduction

As an EMT, you will care for patients experiencing a behavioral crisis or psychiatric emergency. The crisis may be the result of an acute medical situation, mental illness, mind-altering substances, stress, or other causes. This chapter discusses various kinds of psychiatric emergencies and behavioral crises, including those involving drug overdoses, violent behavior, and different forms of mental illness. You will learn how to assess a person who exhibits signs and symptoms of a psychiatric emergency or a behavioral crisis and understand what kind of emergency care may be required in these situations. The chapter also covers legal concerns in dealing with psychiatric emergencies, the dangers of suicide, and issues related to posttraumatic stress disorder. Finally, you will learn how to identify and manage a potentially violent patient, including the use of restraints.

Myth and Reality

At some point, most people experience an emotional crisis, but only rarely does this crisis lead to mental illness. Otherwise healthy people may sustain acute or temporary mental health disorders. Therefore, you should not jump to the conclusion that a patient is mentally ill when exhibiting behaviors discussed in this chapter.

The most common misconception about mental illness is that if you are feeling bad or depressed, you must be “sick.” That is simply not true. There are many perfectly justifiable reasons for feeling depressed, including divorce or the death of a relative or friend. For a teenager who just broke up with his girlfriend of 12 months, it is altogether normal to withdraw from ordinary activities and to feel down for a while. This is a normal reaction to an acute crisis situation. However, when a person finds that the majority of his or her days are characterized by sadness, week after week, he or she may indeed have a mental health problem.

Some people believe anyone with a mental health disorder is dangerous, violent, or otherwise unmanageable. This is also not true. Only a small percentage of people with mental health problems fall into these categories. However, as an EMT, you may be exposed to a higher proportion of violent patients because you are seeing people who are, by definition, considered to be having a behavioral crisis; otherwise, you probably would not be seeing them. You have been called because family members or friends felt unable to manage the patient on their own. The situation may be a result of drug or alcohol use or abuse or medication noncompliance, or the patient may have a long history of mental illness and is reacting to a particularly stressful event.

It is easy to assume the patient having a behavioral crisis does not understand the situation or the message you are trying to convey. However, especially during an acute crisis, many patients still have awareness and understanding. Communication is key. Never make disparaging or inappropriate statements. It is not only poor patient care, but could escalate the situation. You may be able to calm the patient with reassurances and avoid restraints or other physical interactions that can be a danger to you or the patient. In some cases patients will de-escalate when a level of trust is established.

Although you cannot determine what has caused a person’s crisis, you may be able to predict whether the person will become violent. The ability to predict violence is one of your more important assessment tools.

YOU are the Provider — PART 1

At 1920 hours, you are dispatched to 517 East Bandera for a man who, according to a neighbor, is sitting in his yard “acting bizarre.” Law enforcement is en route to the scene but has not yet arrived. You and your partner acknowledge the call, get into the ambulance, and proceed to the scene. The weather is clear, the temperature is 70°F (21°C), and the traffic is moderate.

1. How should you and your partner proceed to this call?
2. Other than an underlying psychiatric condition, what other conditions can affect a person's behavior?

Words of Wisdom

Many people have psychological challenges later in life. They may suffer from the loss of a spouse, have serious health conditions that affect their quality of life, have financial troubles, and/or be worried about maintaining their independence. This should be considered in your interactions with older patients.

Defining a Behavioral Crisis

Behavior is what you can see of a person's response to the environment: his or her actions. Sometimes, it is obvious what is causing a person's response: A person is punched, and he or she runs away, bursts into tears, or hits back. Sometimes, it is less clear, such as when someone is depressed for very complex emotional or biological reasons.

Most of the time, people respond to the environment in reasonable ways. Over the years, people learn to adapt to a variety of situations in daily life, including stress. Stress is managed by the use of coping mechanisms. However, there are times when the stress is so great that the normal means of coping are not enough, or the person uses negative coping mechanisms like withdrawal or numbing with drugs and alcohol. In some cases the reaction is acute, but in other cases it develops over time. Both situations can create a crisis.

The change in behavior may be considered inappropriate or not normal by the person who calls 9-1-1. A **behavioral crisis** or psychiatric emergency includes patients of all ages who exhibit agitated, violent, or uncooperative behavior or who are a danger to themselves or others. EMS is called when behavior has become unacceptable to the patient, family, or community. EMS can be called for an older adult who lives alone and started a kitchen fire when he or she left the burner on or for a person who is in danger from hoarding behavior. In these instances a patient may have dementia or depression, behavior that may interfere with the **activities of daily living**. Chronic **depression** is a persistent feeling of sadness and despair. It may be a symptom of a mental health disorder. There may not be a medical or traumatic emergency but simply a request for a psychologic evaluation.

A person who experiences a panic attack after having a heart attack is not necessarily mentally ill. Likewise, you would expect a person who is fired from a job to have some sort of reaction, often sadness and depression. These problems are short-term and isolated events. However, when a person reacts with a fit of rage, attacking people and property, this behavior has gone beyond what society considers appropriate or normal. That person is likely undergoing a behavioral crisis. Usually, if an abnormal or disturbing pattern of behavior lasts for a month or more, it is regarded as a matter of concern from a mental health standpoint.

When a **psychiatric emergency** arises, patients may show agitation or violence or become a threat to themselves or others. This is more serious than a typical behavioral crisis that causes inappropriate behavior. A psychiatric emergency often leads to severe impairments in the ability to perform activities of daily living and may be accompanied by bizarre behavior.

When there is an immediate threat to the person involved or when a patient's behavior threatens you, family, friends, or bystanders, the situation should be considered a psychiatric emergency. For example, a person might respond to the death of a spouse by attempting suicide. Other patients might respond to an upsetting event by exhibiting bizarre behavior.

The Magnitude of Mental Health Disorders

According to the National Institute of Mental Health, mental disorders are common throughout the United States, affecting tens of millions of people each year. **Psychiatric disorders** are illnesses with psychological or behavioral symptoms that may result in impaired functioning. Anxiety disorders are among the most common mental health disorders and include generalized anxiety disorder, panic disorder, social and other phobias, posttraumatic stress disorder (PTSD), and obsessive-compulsive disorder.

The mental health system in the United States provides many levels of assistance to people with psychologic conditions. Common emotional issues such as marital conflict and parenting issues can often be resolved with the assistance of a professional counselor. More serious issues, such as clinical depression, are often handled by a psychologist who has specialized training dealing with more complex psychological conditions. For the treatment of the most severe conditions, like schizophrenia or bipolar disorder, a psychiatrist may need to prescribe medication. Most psychological disorders can be handled through outpatient visits; however, some people require hospitalization in psychiatric units.

Psychiatric disorders have many underlying causes. These include social and situational stress such as divorce or death of a loved one; psychiatric diseases such as schizophrenia; physical illnesses such as diabetic emergencies; chemical problems such as alcohol or drug use; or biologic disturbances such as electrolyte imbalances. Sometimes these conditions can be compounded by noncompliance with prescribed medication regimens.

Pathophysiology

As an EMT, you are not responsible for diagnosing the underlying cause of a behavioral crisis or psychiatric emergency. However, you should understand the two basic categories of diagnosis that a physician will use: organic (physical) and functional (psychological).

Organic

Organic brain syndrome is a temporary or permanent dysfunction of the brain caused by a disturbance in the physical or physiologic functioning of brain tissue. Causes of organic brain syndrome include sudden illness; traumatic brain injury; seizure disorders; drug and alcohol abuse, overdose, or withdrawal; and diseases of the brain, such as Alzheimer dementia or meningitis.

Altered mental status can arise from a physiological issue such as a hypoglycemia, hypoxia, impaired cerebral blood flow, and/or hyperthermia or hypothermia. In the absence of a physiologic cause, altered mental status may be an indicator of a psychiatric disorder such as bipolar disorder.

Functional

A **functional disorder** is a physiological disorder that impairs bodily function when the body seems to be structurally normal. Something has gone wrong, but the root cause cannot be identified. Schizophrenia, anxiety conditions, and depression are good examples of functional disorders. The chemical or physical basis of these disorders does not alter the appearance of the patient.

Words of Wisdom

A patient displaying bizarre behavior may actually have an acute medical illness that is the cause, or a partial cause, of the behavior. Behavioral changes may be the result or a symptom of a treatable medical condition such as diabetes or a stroke. They can also be the result of a head injury or drug or alcohol intoxication. Medical conditions presenting as psychological disorders must be identified. A patient with hypoglycemia presenting with altered behavior can face a life-threatening situation if the medical condition is not treated.

YOU are the Provider — PART 2

Law enforcement personnel arrive at the scene and inform you it is safe for you to enter. One of the police officers informs you the patient allowed them to check him for any weapons and that he does not have any.

You find the patient, a 44-year-old man, sitting on the lawn in front of his house; one of the police officers is trying to talk to him. He appears sad and withdrawn and is rocking back and forth. You introduce yourself to the patient and perform a primary assessment.

Recording Time: 0 Minutes	
Appearance	Sad withdrawn appearance
Level of consciousness	Conscious and alert
Airway	Open; clear of secretions and foreign bodies
Breathing	Normal rate; adequate depth
Circulation	Normal pulse rate; skin is pink and moist; no obvious bleeding

The patient tells you he "has a lot of problems," but nobody will listen to him.

3. What should be your most immediate concern with this patient?
4. How should you proceed with your assessment of this patient?

Safe Approach to a Behavioral Crisis

All routine EMT skills—patient approach, assessment, patient communication, obtaining the history, and providing care—are used in a behavioral crisis. However, other management techniques are also involved. Follow the general guidelines listed in **Table 22-1** to ensure your safety at the scene of a behavioral crisis or psychiatric emergency.

Table 22-1 Safety Guidelines for a Behavioral Crisis or a Psychiatric Emergency

- **Assess the scene.** Immediately request law enforcement to secure and maintain scene safety. Do not attempt to enter or control a scene where physical violence or weapons are present.
- **Ensure you have a means of communication** if there is an unexpected problem. *Never* let the patient get between you and the door.
- **Know where the exits are.** Park your ambulance in a location that allows you a safe and easy way out if it becomes necessary.
- **Don personal protective equipment.**
- **Have a definite plan of action.** Decide who will do what. If restraint is needed, how will it be accomplished? Avoid restraint unless your safety is an issue. Ensure you have sufficient help if restraint is required.
- **Urgently de-escalate the patient's level of agitation.** This is imperative in the interest of patient safety as well as for you and others on the scene.
- **Calmly identify yourself.** Try to gain the patient's confidence. Ask questions in a low, calm voice, and be patient. Reassure the patient that you are there to help.
- **Be direct.** State your intentions and what you expect of the patient. Let the patient know what you are doing and maintain good eye contact.
- **Be prepared to spend extra time.** It may take longer than normal to assess, listen to, and prepare the patient for transport.
- **Stay with the patient.** Do not let the patient leave the area. You should not leave the area either unless law enforcement personnel can stay with the patient. Remove any stimulus that is distressing to the patient.
- **Do not get too close to a potentially volatile patient.** Patients may object to you invading their personal space, so avoid unnecessary physical contact. A squatting, 45-degree angle approach is usually not confrontational but the position may hinder your movements **Figure 22-1**. Prepare to move quickly if the patient becomes violent; otherwise do not make quick moves. Do not allow anything to hang around your neck like a tie or stethoscope.
- **Express interest in the patient's story.** Let the patient tell you in his or her own words what happened or what is going on now. Listening can be your best skill. Do not tell the patient he or she is not hearing voices; however, do not play along with auditory or visual disturbances, delusions, or hallucinations. Do not tell the patient you understand what he or she is going through. You do not know what he or she is feeling and this statement can trigger anger and escalate the patient's condition.
- **Avoid fighting with the patient.** Remember, the patient is not responding to you in a normal manner. He or she may be wrestling with internal forces over which neither of you has control. You and others may be stimulating these inner forces without knowing it. If you can respond with empathy to the feeling that the patient is expressing, whether the feeling is anger or fear or desperation, you may be able to gain his or her cooperation. If possible, try to involve a friend or family member whom the patient trusts. Always try to talk the patient into cooperating. Do not threaten the patient. Do not talk down to the patient or directly confront him or her. If the patient verbally attacks you, do not take it personally.
- **Be honest and reassuring.** If the patient asks whether he or she has to go to the hospital, the answer should be, "Yes, that is where you can receive help."
- **Do not judge.** Do not judge a patient by behavior over which she or he may not have control. Set aside personal feelings and concentrate on providing care. Always treat the patient with respect.

Figure 22-1 When working with a potentially volatile patient, position yourself at a 45-degree angle, but be aware this position could hinder your movements

Patient Assessment

Scene Size-up

The first things for you to consider at the scene of a behavioral crisis or psychiatric emergency are your safety and the patient's response to the environment. Is the situation potentially dangerous for you and your partner? Do you need immediate law enforcement backup? Should you stage until law enforcement personnel have secured the scene? Does the patient's behavior seem typical or normal for the circumstances? Are there legal issues involved (crime scene, consent, refusal)? Make sure to take appropriate standard precautions. Request any additional resources you may need (law enforcement, additional personnel) early. You can always send them away if they are not needed. Be vigilant, and avoid tunnel vision.

Determine the mechanism of injury and/or nature of illness. Remember, certain injuries and medical conditions can cause altered behavior that can be confused with a psychiatric emergency. Note any medications or substances that may contribute to the complaint or that may be for treatment of a relevant medical condition.

Words of Wisdom

Never leave a patient alone who may be experiencing a behavioral emergency.

Primary Assessment

Begin your assessment from the doorway or from a distance. How does the patient appear? Calm? Agitated? Awake or sleepy? Begin with an introduction of who you are, and let the patient know you are there to help. Allow the patient to tell you what happened or how he or she feels. Perform a rapid physical exam if the patient allows you. Look for trauma, especially head trauma.

Closely observe the patient. Does the patient answer slowly with single word answers or rapidly in long, rambling sentences? Is the patient sitting slumped in a chair, hunched and shuffling around the room, or rigid and standing perfectly still? Is the patient alert and oriented? Use the AVPU scale to check for alertness. To determine orientation, ask the patient, "Who are you?" "Where are you?" "What time is it?" and "What happened?" Asking these questions will allow you to begin to establish a rapport with the patient. This rapport is critical to the success of your interaction. Engage family members or loved ones to encourage the patient's cooperation, if their presence does not worsen the patient's agitation.

Most medical or trauma situations will include a behavioral component. Anyone experiencing an emergency will generally have some level of fear or anxiety. A patient with difficulty breathing will be anxious. The parent of a small child who fell out a second story window will most likely be hysterical and feeling guilty. An assault victim often experiences fear or anger. It is important to treat the whole patient: the behavioral component as well as the medical or traumatic issue.

If your patient is in physical distress, assess the airway to make sure it is patent and adequate. Next, evaluate the patient's breathing and obtain rate and effort. Use pulse oximetry if available. Provide the appropriate interventions based on your assessment findings. Some behavioral situations will involve a compromised airway or inadequate breathing if a patient has ingested prescription medications, drugs, or alcohol.

Next, you will need to assess the pulse rate, quality, and rhythm. Assessing a patient's circulation includes an evaluation for the presence of shock and bleeding. Assess the patient's perfusion by evaluating skin color, temperature, and capillary refill.

Unless your patient is unstable from a medical problem or trauma, prepare to spend time with your patient. It may take time and patience to gain the patient's trust if he or she is fearful or unwilling to cooperate with you.

History Taking

When a medical patient is conscious, the next step of your assessment is to investigate the chief complaint and then obtain a SAMPLE history. Obtain information about the patient and his or her medical history.

Determine the reason for the patient's behavior; your assessment should consider three major areas as possible contributors:

- Is the patient's central nervous system functioning properly? For example, the patient may be experiencing a diabetic emergency such as hypoglycemia. This situation could cause the patient to behave in an unusual or irrational manner.

- Are hallucinogens or other drugs or alcohol a factor? Does the patient see strange things? Is everything distorted? Do you smell alcohol on the patient's breath? Are there clues at the scene that suggest intoxication?
- Are significant life changes, symptoms, or illness (caused by mental rather than physical factors) involved? These might include the death of a loved one, severe depression, history of mental illness, threats of suicide, or some other major interruption of activities of daily living.

During the SAMPLE history, you may be able to elicit information not available to the hospital staff. Ask specifically about previous episodes, treatments, hospitalizations, and medications related to behavioral symptoms Table 22-2.

In geriatric patients, consider Alzheimer disease and dementia as possible causes of abnormal behavior. Determining the patient's baseline mental status will be essential in guiding your treatment and transport decisions and will also be extremely helpful to hospital personnel.

Family, friends, observers, and caregivers may be of great help in answering these questions. Together with your observations and interactions with the patient, they should provide enough data for you to assess the situation. This assessment has two primary goals: recognizing major threats to life and reducing the stress of the situation as much as possible.

Reflective listening is a technique frequently used by mental health professionals to gain insight into a patient's thinking. It involves repeating, in question form, what the patient has said, encouraging the patient to expand on his or her thoughts. Although it often requires more time to be effective than is available in an EMS setting, it may be a helpful tool for you to use when other techniques are unsuccessful at gathering the patient's history.

Table 22-2 **Questions to Ask in Evaluating a Mental Health Disorder**

- Does the patient appropriately answer your questions?
- Does the patient's behavior seem appropriate?
- Does the patient seem to understand you?
- Is the patient withdrawn or detached? Hostile or friendly? Happy or depressed?
- Are the patient's vocabulary and expressions what you would expect under the circumstances?
- Does the patient seem aggressive or dangerous to you or others?
- Is the patient's memory intact? Check orientation to time, place, person, and event: What day, month, and year is it? Who am I?
- Does the patient express disordered thoughts, delusions, or hallucinations?

Words of Wisdom

When assessing a patient in a behavioral crisis or psychiatric emergency, it can be very useful to gather information separately from a relative or caregiver. Splitting up the history-taking process in this way often yields valuable information and can help reduce the potential for violence when there is tension between the people involved. However, if the patient is threatening or uncontrollable, do not enter the room with the patient to obtain a more detailed history unless additional help, such as law enforcement personnel, is there.

Secondary Assessment

In an unconscious patient, begin with a physical exam to look for a reason for the unresponsiveness. Rule out trauma, especially to the head. Follow this rapid exam for hidden life threats with a detailed physical exam and obtain a complete set of vital signs. Obtain vital signs only if you are able to do so without worsening your patient's emotional condition. Make every effort to assess blood pressure, pulse, respirations, skin, and pupils. Then gather what history you can from others. Consider whether prior events such as physical agitation, use of stimulants, alcohol withdrawal, or TASER exposure may be contributing to the patient's condition. (Many law enforcement agencies use TASER devices to immobilize people who are behaving in a violent or aggressive manner.) When physically examining a patient with a history of behavioral crises, check for track marks indicating drug abuse and for signs of self-mutilation.

Sometimes even a conscious patient in a behavioral crisis or psychiatric emergency will not respond to your questions. In those cases, you may be able to tell a lot about the patient's emotional state from facial expressions, pulse rate, and respirations. Tears, sweating, and blushing may be significant indicators of state of mind such as sadness, nervousness, or embarrassment. Also, make sure you look at the patient's eyes; a patient who has a blank gaze or rapidly moving eyes may be experiencing central nervous system dysfunction **Figure 22-2**.

Figure 22-2 Making eye contact with a patient can provide useful clues about a patient's emotional state.

A behavioral crisis or psychiatric emergency puts tremendous stress on a person's coping mechanisms. The person is actually incapable of responding reasonably to the demands of the environment. This state may be temporary, as in an acute illness like drug-induced hallucinations, or more chronic, as in a complex, mental illness such as schizophrenia. The patient's perception of reality may be compromised or distorted.

When available, have law enforcement personnel or firefighters accompany you in the back of the ambulance during transport. This provides you with additional assistance should the patient's behavior change rapidly. If a police officer restrains the patient with handcuffs, the officer must ride in the back of the ambulance to release the cuffs in the case of an emergency. Always follow local protocols regarding the use of physical restraints.

There may be a specific facility to which patients with psychiatric emergencies are transported. Transport by ground rather than by air. If you feel transport may put you at risk, ask law enforcement personnel to accompany you or call for medical direction. Try to make the patient comfortable. Stretchers with foam padding around the head allow the patient to position his or her head for adequate airway patency. Placing the stretcher in Fowler or high Fowler position helps prevent aspiration and reduces physical exertion by relaxing the abdominal muscles.

Reassessment

Never let your guard down. Most patients you treat and transport with emotional complaints pose no danger to you or others, but it is not always possible to determine this while on scene. Remember, many patients experiencing a behavioral crisis will act spontaneously. Be prepared to intervene quickly. If restraints are necessary, reassess and document the patient's respirations, as well as pulse, motor, and sensory functions in all restrained extremities, every 5 minutes. Restraint is discussed later in this chapter.

In terms of interventions, as much as your heart may go out to an emotionally distressed patient, there often is little you will be able to do during the short time you will be treating the patient. Your job is to diffuse and control the situation and safely transport your patient to the hospital. The best treatment may be to be a good listener. Often these patients are happy if someone will listen to their problem. Intervene only as much as it takes to accomplish these tasks. Be caring and careful. Be aware of standard precautions. If the patient is spitting, place a surgical mask loosely over his or her mouth.

In many areas local protocol allows advanced life support (ALS) providers to administer medications to calm a combative patient. This will often make the situation safer for you and your patient. If you encounter a situation where you think pharmacologic restraint might be necessary, request ALS as early as possible.

Words of Wisdom

The medicolegal issues associated with responses to a behavioral crisis put added emphasis on the importance to provide thorough and specific documentation. Record detailed, objective findings that support the conclusion of abnormal behavior (eg, withdrawn, will not talk, crying uncontrollably) and quote the patient's own words when appropriate, for example, "Life isn't worth it any more," or "The voices are telling me to kill people." Avoid judgmental statements that may create the impression you based your care on personal bias rather than the patient's needs.

Give the receiving hospital advance warning when a patient experiencing a psychiatric emergency is coming in. Many hospitals require extra preparation to ensure the appropriate staff and rooms are available. Report whether restraints will be required when the patient arrives.

Thoroughly and carefully document. Think about what you are going to write before you write it, so that you can describe as clearly as possible what are often confusing scenes. Communicate to the hospital the things you observed at the scene that may help explain the patient's situation. These are important facts the hospital will not know unless you tell them. Include observed behaviors or items seen such as medications or weapons. Medications may have contributed to the crisis or may give you information about an otherwise undisclosed medical condition. Because psychiatric emergencies have few or no physical signs, you may have the only documentation clarifying the patient's distress. Because psychiatric emergencies are also fraught with legal dangers, document everything that occurred on the call, particularly situations that required restraint. When restraints are required to protect you or the patient from harm, include why and what type of restraints were used. This information is essential if the case is reviewed for medicolegal reasons.

Acute Psychosis

Psychosis is a state of delusion in which the person is out of touch with reality. Affected people live in their own reality of ideas and feelings. To the person experiencing a psychotic episode the line between reality and fantasy is blurred. That reality may make patients belligerent and angry toward others. Patients may become silent and withdrawn as they give all their attention to the voices and feelings within. Psychotic episodes occur for many reasons; the use of mind-altering substances is one of the most common causes, and that experience may be limited to the duration of the substance within the body. Other causes include intense stress, delusional disorders, and, more commonly, schizophrenia. Some psychotic episodes last for brief periods; others last a lifetime.

Schizophrenia

Schizophrenia is a complex disorder that is not easily defined or easily treated. The typical onset occurs during early adulthood, with symptoms becoming more prominent over time. Some people diagnosed with schizophrenia display signs during early childhood; their disease may be associated with brain damage or may have other causes. Other influences thought to contribute to this disorder include genetics and psychologic and social influences. Patients with schizophrenia may experience symptoms including delusions, hallucinations, a lack of interest in pleasure, and erratic speech.

Dealing with a psychotic patient is difficult. The usual methods of reasoning with a patient are unlikely to be effective because the psychotic person has his or her own rules of logic that may be quite different from nonpsychotic thinking. Follow these guidelines in dealing with a psychotic patient:

- Determine if the situation is a danger to yourself or others.
- Clearly identify yourself. ("I'm Gloria. I'm an EMT with the ambulance service, and this is my partner, Stan. We've come to see if we can help. Can you tell us what is happening?")

YOU are the Provider — PART 3

The patient tells you his wife was killed in a car accident 1 year ago today and he has been to numerous counseling sessions over the past year, but they have not seemed to help him. He further tells you his employer does not seem to care about his problems and has threatened to fire him unless he "snaps out of it." He allows your partner to take his vital signs but refuses to allow you to perform any other assessment or treatment.

Recording Time: 9 Minutes	
Respirations	16 breaths/min; adequate depth
Pulse	88 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	144/84 mm Hg
Oxygen saturation (Spo_2)	98% (on room air)

The patient denies chest pain, shortness of breath, or any other physical symptoms. He tells you it is extremely difficult for him to even get out of bed and face each day and he feels as though his life no longer serves any purpose.

5. What is your field impression of this patient?
6. What care can you provide to this patient in the field?

- Be calm, direct, and straightforward. Your composure and confidence can do a great deal toward calming the patient.
- Maintain an emotional distance. Do not touch the patient, and do not patronize the patient or be effusively reassuring.
- Do not argue. Do not challenge patients regarding the reality of their beliefs or the validity of their perceptions. Do not go along with their delusions simply to humor them, and do not make an issue of the delusions. Talk about real things.
- Explain what you would like to do. ("Let's walk downstairs to the ambulance.")
- Involve people the patient trusts, such as family or friends, to gain the patient's cooperation.

Excited Delirium

A problem sometimes encountered in an EMS response is excited delirium. **Excited delirium** is also known as agitated delirium or exhaustive mania. *Delirium* is a condition of impairment in cognitive function that can present with disorientation, hallucinations, or delusions. *Agitation* is a behavior characterized by restless and irregular physical activity. Although patients experiencing delirium are generally not dangerous, if they exhibit agitated behavior they may strike out irrationally. One of the most important factors to consider in these cases is your personal safety.

The symptoms of agitated delirium may include hyperactive irrational behavior with possible vivid hallucinations, which can create the potential for violent behavior. Common physical symptoms include hypertension, tachycardia, diaphoresis, and dilated pupils. Because hallucinations are erroneous perceptions of reality, the patient may perceive you as a threat.

Agitation is recognized as a biologic attempt to release nervous tension and can produce sudden, unpredictable physical actions in your patient.

If you think you can safely approach the patient, be very calm, supportive, and empathetic. Be an active listener by nodding, indicating understanding, and by limiting your interruptions of the patient's comments. It is extremely important to approach the patient slowly and purposefully and to respect the patient's personal space. Limit physical contact with the patient as much as possible. It is also imperative that you do not leave the patient unattended, unless the situation becomes unsafe for you or your partner.

Use careful interviewing to assess the patient's cognitive functioning. Try to indirectly determine the patient's orientation, memory, concentration, and judgment by asking simple questions such as "When did you first begin to notice these feelings?" Through interviewing, try to determine what the patient is thinking. Are the patient's thoughts disorganized? For example, does the patient begin to answer your question and then drift off only to begin discussing a childhood friend? Is the patient experiencing delusions or hallucinations? Does the patient have any unusual worries or fears? For example, does the patient express anxiety if you go too close to a pile of old newspapers?

Pay particular attention to the patient's ability to communicate clearly, and make notes on the patient's apparent mood. Is the patient anxious, depressed, elated (extremely happy or joyful), or agitated? Pay attention to the patient's appearance, dress, and personal hygiene.

If the patient appears to be experiencing a drug overdose, take all medication bottles or illegal substances with you to the medical facility. The patient should be transported to a hospital with psychiatric facilities capable of handling the condition. Whenever possible, refrain from using lights and siren because bright lights and loud sounds may aggravate the patient's condition.

If the patient's agitation continues, request ALS assistance so chemical restraint can be considered. Uncontrolled or poorly controlled patient agitation and physical violence can place the patient at risk for sudden cardiopulmonary arrest. Physical agitation can lead to sudden death, thought to result from metabolic acidosis. Physical control measures (including TASERs) can contribute to sudden death in these patients. Also, this condition can be worsened by stimulant drugs (eg, cocaine) or alcohol withdrawal. Finally, **positional asphyxia** occurs when a patient's physical position restricts chest wall movements or causes airway obstruction. It can also cause sudden death.

Restraint

In situations when a patient engages in combative behavior, your safety must be your top priority. Therefore, it may be necessary for the patient to be restrained.

Prehospital patient restraint reduces the possibility of patient injury, the potential for injury to EMS providers, and allows for safe and appropriate treatment of an uncooperative patient. The National Association of Emergency Medical Services Physicians (NAEMSP) recommends that every prehospital care transport provider create and follow a prehospital patient restraint protocol. Such protocols consider the appropriateness of restraint, the types of restraints, and care provided to the patient following restraint. Legislation regarding restraints ensures the safety of individuals who are an immediate threat to themselves or others. Your protocol must consider the laws of your state as they pertain to an individual's rights and processes for involuntarily restraining patients.

There is wide variation in prehospital patient restraint protocols throughout the country. Protocols should include only the use of restraint devices that have been approved by the state health department or local EMS agency. Restraints can be soft, leather, or cloth. Soft restraints can include sheets, wide wristlets, and chest harnesses. Hard restraints can include plastic ties, handcuffs, or leather restraints. EMS protocols should avoid the use of hard restraints if possible. If hard restraints are approved, they will most likely be limited to the use of leather wrist restraints.

The method of restraint chosen should be the least restrictive method that will ensure the safety of the patient and providers **Figure 22-3**.

Risks Associated With Patient Restraint

Personnel must be properly trained in the use of restraints. Improperly applied restraints can result in severe and potentially life-threatening complications, such as positional asphyxia, aspiration, severe acidosis, and sudden cardiac death.

If you restrain a person without authority in a non-emergency situation, you expose yourself to a possible lawsuit and to personal danger. Legal actions against you can involve charges of assault, battery, false imprisonment, and violation of civil rights. You may use restraints only to protect yourself or others from bodily harm or to prevent the patient from injuring himself or herself. In either case, you may use reasonable force only as necessary to control the patient, something that courts may define differently. For this reason, follow local protocol and your company prehospital restraint policy, and consult medical control if needed.

You should always involve law enforcement personnel if you are called to assist a patient in a severe behavioral crisis or psychiatric emergency, especially when restraining a competent individual against his or her will. Law enforcement will provide physical backup in managing the patient and serve as the necessary witnesses and legal authority for restraining the patient. A patient who is restrained by law enforcement personnel is in their custody.

Before you consider physical restraint, make a significant effort to use verbal de-escalation techniques to ease the situation and avoid the need for physical restraint. Also, consider asking the family to assist you in calming and reasoning with the patient. Verbal de-escalation is safest because it does not require any physical contact with the patient. Be honest and straightforward with the patient and talk in a calm and friendly tone.

Figure 22-3 Restraints should be used when necessary only to prevent injury and in the least restrictive manner that achieves the needed result.

The Process of Restraining a Patient

Once the decision has been made to restrain a patient, you should carry it out quickly. Make sure you have adequate help to safely restrain a patient. Ideally, five people should be present to carry out the restraint, each being responsible for one extremity and the head. There should also be a team leader who directs the restraining process. Before you begin, discuss the plan of action. As you prepare to restrain the patient, stay outside the patient's range of motion. Use the minimum force that is necessary to control a patient. Avoid acts of physical force that may cause injury to the patient. The level of force will vary, depending on the following factors:

- The degree of force that is necessary to keep the patient from injuring himself, herself, and others.
- A patient's sex, size, strength, and mental status including the possibility of drug-induced states. Phenylcyclohexylpiperidine (PCP) use may make the patient especially difficult to restrain.
- The type of abnormal behavior the patient is exhibiting.

Other important considerations include:

- Somebody, preferably you or your partner, should talk to the patient throughout the process.

- Remember to treat the patient with dignity and respect at all times.
- If possible, a provider of the same gender should attend to the patient.
- Wear appropriate barrier protection during patient restraint activities.
- Avoid direct eye contact and respect the patient's personal space until necessary.
- Never leave a restrained patient unattended.

Physically uncooperative patients should be restrained in the lateral decubitus position with one arm above the head and the other below the waist; however, four-point restraints (both arms and both legs) are preferred. Restraining the hips, thighs, and chest inhibits movement. Restraining the thighs just above the knees prevents kicking and is more effective than restraining the ankles. Do not place anything over the patient's face, head, or neck. If the patient is spitting, a surgical mask may be placed loosely over the patient's mouth. If the patient attempts to bite, a hard cervical collar may be placed on the patient's neck.

Patients should never be transported while hobbled, hog-tied, or restrained in a prone position with hands and feet behind the back, as positional asphyxia could occur. It is impossible to adequately monitor the patient in this position, and it may inhibit the breathing of an impaired or exhausted patient. Patients should never be transported while sandwiched between backboards or mattresses. Stretcher straps should be applied during transport as the standard procedure for all patients. Sheets can be used as additional stretcher straps if necessary. Stretcher straps and sheets should never restrict the patient's chest wall motion.

Respiratory and circulatory problems have been known to occur in combative patients who are restrained. A physically restrained patient struggling against restraints can experience severe acidosis or fatal dysrhythmia. Monitor the patient for vomiting, airway obstruction, respiratory status, circulatory status (blood pressure), and changes in level of consciousness. Drug or alcohol intoxication may initially cause violent behavior that may lead to physical deterioration. Reassess airway and breathing continuously. You should make frequent checks of circulation on all restrained extremities, regardless of patient position **Figure 22-4**.

If physical restraint is not effective or the patient still poses a danger to himself, herself, or others, chemical restraint administered by ALS personnel is an effective way to safely transport and treat the violent, combative, or agitated patient.

Words of Wisdom

For patients with key-locking restraint devices applied by another agency, consider the following options:

- Remove the restraint device and replace it with a restraint device that does not require a key.
- Transport the patient accompanied by a person who has the key for the device.
- Transport the patient in the vehicle of the person with the device's key if the medical condition of the patient is deemed stable, direct medical oversight so authorizes, and the law allows.

Restraints applied in the field should not be removed until the patient is evaluated at the receiving facility. Release the restraints only if necessary to provide emergency patient care and only if you have assistance. Be especially careful if a combative patient suddenly becomes calm and cooperative. This is not the time to relax but to be vigilant. The patient may suddenly become combative again and injure someone. Keep in mind that you may use reasonable force to defend yourself against an attack by an emotionally disturbed patient. It is extremely helpful to have (and document) witnesses in attendance, even during transport, to protect against false accusations. EMTs have been accused of sexual misconduct and other physical abuse in such circumstances. Also document the reason for the restraint, the type of restraint used, and the technique that was used.

Figure 22-4 Frequently assess circulation while a patient is restrained.

Performing Patient Restraint

The steps in **Skill Drill 22-1** show an example of four-point restraint technique.

1. Law enforcement officers should bring down the patient into the prone position.
2. Acting at the same time, secure the patient in the supine or left lateral position.
3. Secure the patient's extremities with wrist and ankle restraints Step 1.
4. Use stretcher straps or sheets to secure the legs Step 2.

Skill Drill 22-1 Restraining a Patient

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 1

Law enforcement officers should bring down the patient into the prone position. Then, acting at the same time, secure the patient in the supine or left lateral position with wrist and ankle restraints.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 2

Use stretcher straps or sheets to secure the legs.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 3

Fasten the remaining stretcher straps.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 4

Continue to verbally reassure and calm the patient following chemical/physical restraints. Regularly check circulation to the extremities.

5. Fasten the remaining straps, including chest and pelvis straps if available Step 3. Do not use multiple knots.
6. Continue to verbally reassure and calm the patient following chemical/physical restraints.
7. Regularly check circulation to the extremities Step 4.

A two-point restraint technique is an option if allowed per local protocols. This technique is performed in the same way as four-point restraint, except instead of restraining all four extremities to the stationary frame of the stretcher, one arm is placed upward toward the head and the other is placed downward toward the waist Figure 22-5.

Once a patient has been restrained, reassess the airway and breathing. Document this information in your patient care report.

The Potentially Violent Patient

Violent patients make up only a small percentage of the patients undergoing a behavioral or psychiatric crisis. However, the potential for violence is always a critical consideration for you Figure 22-6.

Use the following list of risk factors to assess the level of danger:

- **History.** Has the patient previously exhibited hostile, overly aggressive, or violent behavior? Ask people at the scene, or request this information from law enforcement personnel or family.

Figure 22-5 In two-point restraint, one arm is placed upward while the other is placed downward.

- **Posture.** How is the patient sitting or standing? Is the patient tense, rigid, or sitting on the edge of his or her seat? Such physical tension is often a warning signal of impending hostility.
- **The scene.** Is the patient holding or near potentially lethal objects such as a knife, gun, glass, poker, or bat (or near a window or glass door)?
- **Vocal activity.** What kind of speech is the patient using? Loud, obscene, erratic, and bizarre speech patterns usually indicate emotional distress. Someone using quiet, ordered speech is not as likely to strike out as someone who is yelling and screaming.

YOU are the Provider — PART 4

The patient is initially reluctant to allow you to transport him to the hospital. However, after you express your concern about his safety and well-being, he consents to transport. Other than allowing you to reassess his vital signs, he tells you he would prefer to just be taken to the hospital; he does not want to be physically assessed.

Recording Time: 20 Minutes

Level of consciousness	Conscious and alert
Respirations	16 breaths/min; adequate depth
Pulse	76 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	**138/86 mm Hg**
Spo_2	98% (on room air)

7. Should you perform a physical assessment of this patient despite the fact that he requested you do not? Why or why not?

Figure 22-6 Watch for indicators of potential violence when approaching the scene.

Words of Wisdom

When working with a potentially hostile or violent patient, remove everyone from the scene who is not needed, such as family, friends, or bystanders. This will prevent injury or the likelihood of someone agitating the patient. Conversely, if a family member has a positive influence on the patient, you may consider allowing him or her to help.

- **Physical activity.** The motor activity of a person undergoing a psychiatric emergency may be the most telling factor of all. A patient who has tense muscles, clenched fists, or glaring eyes; is pacing; cannot sit still; or is fiercely protecting personal space requires careful watching. Agitation may predict a quick escalation to violence.

Other factors to consider in assessing a patient's potential for violence include the following:

- Poor impulse control
- A history of truancy, fighting, and uncontrollable temper
- History of substance abuse

- Depression, which accounts for 20% of violent attacks
- Functional disorder (If the patient tells you voices are telling him or her to kill, believe it.)

Special Populations

In general, children may experience behavioral crises as commonly as adults, but often the children's situations are managed by their parents or caregivers. If you are called to help with a child experiencing a behavioral crisis, it is imperative to listen to the caregiver and follow his or her lead on how to best approach the child. Aggressive behavior in children, especially when it seems to be a pattern, may be a symptom of an underlying medical or psychologic condition. As a precaution against them hurting themselves or others, children need a thorough evaluation from a mental health professional. Although some children with a behavioral crisis may be physically large, do not make the mistake of assuming you can treat them like adults.

One specific behavioral crisis that is common among teenagers is suicide. Teenagers are one of the largest age groups to attempt suicide. Although we sometimes tend to view a teenager's problems as minor, problems often appear insurmountable to them. Never discount a teenager's comments about suicide as being "just an attempt to get attention."

Common factors that lead to suicide attempts in adults are often also found in teenagers. One of them is dealing with the end of a relationship. Teenagers are just beginning to relate to others in an intimate way, so when a relationship ends, they often do not know how to handle the apparent rejection. Adults who attempt suicide may have a drug or alcohol addiction, and this is common among teenagers as well. Teenage suicide victims may have a history of disciplinary problems or may have a very unstable home life. Another factor that is sometimes involved with teenage suicide victims is social pressures. Peer approval is one of the most important aspects of a teenager's life, and teenagers who seem to have poor relationships with their peers may be at a higher risk for suicide. In other cases, teenagers can be influenced by peers to commit suicide either individually or as part of a pact. Another risk factor to consider is that children of parents who committed suicide are more likely to attempt it themselves.

Expression of thoughts of suicide and attempts at suicide by teenagers should always be taken seriously. Never disregard suicide comments, even if a parent insists the child "is faking." Take action to ensure that teenagers are treated for attempting or considering suicide because it is very important for their long-term emotional well-being.

Special Populations

Geriatric patients may be struggling with the loss of loved ones, health issues including the diagnosis of a serious illness like cancer or dementia, living on a fixed income, and fear of losing their independence. Depression is understandable and not uncommon. When you visit the home of a geriatric patient, especially one who lives alone, ensure he or she is living in a safe and healthy environment. If you have concerns, call adult protective services.

Suicide

The single most significant factor that contributes to suicide is depression. Any time you encounter an emotionally depressed patient, you must consider the possibility of suicide. The risk factors for suicide are listed in Table 22-3.

It is a common misconception that people who threaten suicide never commit it. Suicide is a cry for help. Threatening suicide is an indication that someone is in a crisis that he or she cannot handle alone. Immediate intervention is necessary.

Whether the patient has any of these risk factors, you must be alert to the following warning signs:

- Does the patient have an air of tearfulness, sadness, deep despair, or hopelessness that suggests depression?
- Does the patient avoid eye contact, speak slowly or haltingly, and project a sense of vacancy, as if he or she really is not there?
- Does the patient seem unable to talk about the future? Ask the patient whether he or she has any vacation plans. Suicidal people consider the future so uninteresting that they do not think about it; people who are seriously depressed consider the future so distant that they may not be able to think about it at all.
- Is there any suggestion of suicide? Even vague suggestions should not be taken lightly, even if presented as a joke. If you think that suicide is a possibility, do not hesitate to bring up the subject. You will not give the patient ideas if you ask directly, "Are you considering suicide?"
- Does the patient have any specific plans related to death? Has the patient recently prepared a will? Has the patient given

away significant possessions or told close friends what he or she would like done with them? Arranged for a funeral service? These are critical warning signs.

Table 22-3 Risk Factors for Suicide

- Depression at any age, feeling trapped or purposeless
- Previous suicide attempt (About 80% of successful suicides were preceded by at least one prior attempt.)
- Current expression of wanting to commit suicide or sense of hopelessness
- Specific plan for suicide
- Family history of suicide
- People older than 40 years, particularly if single, widowed, divorced, alcoholic, or depressed (Men who are older than 55 years have an especially high risk and are very often successful if they make an attempt.)
- Recent loss of spouse, significant other, family member, or support system
- Chronic debilitating illness or recent diagnosis of serious illness
- Feeling anxious, agitated, angry, reckless, or aggressive; also dramatic mood changes such as from depression to agitation
- Financial setback, loss of job, police arrest, imprisonment, or some sort of social embarrassment
- Alcohol and substance abuse, particularly with increasing use
- Children of an alcoholic or abusive parent
- Withdrawal from family and friends or a lack of social support, resulting in isolation
- Significant anniversaries of sentinel events
- Unusual collection or acquisition of things that can cause death, such as a gun, a large volume of pills

Consider also the following additional risk factors for suicide:

- Are there any unsafe objects in the patient’s hands or nearby (a sharp knife, glass, poisons, or a gun)?
- Is the environment unsafe (an open window in a high-rise building, a patient standing on a bridge or precipice)?
- Is there evidence of self-destructive behavior (partially cut wrists, excessive alcohol or drug use)?

- Is there an imminent threat to the patient or others?
- Is there an underlying medical problem?
- Are there cultural, religious, or social beliefs promoting suicide?
- Has there been trauma?

On the basis of your observations and conversations with the patient, you may need to determine if interventions such as restraints are needed. Remember, a suicidal patient may be homicidal as well. Do not jeopardize your life or the lives of your partners. If you have reason to believe that you are in danger, you must obtain police intervention. In the meantime, try not to frighten the patient or make him or her suspicious. Remember, the most important service you can provide for a suicidal patient is compassionate transportation to a medical facility where the patient can receive proper treatment.

Safety Tips

Patients with suicidal thoughts, especially patients who have made a threat or unsuccessful attempt, may not be thinking clearly and may behave in very unpredictable ways. Some recognize that if they get into the ambulance or enter the hospital, they will not have the opportunity to complete their threat or intent. Therefore, they may make a last effort to kill themselves. Suicidal/homicidal patients will not hesitate to hurt you or your partner. Be very careful how you assess the situation; make certain you, your team, and the patient are safe.

Posttraumatic Stress Disorder and Returning Combat Veterans

Posttraumatic stress disorder (PTSD) can occur after exposure to, or injury from, a traumatic event. Such events may include sexual or physical assault, child abuse, a serious accident, a natural disaster, war, loss of a loved one, or stressful life changes. People may have experienced fear of danger, helplessness, or a severe reaction during the event. The reaction could be to trauma that occurred long ago or may be the result of multiple traumatic events over time. It is not necessarily the result of one isolated or recent event.

It is estimated that 7% to 8% of the general population will experience signs of PTSD at some point in their lives. For health care workers returning from a warfare environment, which could include disaster workers, threat of personal harm is considered a predictive factor in determining in whom PTSD will develop.

Military personnel who experienced combat have a high incidence of PTSD. PTSD occurred in up to 20% of veterans of the Iraq and Afghanistan Wars, 10% of Gulf War veterans, and 30% of Vietnam veterans. Reminders of their experiences in the military such as news coverage or gatherings of veterans can also be triggers.

Signs and Symptoms of PTSD

Symptoms of PTSD include feelings of helplessness, anxiety, anger, and fear. People with PTSD may avoid things that remind them of the trauma, including loud noises or smells, and sometimes avoid interactions with other people. This emotional and physical distancing from others can have a negative impact on one’s quality of life. Memories of the trauma linger and continue to be disruptive. Symptoms of PTSD may be made worse in the context of other mental health challenges.

The sympathetic nervous system provides the protection of the “fight-or-flight” mechanism to help protect us in a perceived dangerous situation. It is not intended to last any longer than it takes to mitigate the threat. People with PTSD suffer nervous system arousal that continues and is not easily suppressed. Heart rate increases to channel blood into the heart, lungs, and brain; pupils dilate; and systolic blood pressure is increased. Senses are sharpened and mental acuity is heightened. The victim may be hypervigilant or display an exaggerated startle response to perceived danger.

People with PTSD can relive the traumatic event through intrusive thoughts, nightmares, or even flashbacks. *Flashbacks* are uncontrollable events triggered by a sound, sight, or smell. The patient may experience the same visceral response he or she did when he or she initially encountered the stress. These episodes can last seconds or hours and can occur at any time, even years after the exposure. The person fears his or her inability to control a flashback and that it will present as irrational behavior. Recent traumatic events may also trigger old memories and create a reflex reaction of preparing for the worst. A person who has experienced flashbacks may become preoccupied with the perception of danger. Hypervigilance and trouble sleeping are not unusual.

Dissociative PTSD occurs when the person attempts to find an escape from constant internal distress or a particularly disturbing event. His or her altered consciousness allows him or her to continue functioning under negative conditions. Some people may undergo an out-of-body experience. Others experience delusions. Other psychologic conditions such as personality disorders and increased functional impairment can develop in those with a dissociative subtype of PTSD.

Guilt, shame, paranoia, hostility, and depression are not uncommon for combat veterans. Alcohol and/or drug use is a common way to suppress the sympathetic nervous system activity and slow down the body. This attempt at anesthesia can easily become addictive. Suicide is sometimes sought to end the pain. Veterans are much more likely to harm themselves or try to harm themselves. They also sustain a host of physical conditions, some from injuries sustained in combat, and sometimes vague, unfocused pain not associated with any specific part of the body. This perception of physical pain may be a sign of their anguish. Combat veterans, in particular, may have heart disease earlier than expected, a higher incidence of type II diabetes, and a loss of brain gray matter. High cholesterol and hypertension are not uncommon and are often undiagnosed or misdiagnosed.

Another consideration for the combat veteran is the higher incidence of traumatic brain injury (TBI) sustained from trauma secondary to the explosion of an improvised explosive device (IED). In some cases the TBI may go undiagnosed due to similarities with the symptoms of PTSD or because the patient downplays the symptoms. People with TBI can sustain sensory dysfunction, confusion headaches, memory loss, and general disorientation. Memory loss can include retrograde and anterograde amnesia (before and after the event). Try to eliminate excess noise. Do not touch or do anything to the veteran without an explanation. Interestingly, diesel fumes can be a trigger for combat veterans. Keep your diesel equipment far enough away.

Caring for the Combat Veteran

How do you recognize returning veterans? They often continue to adhere to their military identity with short haircuts, wearing military clothing with combat patches, and often have tattoos. Their homes may have flags, memorials, commendations, and military photos. They may have a military appearance and use military vocabulary. They tend to show respect for authority but may be reluctant to talk to you about PTSD. They may not be aware that they have it, or do not want to be considered “mental.” They might have trouble asking for help. Asking, “How do you want me to help you?” or “What is it you need right now?” are good ways to open the conversation.

The returning combat veteran is a patient who will require a unique level of understanding, compassion, and specialized attention. These patients experience pain that is emotional as well as physical. You will need to take time to establish the history of this patient and listen to his or her concerns. Approach this patient with sensitivity and respect. Be careful how you phrase your questions. “Were you in combat?” is an appropriate question, but, in some cases, veterans may be in denial or do not believe they were in combat. A better question might be, “Were you shot at or under fire?” If you served in combat, you can create trust by letting the patient know. Ask questions about the patient’s service (branch, rank, etc.). You may get enough information out of that conversation to eliminate probing with specific questions.

YOU are the Provider — PART 5

You depart the scene and begin transport to a hospital located 8 miles away. The patient remains conscious and alert but is still withdrawn and sad. You ask him additional questions about his present situation, but he does not answer you; he briefly looks up at you and then looks back down. You reassess his vital signs and then call in your report to the receiving facility.

Recording Time: 30 Minutes	
Level of consciousness	Conscious and alert
Respirations	16 breaths/min; adequate depth
Pulse	72 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	130/80 mm Hg
Spo_2	99% (on room air)

You arrive at the destination hospital and give your verbal report to the charge nurse. After transferring patient care to the hospital staff, you return to service.

8. What factors should you consider before transporting a patient with an emotional crisis?
9. If the patient does not answer your questions, should you continue to encourage him to talk? Why or why not?

Use a calm, firm voice, but be in charge. Respect a veteran's personal space. Limit the number of people involved, or move to a private and quiet space. In some cases, supportive family or friends can be helpful. Ask about suicidal intentions. This might create an opportunity for the patient to reach out. Military veterans are trained to use weapons and are also resourceful in improvising weapons. If you are concerned about suicide, ensure there is nothing the patient can access and use as a weapon.

Physical restraint will not be effective with this population and may only escalate the problem. Even seat belts on the stretcher can aggravate a patient. If it is necessary to calm the patient, especially in the face of safety considerations, chemical restraints administered by ALS should be considered.

Medicolegal Considerations

The medical and legal aspects of emergency medical care become more complicated when the patient is undergoing a behavioral crisis or psychiatric emergency. Nevertheless, legal issues are greatly reduced when an emotionally disturbed patient consents to care. Gaining the patient's confidence is, therefore, a critical task for you.

Mental incapacity can take many forms: unconsciousness (as a result of hypoxia, alcohol, or drugs), temporary but severe stress, and depression. Once you have determined that a patient has impaired mental capacity, you must decide whether he or she requires immediate emergency medical care. A patient in a mentally unstable condition may resist your attempts to provide care. Nevertheless, you must not leave the patient alone. Doing so may result in harm to the patient and expose you to civil action for abandonment or negligence. In such situations, you should request that law enforcement personnel handle the patient. Another reason for seeking law enforcement support is for the patient who resists transport: such a patient often threatens you and others. Violent or dangerous people must be taken into custody by law enforcement before emergency care can be rendered.

Consent

When a patient is not mentally competent to grant consent for emergency medical care, the law assumes that there is implied consent. For example, the consent of an unconscious patient is implied if life or health is at risk. The law refers to this as the emergency doctrine: Consent is implied because of the necessity for immediate emergency treatment. In a situation that is not immediately life threatening, emergency medical care or transportation may be delayed until the proper consent is obtained.

In cases involving psychiatric emergencies, however, the matter is not always clear-cut. Does a life-threatening emergency exist or not? If you are not sure, you should request the assistance of law enforcement personnel. Medical control may also offer guidance.

Limited Legal Authority

As an EMT, you do not have legal authority to require a patient to undergo emergency medical care if the patient is competent and understands the risks and benefits of transport versus refusal. Patients have the right to refuse care. However, most states have legal statutes regarding the emergency care of mentally ill and drug-impaired people. These statutory provisions may permit law enforcement personnel to place the person in protective custody so that emergency care can be given. You should be familiar with your local and state laws regarding these situations.

The typical provision may state that:

> *Any police officer who has reasonable cause to believe that a person is mentally ill and dangerous to himself, herself, or others or gravely disabled ... may take such person into custody and take or cause such person to be taken to a general hospital for emergency examination ...*

The general rule of law is that a competent adult has the right to refuse treatment, even if life-saving care is involved. However, in psychiatric cases, a court of law would probably consider your actions in providing lifesaving care to be appropriate, particularly if you have a reasonable belief that the patient would harm himself, herself, or others without your intervention. If you decide a patient must be transported against his or her will, make sure you have the appropriate resources on scene to avoid unnecessary injury to the patient, you, or your partner. In addition, a patient who is impaired in any way, whether by mental illness, medical condition, or intoxication, may not be considered competent to refuse treatment or transportation. These situations are among the most perilous you will encounter from a legal standpoint. When in doubt, consult with your supervisor, police, or medical control. Always maintain a high index of suspicion regarding your patient's condition—assume the worst and hope for the best. Err on the side of treatment and transport. Carefully document the patient's statements and behavior to support your actions.

Special Populations

As the population ages, you will begin to see more patients older than 65 years. In responding to an increasing number of geriatric patients, you will probably notice some behavioral or psychiatric symptoms, including depression, dementia, and delirium. These changes in mental status can affect your ability to thoroughly assess and treat an ill or injured geriatric patient. Understanding the causes of altered behavior in geriatric patients will help you with patient care.

For example, consider a woman in her 80s who has suffered the loss of her spouse of 40 years and the loss of her parents, siblings, and friends. Her children may live far away. Her only income may be a small pension and social security. More than anything, she wants to stay in the home she shared with her husband. When she has medical concerns she does not call 9-1-1 because she is afraid she will be taken to the hospital and then forced into a care home.

When you visit the home of an older adult, especially one who lives alone, ensure the person is living in a safe and healthy environment. Does he or she have food and medications? Is the home sanitary or overrun with bugs or rodents? Is there hoarding behavior? Is the person's mental status in question? If you have concerns, call adult protective services.

Depression is one of the mental health symptoms that you will see in older adults. Depression has a number of causes. A diagnosis of major illness such as cancer or dementia can lead to depression. Medications can induce a feeling of depression, possibly because of an interaction with other drugs. In addition, changes in the endocrine system such as menopause can cause depression. Depression might also be caused by an imbalance in brain chemicals.

With all the possible causes of depression, an older adult can feel helpless and hopeless. A depressed person may be argumentative or passive. He or she might trivialize complaints, not wanting to be a bother to anyone. Someone who sees no way out of his or her situation may turn to suicide. Be alert for a suicidal gesture or ideation, even though it may not be obvious. As an EMT, your interaction with a depressed older person might prevent a suicide.

Although depression can create a behavioral crisis in geriatric patients, dementia is another cause of abnormal behavior. According to the Alzheimer's Association, more than 5 million people are afflicted with this condition; it is the sixth leading cause of death in the United States. Each year, 500,000 people die from it, and 1 in 3 older adults die from Alzheimer or some other dementia.

Currently, there is no cure for Alzheimer dementia, but there are medications that can slow the progression of the disease. Openly hostile behavior can develop in patients with Alzheimer dementia, including kicking, yelling, pinching, and hitting you, your partner, or the patient's caregiver. You might need to restrain a violent patient, but do so gently and only to the point at which the violent behavior stops.

As with any patient, you want to rule out medical causes for altered behavior, especially those you can treat. Causes of altered behavior include diabetic emergencies, heat- and cold-related illnesses, poisoning and overdose, strokes and transient ischemic attacks, infection, hypoxia, and head injury. Although the mechanism is not understood, urinary tract infection and constipation can alter an older person's behavior.

As the EMT responding to a call for help, you should accept the possibility of depression in a geriatric patient. Do not discount the patient's feelings or devalue his or her emotions. Be alert for a suicidal gesture, and pay attention to any statements about death. To get the patient's cooperation, you can elicit his or her help in providing care for the acute illness or injury. A smile and a touch can go a long way in alleviating fear in all of your patients, especially older patients.

YOU are the Provider — SUMMARY

1. How should you and your partner proceed to this call?

The patient's reported behavior, "acting bizarre," is a very broad description that could indicate any number of conditions. In the interest of your safety, you should assume that the patient is a danger to himself or others. This is not a scene that you should enter without the protection of law enforcement. Never approach a scene of actual or potential violence until law enforcement personnel have arrived and deemed the scene safe for you to enter. In this case, you and your partner should stage a few blocks away from the scene and wait for law enforcement personnel to arrive. Proceed to the scene *only* after they have notified you and given you the "all clear."

2. Other than an underlying psychiatric condition, what other conditions can affect a person's behavior?

A multitude of factors can affect a person's behavior; the presence of an underlying psychiatric condition is only one. Conditions such as hypoxemia, hypoglycemia, metabolic disorders, drug- or alcohol-related issues, stress-related issues, head trauma, and brain tumors (among others) can profoundly affect a person's behavior; these conditions may even cause the patient to become violent.

3. What should be your most immediate concern with this patient?

Personal safety should be your primary concern when caring for *any* patient. This is especially true when caring for patients who are displaying abnormal or bizarre behavior. When caring for a patient who is experiencing a behavioral crisis, you must always consider his or her potential for violence. There are certain behaviors and risk factors that you should look for when assessing a patient's potential for violence: patient history, posture, and verbal and physical activity. Does the patient have a history of hostile, overly aggressive, or violent behavior? Observe the patient's speech. Loud, obscene, erratic, or bizarre speech patterns are clear indicators of emotional distress.

Your patient is sitting on the ground, rocking back and forth; this could indicate a general state of nervousness or increasing agitation.

4. How should you proceed with your assessment of this patient?

The patient has something to say; he states he "has a lot of problems," but also notes that nobody will listen to him. Therefore, use the most important assessment tool you have: listening. Actively listen to what the patient is saying. It may give you clues as to the underlying cause of his behavior; it also reassures him that you *are* listening.

Express sincere interest in what the patient is saying. Let him tell you in his own words what happened or what is going on. Do not interrupt him. Allow him to finish what he is saying before you ask him any questions—just as you would with any other patient.

When you are caring for a patient with a behavioral crisis, you must be prepared to spend extra time with him or her. It often takes longer to assess, listen to, and prepare the patient for transport.

5. What is your field impression of this patient?

The field impression of the patient is based on a number of factors, including physical assessment, medical history, and chief complaint. On the basis of your field impression, you can begin treatment most appropriate for the situation.

Your patient is displaying clear signs of depression. Despite attending counseling sessions, he is unable to cope with the loss of his wife; this has brought him to the point of lacking the desire to even get out of bed in the morning. He no longer feels as though he has a purpose in life. He has experienced emotional distress for a year, and today—the anniversary of his wife's death—has precipitated an acute emotional crisis.

6. What care can you provide to this patient in the field?

Although the patient does not appear to be experiencing any physical problems, clearly, he is emotionally overwhelmed. The fact that your patient is severely depressed places him in a high-risk category for suicide. He should *not* be left alone! Patients who are experiencing a behavioral crisis require a great deal of emotional support and active listening.

7. Should you perform a physical assessment of this patient despite the fact that he requested you do not? Why or why not?

The patient—although severely depressed—still has decision-making capacity. He is conscious and alert, able to answer your questions appropriately, and is not displaying any psychotic behavior (eg, hallucinations, delusions). Therefore, he maintains the legal right to refuse a physical examination; touching him without his consent could lead to allegations of assault and battery against you.

Unless there is an accompanying physical complaint, a detailed physical exam is rarely indicated in a patient with an emotional crisis; in fact, it may be detrimental to your gaining the patient's trust.

8. What factors should you consider before transporting a patient with an emotional crisis?

On arriving at the scene of a patient with an emotional crisis, you must assess him or her for signs of potential violence. These observations should continue throughout the *entire* patient encounter. Even though this patient is calm right now, this could easily change and he could become acutely violent. The worst time for this to happen is in the back of the ambulance, where you will be the only EMT. Do not let your guard down when caring for a patient with an emotional crisis; continuously monitor his or her behavior. Stay attentive at all times.

If you have reason to believe that the patient is at an increased risk for becoming violent, you should have other authorized personnel, such as a police officer or firefighter, ride in the back of the ambulance. If it is necessary to restrain the patient, use just enough force to effectively accomplish the task. Unless it is absolutely necessary to provide patient care, do not release the restraints—regardless of any promises to calm down the patient makes. Never hesitate to call for ALS assistance if available for consideration of use of medications.

9. If the patient does not answer your questions, should you continue to encourage him to talk? Why or why not?

Some patients who are experiencing a behavioral crisis talk excessively, while others talk very little or not at all (as in depression). If the patient wants to talk, you should encourage him or her to do so. Many patients find relief—even if it is only temporary—by simply having someone to talk to. If the patient prefers not to talk, *do not force the issue.*

Depressed patients are typically withdrawn and are not very talkative. Instead of persistently encouraging a patient to talk, you should continue to monitor his or her behavior.

EMS Patient Care Report (PCR)

Date: 11-23-16	**Incident No.:** 012009	**Nature of Call:** Behavioral crisis		**Location:** 517 E. Bandera

Narrative

Medic 1780 dispatched to a residence for a man who is "acting bizarre." Staged at 5th Street and Elm until law enforcement arrived on scene and advised that it was safe to enter. On arriving at the scene, found the patient, a 44-year-old man, sitting on the lawn in front of his house, rocking back and forth. He was conscious and alert; however, he appeared sad and was clearly withdrawn. His airway was patent, and his breathing was adequate. A law enforcement official advised EMS that the patient had been checked for any weapons on his person and that none were found.

Introduced EMS crew to patient and performed primary assessment; no gross abnormalities noted during this examination. The patient advised that today is the anniversary of his wife's death and that he finds it extremely difficult to even get out of bed in the morning. He further advised he feels as though his life has no purpose anymore. According to the patient, he has been to several counseling sessions over the past year, but they have not seemed to help him.

He further said his employer does not seem to care about his problems and has threatened to fire him unless his depressed behavior improves. Patient would only consent to assessment of his vital signs; he would not consent to further assessment or treatment. Visual examination did not reveal any gross injuries or life-threatening conditions, and the patient continued to remain conscious, alert, calm, and oriented and was able to answer questions appropriately.

Because of the patient's significantly depressed state, it was advisable to transport him to the emergency department. Initially, he refused EMS transport; however, after explaining to him that there could be an underlying medical problem contributing to his depression, he consented to transport and vital sign monitoring only; he maintained his refusal of a physical examination. Careful assessment of the patient did not reveal any gross indicators of potential violence. Patient walked to the ambulance on his own accord and was safely secured to the stretcher. Began transport to the hospital and continued to monitor the patient's behavior and vital signs en route. No changes in the patient's status were noted en route, and he remained calm but did not want to talk.

Remainder of transport was uneventful. Delivered patient to ED staff and gave verbal report to charge nurse. After transferring patient care to the hospital staff, Medic 1780 returned to service.**End of report**

Prep Kit

Ready for Review

- A behavioral crisis is any reaction to events that interferes with the activities of daily living or has become unacceptable to the patient, family, or community.
- During a psychiatric emergency, a patient may show agitation or violence or become a threat to himself, herself, or others. This is more serious than the more typical behavioral crisis that causes inappropriate behavior such as interference with activities of daily living or bizarre behavior.
- According to the National Institute of Mental Health, mental disorders are common throughout the United States, affecting tens of millions of people each year. Psychiatric disorders are illnesses with psychologic or behavioral symptoms that may result in impaired functioning.
- Psychiatric disorders have many possible underlying causes including social or situational stress such as divorce or death of a loved one; psychiatric disorders such as schizophrenia; physical illnesses such as diabetic emergencies; chemical problems such as alcohol or drug use; or biologic disturbances such as electrolyte imbalances. Sometimes these conditions can be compounded by noncompliance with prescribed medication regimens.
- As an EMT, you are not responsible for diagnosing the underlying cause of a behavioral crisis or psychiatric emergency.
- Your job is to diffuse and control the situation and safely transport your patient to the hospital. Intervene only as much as it takes to accomplish these tasks. Be caring and careful.
- To the person experiencing a psychiatric emergency, the line between his or her reality and fantasy is blurred.
- The threat of suicide requires immediate intervention. Depression is the most significant risk factor for suicide.
- A patient with PTSD has experienced fear of danger, helplessness during the event, or has had a severe reaction during the event. In PTSD, memories of the trauma linger and continue to be disruptive. It can be made worse with the existence of current mental health issues.
- Patients experiencing delirium are generally not dangerous, but if they exhibit agitated behavior they may strike out irrationally. One of the most important factors to consider in these cases is your personal safety.
- A patient in a mentally unstable condition may resist your attempts to provide care. In such situations, request that law enforcement personnel handle the patient. Another reason for seeking law enforcement support is for a patient who resists treatment; such a patient often threatens you and others. Violent or dangerous people must be taken into custody by the police before emergency care can be rendered.
- Always consult medical control and contact law enforcement personnel for help before restraining a patient. If restraints are required, use the minimum force necessary. Assess the airway and circulation frequently while the patient is restrained.

Vital Vocabulary

activities of daily living The basic activities a person usually accomplishes during a normal day, such as eating, dressing, and bathing.

altered mental status A change in the way a person thinks and behaves that may signal disease in the central nervous system or elsewhere in the body.

behavior How a person functions or acts in response to his or her environment.

behavioral crisis The point at which a person's reactions to events interfere with activities of daily living; this becomes a psychiatric emergency when it causes a major life interruption, such as attempted suicide.

depression A persistent mood of sadness, despair, and discouragement; may be a symptom of many different mental and physical disorders, or it may be a disorder on its own.

excited delirium A serious behavioral condition in which a person exhibits agitated behavior combined with disorientation, hallucinations, or delusions; also called agitated delirium or exhaustive mania.

functional disorder A disorder in which there is no known physiologic reason for the abnormal functioning of an organ or organ system.

organic brain syndrome Temporary or permanent dysfunction of the brain, caused by a disturbance in the physical or physiologic functioning of brain tissue.

positional asphyxia Restriction of chest wall movements and/or airway obstruction; can rapidly lead to sudden death.

posttraumatic stress disorder A delayed stress reaction that develops after a horrifying ordeal that involved physical harm or the threat of physical harm.

psychiatric disorder An illness with psychological or behavioral symptoms and/or impairment in functioning caused by a social, psychological, genetic, physical, chemical, or biologic distur bance.

psychiatric emergency An emergency in which abnormal behavior threatens a person's own health and safety or the health and safety of another person, for example when a person becomes suicidal, homicidal, or has a psychotic episode.

psychosis A mental disorder characterized by the loss of contact with reality.

schizophrenia A complex, difficult-to-identify mental disorder whose onset typically occurs during early adulthood. Symptoms typically become more prominent over time and include delusions, hallucinations, a lack of interest in pleasure, and erratic speech.

Assessment *in Action*

It is July 10th and you are called for a 57-year-old man who is "acting strangely." An ALS fire engine has been called and you have been cleared to enter. Police and several bystanders are present in the area. The man is cowering against a wall in an alley. He is wearing a worn and dirty military uniform and boots that seem out of place in this hot weather. His head is bleeding. The patient watches your approach with skepticism and fear in his eyes.

Police tell you some kids were blowing up post 4th of July fireworks nearby. According to bystanders, the patient started running around and yelling about an IED. He started fighting with police when they encountered him, but they confirmed he doesn't have any weapons. The patient pulled away from them and cowered against the wall.

A woman comes forward to tell you the patient's name is Charlie and he got back from Afghanistan about 6 months ago. He was in the Army but was medically discharged. He was having problems adjusting to civilian life and his wife said he has had frequent angry outbursts. She threw him out of the house a few weeks ago. You ask if she is aware of any medical conditions. She states he takes medications for a few conditions but she isn't sure what.

Charlie allows you to approach but still seems very afraid. You ask him if you can look at the wound on his head and ask him how it happened. He tells you it was from shrapnel from the IED. You ask him if he has any medical problems, takes medication, or has any allergies. He tells you he's allergic to sulfa and has high blood pressure and diabetes, but he has had no medication available. He complains of a headache. You ask him what happened today. He tells you the IED scared him and killed his friend, Nate. You ask him where he is and he tells you, "Afghanistan."

1. Which of the following points given by the neighbor is the most important to your care?

   A. He got back from Afghanistan about 6 months ago.
   B. He was in the Army but was medically discharged.
   C. His wife said he has had constant angry outbursts.
   D. She threw him out of the house a few weeks ago.

2. What is the significant concern in his story about the IED?

   A. His friend died.
   B. It was in Afghanistan.
   C. The IED explosion scared him.
   D. He believes it was an IED rather than fireworks.

3. What is the most likely psychologic condition?

   A. Alzheimer disease
   B. Depression
   C. Posttraumatic stress disorder
   D. Hypertension

4. Which of the following statements may help you provide care for Charlie?

   A. I know how you feel.
   B. I'm sorry about your loss.
   C. Come with me, and let's go to a place where they can help you.
   D. It wasn't an IED, it was just fireworks.

5. Which of the following treatments would be appropriate for Charlie?

   A. Sedative medication
   B. Oxygen by mask
   C. Glucose, if his blood glucose level is low
   D. High blood pressure medication

6. Would it be wise to restrain this patient to the stretcher?

   A. Yes, he is potentially violent.
   B. Yes, it is best to restrain psychiatric patients.
   C. No, restraint is unethical.
   D. No, it may only aggravate the situation.

7. Which of the following statements is true regarding the returning veteran?

   A. A person's altered consciousness can allow him or her to continue functioning under negative conditions.
   B. Guilt, shame, paranoia, and hostility are rare with combat veterans.
   C. Alcohol and/or drug use is a common way to activate the sympathetic nervous system.
   D. Suicide is rare in these patients.

8. What scene safety issues should you consider?

9. What medical issues could be the cause of Charlie’s emergency?
10. What are some techniques you could use when approaching him?

CHAPTER 23

Gynecologic Emergencies

National EMS Education Standard Competencies

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Gynecology

› Recognition and management of shock associated with
- Vaginal bleeding (pp 833, 835–836)

› Anatomy, physiology, assessment findings, and management of
- Vaginal bleeding (pp 829–830, 832–836)
- Sexual assault (to include appropriate emotional support) (pp 837–839)
- Infections (pp 829–837)

Knowledge Objectives

1. Describe the anatomy and physiology of the female reproductive system; include the developmental changes that occur during puberty and menopause. (pp 829–830)
2. Discuss the special, age-related patient management considerations EMTs should provide for both younger and older female patients who are experiencing gynecologic emergencies. (pp 830–831)
3. List three common examples of gynecologic emergencies; include the causes, risk factors, assessment findings, and patient management considerations. (pp 831–832)
4. Explain how an EMT would recognize conditions associated with hemorrhage during pregnancy. (p 832)
5. Discuss the assessment and management of a patient who is experiencing a gynecologic emergency; include a discussion of specific assessment findings. (pp 832–835)
6. Explain the general management of a patient who is experiencing a gynecologic emergency in relation to privacy and communication. (pp 833–835)
7. Give examples of the personal protective equipment EMTs should use when treating patients with gynecologic

emergencies. (p 836)

8. Discuss the special considerations and precautions EMTs must observe when arriving at the scene of a suspected case of sexual assault or rape. (pp 837–838)
9. Discuss the assessment and management of a patient who has been sexually assaulted or raped; include the additional steps EMTs must take on behalf of the patient. (pp 837–839)

Skills Objectives

There are no skills objectives for this chapter.

Introduction

The most obvious difference between men and women is that women are uniquely formed to conceive and give birth. This difference makes women susceptible to a number of conditions that do not occur with men. This chapter examines a few of those conditions. Female anatomy is discussed first, followed by conditions that may be encountered in the prehospital setting. Vaginal bleeding is always an important consideration. Health concerns specific to the very young and the very old are discussed. The principles of managing a woman who has been the victim of sexual assault or rape, as well as recognizing the potential use of date rape drugs, are also discussed.

Anatomy and Physiology

The female reproductive system includes internal and external structures. The external female genitalia consist of the vaginal opening just posterior to the urethral opening **Figure 23-1**. The **labia majora** and **labia minora** are folds of tissue that surround the urethral and vaginal openings. At the anterior end of the labia is the clitoris, and at the posterior end is the anus. The **perineum** is the area of tissue between the vagina and the anus. The labia are extremely vascular and can be injured, but because of their location, they seldom are except in cases of sexual abuse.

In terms of internal structures, the **ovaries** are the primary female reproductive organ **Figure 23-2**. The ovaries are located on each side of the lower abdomen and produce an ovum, or egg, that, if fertilized, will develop into a fetus. The **fallopian tubes** connect each ovary to the uterus. The **uterus** is the muscular organ where the fetus grows during pregnancy. The narrowest portion of the uterus, the **cervix**, opens into the vagina. The **vagina** is the outermost cavity of a woman's reproductive system and forms the lower part of the birth canal.

When a female reaches puberty, she begins to ovulate and experience menstruation. **Ovulation** is the cycle in which the ovum is released. The onset of menstruation is called *menarche* and usually occurs between the ages of 11 and 16 years, although it can occur earlier or later. Any female who has reached menarche is capable of becoming pregnant. Women continue to experience the cycle of ovulation and menstruation until they reach *menopause*, which marks the end of menstrual activity. Women reach menopause at widely varying ages, but it commonly occurs around the age of 50 years.

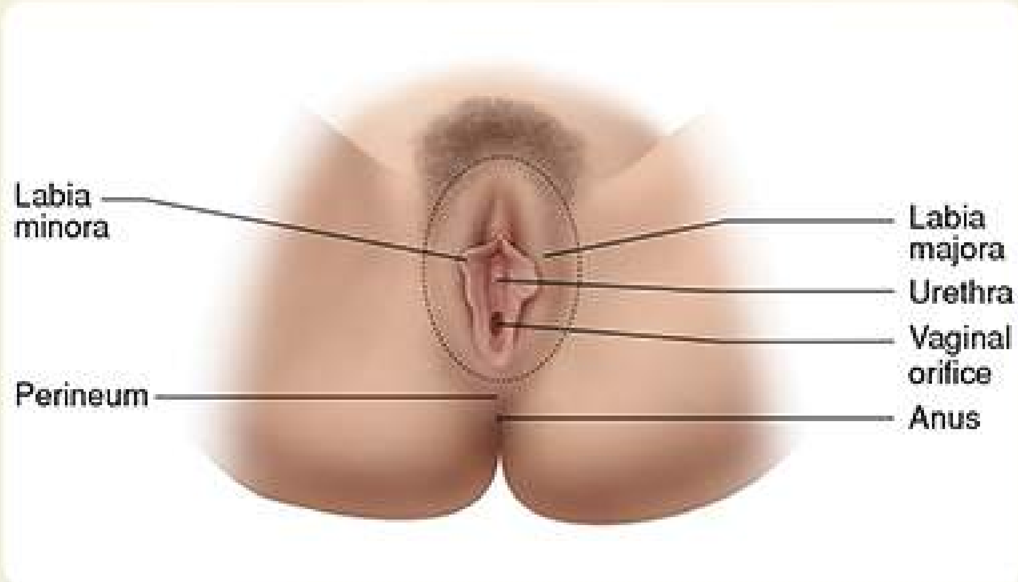

Figure 23-1 The external genitalia of the female reproductive system.

YOU are the Provider — PART 1

At 0555 hours, law enforcement personnel request your assistance at 4300 West Avenue for a young woman who was assaulted. You and your partner respond to the scene, which is located about 4 miles away. While you are en route, an on-scene law enforcement officer radios you over a private channel and informs you the patient has been sexually assaulted and that the scene is safe. The weather is overcast, the temperature is 78°F (26°C), and the traffic is light.

1. What factors should you consider while responding to this call?
2. What are some unique aspects about assessing and treating a woman who has been sexually assaulted?

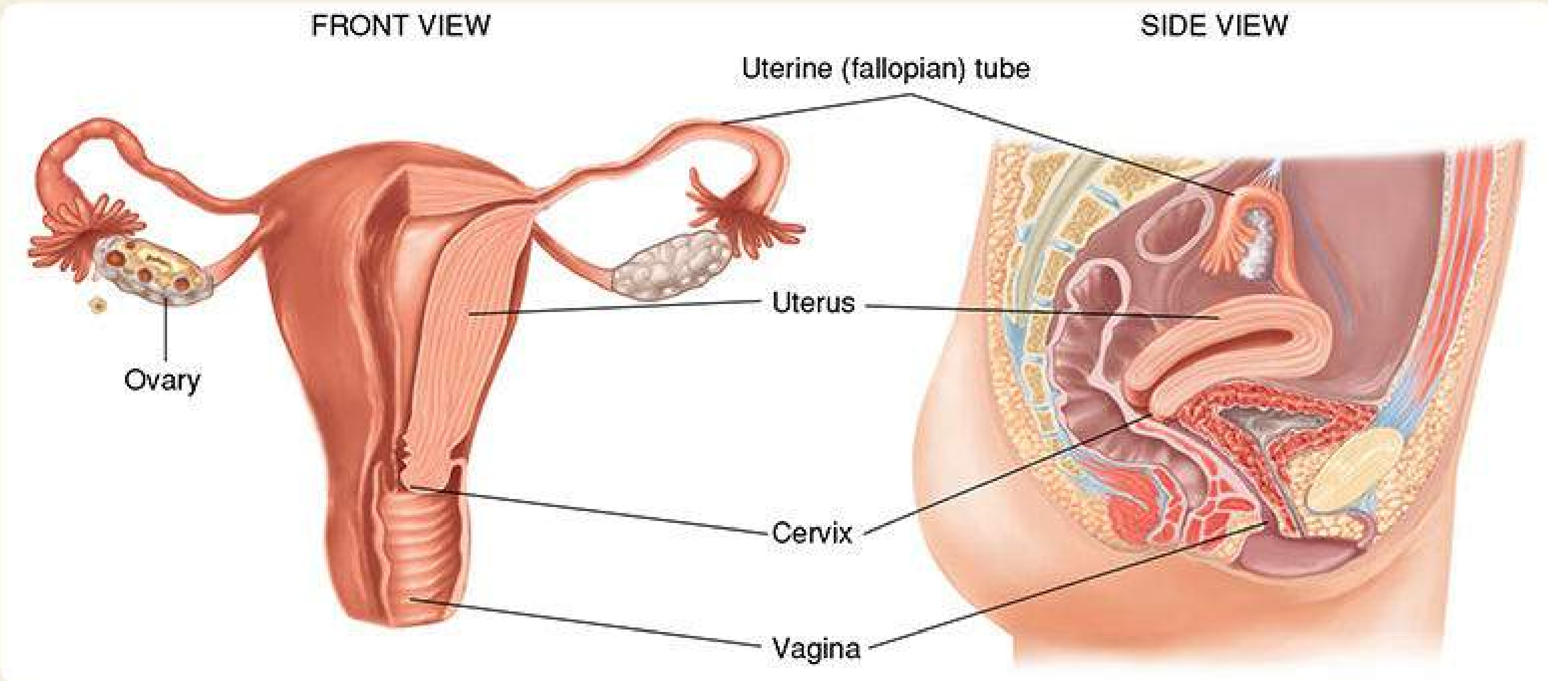

Figure 23-2 Front and side views of the female reproductive system.

Each ovary produces an ovum in alternating months and releases it into the fallopian tube. Some women experience minor cramping pain during ovulation when an ovum is released. The pain is sometimes described as a dull pain on one side of the lower abdomen. For some women the pain is severe enough to keep them bedridden during this time. The quality and severity of the pain vary for each woman.

The process of fertilization begins in the vagina, where sperm from the male penis are deposited in the female reproductive tract. The sperm pass through the cervix into the uterus and eventually up the fallopian tubes. As the ovum moves slowly down the fallopian tube, sperm moving up the tube can surround it, and one sperm fertilizes it. When an ovum is fertilized in the fallopian tube, the developing embryo travels into the uterus where the lining of the walls of the uterus has become engorged with blood in anticipation of receiving a fertilized ovum. Here, the embryo attaches to the uterine wall and continues to grow.

If the ovum is not fertilized in the fallopian tube, it continues to travel into the uterus. Because fertilization has not occurred within about 14 days of ovulation, the lining of the uterus begins to separate and menstruation occurs. The menstrual flow consists of blood from the separated lining of the uterus and lasts about 1 week. Female hormones produced primarily in the ovaries control the process of ovulation and menstruation.

Special Populations

The onset of menarche in girls can be an emotionally and physically disturbing event. It is not uncommon for this event to be preceded by cramping pain that can be misinterpreted by the girl who has not yet experienced menstruation. Most girls have learned about the menstrual process from their parents or from health classes at school, but some are still unprepared when it finally occurs. Girls who have led a very sheltered life or who do not have a female parent in the home are more likely to be surprised by the onset of their menstruation. Parents may also be in denial, insisting that their little girl is too young to be experiencing menstruation.

Approach the patient (and her parents) in the most professional manner possible. Empathize with their concerns, and provide transport to the hospital to help ease the parents' concerns and also to help determine if some other condition is causing or contributing to the situation. Whenever possible, have a female EMT or a female family member accompany the patient.

Pathophysiology

The causes of gynecologic emergencies are varied and range from sexually transmitted diseases to trauma. You should recognize and properly manage female patients with any kind of abdominal or pelvic pain and consider problems that could be potentially life threatening.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an infection of the upper female reproductive organs—specifically, the uterus, ovaries, and fallopian tubes—that occurs almost exclusively in sexually active women. Disease-causing organisms enter the vagina during sexual activity and migrate through the opening of the cervix and into the uterine cavity. The infection may then expand to the fallopian tubes (producing scarring that can increase the risk of life-threatening ectopic pregnancy or sterility), eventually involving the ovaries (leading to the development of a life-threatening abscess). *Ectopic pregnancy* is a pregnancy that develops outside the uterus, most often in the fallopian tube. Although PID itself is seldom a threat to life, it can lead to an ectopic pregnancy or an abscess, which can cause death. The most common presenting sign of PID is generalized lower abdominal pain. Other signs and symptoms include an abnormal and often foul-smelling vaginal discharge, increased pain during sexual intercourse, fever, general malaise, and nausea and vomiting.

Special Populations

Menopause is the end of a woman's menstrual cycle. The process of menopause is a complicated one. As menopause approaches, menstrual periods may become irregular and vary in severity. It is not uncommon for women at this stage to continue to have irregular menstrual periods for several months to a year as the process progresses. It is important to recognize that during this time it is still possible for women to become pregnant. If a woman and her partner no longer use birth control methods because they believe they can no longer become pregnant, they may be in denial when the signs of pregnancy occur. Treat patients with compassion and reassure them, but also transport them for examination by a physician to determine if this or something else (such as a tumor or cyst) is causing the problem.

Sexually Transmitted Diseases

Sexually transmitted diseases can lead to more serious conditions. For example, untreated gonorrhea and chlamydia often progress to PID.

YOU are the Provider — PART 2

You arrive at the scene and find the patient, a 25-year-old woman, sitting on the ground near her car. She is conscious and alert but is crying. Her shirt is torn, and she is nude from the waist down. A police officer covered her with a blanket. After introducing yourself and your partner, you perform a primary assessment.

Recording Time: 0 Minutes	
Appearance	Obvious emotional distress
Level of consciousness	Conscious and alert
Airway	Open; clear of secretions and foreign bodies
Breathing	Normal rate; adequate depth
Circulation	Radial pulses, normal rate and strong; skin is pink, warm, and moist; no obvious bleeding

A police officer informs you the patient was apparently assaulted in her vehicle and the last thing she remembered was talking to a young man she met while listening to music and drinking a margarita with her friends at a local nightclub at about 2100 hours last night.

3. What immediate medical treatment, if any, does this patient require?
4. On the basis of the police officer's report, what should you suspect regarding the events that preceded the patient's assault?

Chlamydia is caused by the bacterium *Chlamydia trachomatis*. According to the Centers for Disease Control and Prevention (CDC), chlamydia is currently the most commonly reported sexually transmitted disease in the United States. Although the symptoms of chlamydia are usually mild or absent, some women may report lower abdominal pain, low back pain, nausea, fever, pain during sexual intercourse, and/or bleeding between menstrual periods. Chlamydial infection of the cervix can spread to the rectum, leading to rectal pain, discharge, or bleeding. If it is left untreated, the disease can progress to PID. In rare cases, chlamydia causes arthritis that may be accompanied by skin lesions and inflammation of the eye and urethra.

Bacterial vaginosis is the most common vaginal infection in women age 15 to 44, according to the CDC. In this infection, normal bacteria in the vagina are replaced by an overgrowth of other bacterial forms. Symptoms may include itching, burning, or pain and may be accompanied by a “fishy,” foul-smelling discharge. Pregnant women with bacterial vaginosis may have premature babies or babies born with low birth weight. If it is left untreated, bacterial vaginosis can lead to more serious infections, or result in PID.

Gonorrhea is caused by *Neisseria gonorrhoeae*, a bacterium that can grow and multiply rapidly in the warm, moist areas of the reproductive tract, including the cervix, uterus, and fallopian tubes in women and in the urethra in women and men. The bacterium can also grow in the mouth, throat, eyes, and anus. Symptoms, which are generally more severe in men than in women, appear approximately 2 to 10 days after exposure. Women may be infected with gonorrhea for months but not have any symptoms, or only mild ones, until the infection has spread to other parts of the reproductive system. When symptoms do appear in women, they generally present as painful urination, with associated burning or itching; a yellowish or bloody vaginal discharge, usually with a foul odor; and blood associated with vaginal sexual intercourse. More severe infections may present with cramping and abdominal pain, nausea and vomiting, and bleeding between menstrual periods; these symptoms indicate that the infection has progressed to PID. Rectal infections generally present with anal discharge and itching and occasional painful bowel movements with fecal blood spotting. Infection of the throat (for which oral sex is the introducing factor) usually results in mild symptoms consisting of painful or difficult swallowing, sore throat, swollen lymph glands, and fever. Headache and nasal congestion may also be present. If the infection is not treated, the bacterium may enter the bloodstream and spread to other parts of the body, including the brain.

Vaginal Bleeding

Because menstrual bleeding occurs monthly in most women, vaginal bleeding that is the result of other causes may initially be overlooked. Some possible causes of vaginal bleeding include abnormal menstruation, vaginal trauma, ectopic pregnancy, spontaneous abortion (miscarriage), cervical polyps, and even cancer. Trauma to the internal female genitalia from any cause other than vaginal penetration is rare because these organs are located deep within the pelvis. Injuries to the vagina and external genitalia are very painful and serious because of the large quantity of nerves and blood vessels in this area. In contrast, internal bleeding from polyps or cancer, while also very serious, may be relatively painless.

Ectopic pregnancy and spontaneous abortion are two conditions that can cause vaginal bleeding in women who do not appear to be pregnant and who may not realize they are pregnant. These potentially life-threatening conditions are covered in Chapter 33, *Obstetrics and Neonatal Care*. All cases of vaginal bleeding should be taken seriously, and the patient should be transported to the hospital for a thorough gynecologic examination.

Patient Assessment

Obtaining an accurate and detailed patient assessment is critically important when dealing with gynecologic issues. You will be able to gain only a primary impression of the problem in the field, yet a thorough patient assessment will help determine just how sick the patient is and whether you should initiate life-saving measures. This is especially true when dealing with abdominal pain.

Women have many of the same conditions that cause abdominal pain in men, for example, ulcers and appendicitis. In addition, there are numerous gynecologic causes of abdominal pain. An old medical axiom states, “Anyone who neglects to consider a gynecologic cause in a woman of childbearing age who reports abdominal pain will miss the diagnosis at least 50% of the time.” Missing the diagnosis may be fatal for the patient.

Scene Size-up

Every emergency call—including calls involving gynecologic emergencies—begins with a thorough scene size-up. Is the scene safe? Will you need assistance? How many patients do you have? What is the nature of illness (NOI)? Have you taken standard precautions? Gynecologic emergencies can be very messy, sometimes involving significant amounts of blood and body fluids contaminated with organisms that can potentially cause communicable diseases.

Where and in what position is the patient found **Figure 23-3** ? If she is at home, what is the condition of the residence? Is it clean or dirty? Do you see evidence of a fight? Is alcohol, tobacco products, or evidence of drug use present? Are there photos of loved ones or is there a noticeable absence of photos? Does the patient live alone or with other people? All of the information you obtain contributes to your assessment of the patient’s overall health and the safety of the scene. In the case of a crime scene, you may also be required to testify in court regarding the conditions on your arrival. Your documentation needs to be accurate and thorough. Involve law enforcement if any type of assault is suspected. In cases of sexual assault, it is important to have a female EMT provide patient care, so consider calling for one early if you and your partner are men.

Often the NOI or mechanism of injury (MOI) in patients with gynecologic emergencies will be understood from the dispatch information, such as in cases of sexual assault. In other patients, the exact nature of the condition will not emerge until you gather patient history information. For example, your patient may present with vague symptoms such as abdominal pain, and you will not be able to determine the exact nature of the problem until you gather more information during the patient history.

Figure 23-3 Note the position of the patient during your assessment.

Primary Assessment

The general impression is an important aspect of all patient assessments. As you approach the patient, you should quickly determine if her condition is stable or unstable. Use this information to help you as you proceed further with the assessment. Use the AVPU scale to determine the patient's level of consciousness.

Always evaluate the airway and breathing immediately to ensure they are adequate, and treat any airway or breathing problem that is identified according to established guidelines and local protocol. Identifying and treating life threats takes precedence over all other assessment and treatment.

It is important to carefully assess the circulation in all patients. Palpate a pulse and evaluate skin color, temperature, and moisture to help identify the patient who might have blood loss. If the patient has experienced significant blood loss because of vaginal bleeding, she may not demonstrate obvious signs of shock but may still be hypovolemic. If the patient has a weak or rapid pulse or has pale, cool, or diaphoretic skin, place the patient in a supine position. Cover the patient to keep her warm, and then transport to the nearest appropriate receiving facility for treatment.

Most cases of gynecologic emergencies are not life threatening; however, if signs of shock exist because of bleeding, then rapid transport is necessary. The remainder of the assessment can be performed en route to the hospital.

History Taking

Begin by asking about the patient's chief complaint, but realize some of the questions you must ask may be considered extremely personal. Be sensitive to the patient's feelings and ensure her privacy and dignity are protected. Gynecologic emergencies can be highly embarrassing for the patient, and many women may be extremely uncomfortable with discussing their sexual history in front of strangers or even close family members. An adolescent girl may want to keep her sexual history from her parents.

For a report of abdominal pain, ask specific questions about onset, duration, quality, and radiation. Provoking or relieving factors and associated symptoms such as syncope, light-headedness, nausea, vomiting, and fever are also relevant. For a report of vaginal bleeding ask about onset, duration, quantity (number of sanitary pads soaked), and associated symptoms such as syncope and light-headedness.

Obtain a SAMPLE history beginning with her current symptoms. Make note of any allergies she has or any over-the-counter or prescription medications she is taking, such as birth control pills and any birth control devices she uses. Ask the patient about medical conditions, and ask specifically about her last menstrual period. This will help determine if the patient is possibly pregnant. Ask about the possibility of sexually transmitted diseases and the possibility of pregnancy. Find out when she last ate or drank and what events led up to her calling for EMS. Use her NOI, her chief complaint, and her answers to your other questions to lead further questioning. For example, if she answers that she is sexually active, ask her about birth control and also about symptoms of pregnancy. If she has vaginal bleeding, ask how many sanitary pads she is using per hour. This information can help create an estimate of blood loss.

Secondary Assessment

The secondary assessment may be performed on scene, en route to the emergency department (ED), or, in some instances, not at all. If the patient is critically ill or injured or the transport time is short, you may not have time to conduct this part of the patient assessment process.

Pertinent secondary assessment findings should include:

- **Vital signs:** blood pressure, pulse, skin color, orthostatic vital signs
- **Abdomen:** distention and tenderness
- **Genitourinary:** visible bleeding
- **Neurologic:** mental status

Your physical examination of a gynecologic patient should be limited and professional. Only examine the genitalia if it is necessary to do so to treat the patient. Protect the woman's privacy during the physical examination. Few women are comfortable with having their body exposed to a crowd of family, neighbors, EMTs, police officers, or firefighters. Limit the personnel present to only those required to perform the necessary tasks; show the patient you respect her by being an advocate for her modesty. You also serve as a role model for other EMS providers when you act this way.

The population of women over the age of 65 is growing and, even though they are past their childbearing years, many will have other gynecologic problems. They may have concerns specific to hormone replacement therapy, have an increased risk of cancer, or could be suffering from internal physical changes in the female organs caused by age, for example pelvic floor prolapse and urinary incontinence. Although these problems cannot be treated in the prehospital environment, perform and record a thorough assessment and treat any of the patient's immediate needs.

YOU are the Provider — PART 3

The patient remains conscious and alert but is still in obvious emotional distress. She gives you consent to take her vital signs. A female police officer is present when you ask the patient if she is injured. She tells you she is experiencing vaginal pain but denies vaginal bleeding. The only obvious injuries you can see are minor abrasions to her forearms.

Recording Time: 8 Minutes	
Respirations	14 breaths/min; adequate depth
Pulse	72 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	110/70 mm Hg
Oxygen saturation (Spo_2)	98% (on room air)

The patient tells you she wants to take a shower and change her clothes. She also tells you she needs to urinate. She asks a police officer to call a friend of hers and ask the friend to come to the scene.

5. What additional assessment should you perform on this patient?

6. How should you respond to the patient's request to take a shower, change her clothes, and use the washroom?

Focus your physical examination on the NOI and the patient's chief complaint. If vaginal bleeding is the NOI, you should visualize the bleeding and ask about its quality and quantity. Use external sanitary pads to control the bleeding, and keep the possibility of hypoperfusion or shock in mind. Always ask if there is pain associated with the vaginal bleeding or discharge. Never insert anything into the vagina to control bleeding, including a tampon.

Vaginal discharge is another condition that should be observed if possible. Make observations about the discharge, and ask the patient about any qualities she noticed and the history of the discharge.

Fever, nausea, and vomiting are common with many medical conditions but should be considered especially significant with gynecologic emergencies. Fever should always be considered a sign of an infectious process. Any report of syncope on the part of the patient, especially if she reports vaginal bleeding, is considered significant. Treat the patient reporting this symptom as being in shock until proven otherwise.

Words of Wisdom

During the assessment, explain to the patient what you are about to do and why. This will help gain her trust and confidence.

Assess the patient's vital signs, including heart rate, rhythm, and quality; respiratory rate, rhythm, and quality; skin color, temperature, and condition; capillary refill time; and blood pressure. Consider obtaining orthostatic vital signs if bleeding is known or suspected. Pay special attention to the presence of tachycardia and hypotension, which could indicate hemorrhagic shock.

Use the appropriate monitoring devices, such as pulse oximetry, to track the patient's condition. Also consider using noninvasive blood pressure monitoring to continuously track the patient's blood pressure. Assess the patient's first blood pressure manually with a sphygmomanometer (blood pressure cuff) and stethoscope. Remember, pulse oximetry readings may not be accurate in the setting of hypovolemia.

Reassessment

Repeat the primary assessment. Reassess the patient's vital signs and the chief complaint. Reassess the patient's vital signs every 5 minutes to identify hypoperfusion from excessive blood loss. If the patient shows signs of shock, begin treatment and rapid transport.

How is the patient's condition improving with the interventions? Identify and treat any changes in the patient's condition. For example, if the patient appears to be losing consciousness, position her in the supine position, and perform a reassessment. Finally, pay specific attention to the needs of your patient, and respect her desire for conversation or silence. Provide her with calm reassurance. Explain to her that the hospital staff will be sympathetic to her condition and will be well qualified to treat her.

There are very few interventions that can or should be done for a patient with a gynecologic emergency. If the patient has vaginal bleeding, treat her for hypoperfusion or shock. Keep her warm, place her in a supine position, and provide her with supplemental oxygen even if she is not experiencing difficulty breathing. Consider advanced life support intercept for fluid replacement, then transport to the nearest appropriate receiving facility.

Notify staff at the receiving hospital of all relevant information, including the possibility of pregnancy, so a proper response can be prepared. Carefully document the patient's condition, her chief complaint, the scene, and all interventions, especially in cases of sexual assault.

Words of Wisdom

Gynecologic emergencies can occur at any age during a woman's lifetime. As an EMT, there is little you can do in this type of emergency; therefore, you should focus on assessing and correcting the patient's ABCs and consider rapid transport as an important part of the call.

Emergency Medical Care

Whenever you care for patients with gynecologic emergencies, you must maintain the patient's privacy as much as possible. If the patient is in a public place, move her to the ambulance. Gain the patient's confidence by communicating appropriately. Have a female EMT participate in the patient's care if possible.

Excessive internal vaginal bleeding can have many causes and can possibly lead to hypoperfusion or shock. Determining the cause of the bleeding should be less important than treating for shock and transporting the patient to an appropriate facility. Use sanitary pads on the external genitalia to absorb the blood. Most women will use sanitary pads before you arrive, so you may continue that approach. Document the number of sanitary pads that were saturated with blood. If the woman has a tampon in place, it is not necessary to have her remove it. Vaginal bleeding is rarely significant enough to cause hemorrhagic shock, but the patient should be treated for shock nevertheless. Apply oxygen, keep the patient supine and warm, and promptly transport to the hospital.

The genitals have a rich nerve supply, making injuries very painful. Treat any external lacerations, abrasions, and tears with sterile compresses, using local pressure to control bleeding and a diaper-type bandage to hold the dressings in place. Leave any foreign bodies in place after stabilizing them with bandages. Under no circumstances should you pack or place dressings inside the vagina. Continue to assess the patient while transporting her to the ED. Contusions and other blunt trauma will require careful in-hospital evaluation.

Words of Wisdom

Gynecologic emergencies may involve significant blood and body fluids. Personal protective equipment (PPE), including gloves, eye protection, and a mask, must be considered.

Assessment and Management of Specific Conditions

Pelvic Inflammatory Disease

A patient with PID will report abdominal pain. The pain generally starts during or after normal menstruation, so inquiring about the date of the patient's last menstrual period is an important detail of the patient's history. The pain may be described as "achy" and may be made worse by walking. Other symptoms may include vaginal discharge, fever and chills, and pain or burning on urination. Patients often present with a distinctive gait that appears as a shuffle when they walk.

Safety Tips

Remember that many sexually transmitted diseases can also be transmitted by contact with blood. Some examples of these diseases include syphilis, many types of hepatitis, and human immunodeficiency virus (HIV).

YOU are the Provider — PART 4

The patient refuses to go to the hospital and tells you all she wants to do is take a shower and change her clothes. Her friend arrives at the scene and asks if she can talk to the patient alone. After a brief conversation, the patient tells you she will go to the hospital, but only if her friend can come with her. You tell her that will be fine. You secure her to the stretcher, reassess her vital signs, and begin transport.

Recording Time: 28 Minutes	
Level of consciousness	Conscious and alert
Respirations	14 breaths/min; adequate depth
Pulse	80 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	118/68 mm Hg

Spo_2	99% (on room air)

7. How should you respond to the patient's refusal to go to the hospital?
8. Whose responsibility is it to determine why the patient was sexually assaulted?

Prehospital treatment is limited, and nonemergency transport is usually recommended. As stated earlier, PID itself is seldom life threatening, but it is serious enough to require transport and evaluation in the hospital.

Sexual Assault and Rape

Unfortunately, **sexual assault** and **rape** are all too common occurrences. According to a government survey, approximately 18% of women (or 1 in 5) in the United States reported being raped during their lifetime, and 1 in every 4 have been sexually abused in some form, often before the age of 12 years. EMTs called to treat a victim of sexual assault, sexual abuse, or actual or alleged rape face many complex issues, ranging from obvious medical ones to serious psychologic and legal issues. You may be the first person the victim has contact with after the encounter, and how you manage the situation from first contact throughout treatment and transport may have a lasting effect for the patient and you. Being professional, respectful, and sensitive is very important.

When performing your assessment, be aware of information suggesting the potential use of date rape or "club" drugs. The patient may or may not be aware of the use of drugs in her assault but an inability to remember the event should create suspicion. Drugs such as Rohypnol (flunitrazepam), known as "roofies"; GHB (gamma-hydroxybutyric acid), known as "Liquid Ecstasy"; Ketalar (ketamine), known as "Special K"; Klonopin (clonazepam); MDMA, known as "Ecstasy"; Xanax (alprazolam); and alcohol are drugs typically used during sexual assault and rape for the intended purpose of incapacitating a person.

These drugs can be put into a person's drink and may go undetected because they often do not have a color, smell, or taste. The effects may be immediate and are made more active with alcohol. The patient may become weak and confused and may even have a loss of consciousness. These drugs cause muscle relaxation and loss of muscle compliance, which may make the victim more compliant during a sexual assault. If these drugs are still in the patient's system during your assessment you may see hypotension, bradycardia, abdominal complaints, difficulty breathing, seizures, coma, and even death.

Because sexual assault and rape are crimes, you can generally expect law enforcement to be involved early in the situation. In many cases, EMS may be called by law enforcement. Police officers generally have basic medical training, since many states require at least basic training at the first responder (emergency medical responder) level. Nevertheless, primary training for police officers focuses on crime investigation, not patient care.

A rape victim has just experienced a major trauma of her body and mind. The last thing she wants to do is give a concise, detailed report of what she has just experienced. If you attempt to gather patient information in this manner it will most likely cause her to "shut down." Whenever possible, a female rape victim should be given the option of being treated by a female EMT, because the patient may be experiencing mixed feelings toward men; these feelings will hinder the patient assessment and the patient's well-being.

The job of law enforcement is to solve the crime, arrest the perpetrator, and see justice served. Your job, as the EMT, is to handle the medical and psychological aspects of the case and to act as the patient advocate. In this capacity, it is important for you to focus on several key components.

The first component is the medical treatment of the patient. Is she physically injured? Are any life-threatening injuries present? Does the patient report any pain?

The second component is your psychologic care of the patient. Do not cross-examine the patient or attempt to obtain information for the benefit of the police. These issues will be handled later by the hospital staff and police. Do not pass judgment on the patient, and protect her from the judgment of others on the scene. A crime may have been committed, and you need to remain aware of that fact. Many women report feeling violated when subjected to interrogation, criticism, or disbelief.

Last, remember that you are at a crime scene. Although your job is to treat the medical aspects of the incident and not to collect evidence, you still have a responsibility to preserve evidence. Do not cut through any clothing or throw away anything from the scene. Place bloodstained clothing and anything else that could be evidence in separate paper (not plastic) bags. Obtain evidence bags from the police if necessary. Paper bags allow wet items to dry naturally, whereas plastic allows mold to grow and may destroy biologic evidence.

It may be necessary to gently discourage the patient from cleaning herself. Victims tend to want to "wash away" the humiliation and embarrassment of the assault. Valuable evidence can be destroyed in this process. Also discourage the patient from urinating, changing clothes, moving her bowels, or rinsing out her mouth. She will be photographed and examined by nurses trained in sexual assault examination and management (sometimes called Sexual Assault Nurse Examiners [SANE nurses]) or law enforcement personnel as well, and the evidence needs to be as accurate as possible. If you cannot discourage the patient from taking these actions, respect her feelings. Some patients may refuse transport altogether, and they have the right to do so. In such cases, follow your system's refusal of treatment policy or procedure for sexual assault victims without judging or talking down to the patient. Your compassion is the best tool you have to gain the patient's confidence and encourage her to get help.

If the patient refuses transport, offer to call the local rape crisis center for her. Many communities have rape crisis centers with victim advocacy hotlines. Having a professional advocate at the scene may help the patient deal with the trauma, and the advocate can better explain in more compassionate detail the necessity of preserving evidence. Many victim advocates are rape-trauma survivors themselves. They can provide support to the patient in the hospital during any additional physical examinations.

Take the patient's history, and limit any physical examination to a brief survey for life-threatening injuries. Treat all other injuries such as contusions or lacerations according to the appropriate procedures and protocols for your EMS system. Follow standard precautions. Expose and examine the vaginal area only if there is evidence of bleeding that needs to be treated. Cover and protect the patient from curious onlookers. Examine and interview the patient with a minimum of people present; move her to the ambulance if necessary.

The patient report is a legal document and, should the case result in an arrest and subsequent trial, may be subpoenaed. Keep the report concise, and record only what the patient stated in her own words. Use quotation marks to indicate you are reporting the patient's version of events. Do not insert your own "opinion" as to whether the patient was sexually assaulted or raped or offer any conclusions that would prove or disprove the patient's account of the event. Focus on the facts. Record all of your observations during the physical examination—the patient's emotional state, the condition of her clothing, obvious injuries, and so forth. Remember that rape is a legal diagnosis, not a medical diagnosis. The medical team can establish only whether sexual intercourse occurred; a court must decide whether sexual intercourse was forcibly inflicted against her will. Table 23-1 lists the treatment principles you should use when dealing with a victim of sexual assault.

Often the most important intervention for sexual assault patients is comforting reassurance and transport to a facility that has employees who are certified to perform the proper physical examination in this type of case. Reminding the patient that she is safe with you and that the hospital staff and the police will take good care of her may help reassure her. Sometimes just the presence of a female EMT can be emotionally helpful. Do not insist the patient talk to you, but listen carefully and do not be judgmental if she does want to talk. Remember that victims of sexual assault also need medical assistance; therefore, treat the medical injuries, but also remember to ensure the patient's privacy and provide her emotional support.

YOU are the Provider — PART 5

You reassess the patient en route to the hospital; her mental status and vital signs indicate that she is stable. Her friend provides emotional support to her and assures her what happened was not her fault. You call your radio report to the receiving facility and give them your estimated time of arrival.

Recording Time: 38 Minutes	
Level of consciousness	Conscious and alert
Respirations	16 breaths/min; adequate depth
Pulse	76 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	122/72 mm Hg
Spo_2	98% (on room air)

9. Why is it important to transport a sexual assault victim to the hospital, even if she does not have any obvious injuries?

Table 23-1 Treatment Principles for Sexual Assault

In addition to the usual treatment principles that apply to all victims, follow these special steps when treating patients who have been sexually assaulted:

1. Document the patient's history, assessment, treatment, and response to treatment in detail because you may have to appear in court as long as 2 to 3 years later. Do not speculate. Record only the facts.
2. Complete the SAMPLE history objectively.
3. Follow any crime scene policy established by your system to protect the scene and any potential evidence for police, particularly policies regarding evidence collection. If the patient will tolerate being wrapped in a sterile burn sheet, this may help investigators find any hair, fluid, or fiber from the alleged offender.
4. Do not examine the genitalia unless there is major bleeding. If an object has been inserted into the vagina or rectum, do not attempt to remove it.
5. Whenever possible, reduce the patient's anxiety by using an EMT who is the same gender as the patient.
6. Discourage the patient from bathing, voiding, or cleaning any wounds until after the hospital staff has completed an assessment. Handle the patient's clothes as little as possible, placing clothing and any other evidence in paper bags. If the patient insists on urinating, ask the patient to do so in a sterile urine container (if available). Also, deposit the toilet paper in a paper bag. Seal and label the bag for law enforcement. This can be critically important evidence.
7. If possible, transport the patient to a hospital with specialized staff such as sexual assault nurse examiners (SANE) who can fully evaluate these patients, perform medical and forensic examinations, and provide all aspects of medical and supportive care for these patients.

YOU are the Provider — SUMMARY

1. What factors should you consider while responding to this call?

As with any call, your first priority should be to ensure the scene is safe for you to enter; this is especially true when you respond to an assault or any other call that has a higher than usual risk for violence. Although an on-scene law enforcement officer has informed you that the scene is safe, you must still remain aware of your surroundings when you arrive. While the scene may initially be safe, it can quickly turn violent.

Your next consideration should be for the patient. Although you should avoid asking specific questions over the radio regarding a sexual assault, you should determine if the patient is conscious and if she appears to have any life-threatening injuries or major bleeding. As with any patient, the more information you obtain while en route to the scene, the better prepared you will be to provide immediate care when you arrive.

Last, you should consider the fact that you are responding to a crime scene. While your job is to treat the *medical* aspects of the incident and not to collect evidence, you still have a responsibility to preserve evidence, to the extent possible, without sacrificing patient care.

2. What are some unique aspects about assessing and treating a woman who has been sexually assaulted?

The medical treatment you provide to a sexual assault victim follows the same principles as with any other patient—identify and treat life-threatening injuries. However, it is important to remember that the emotional effects on the patient are devastating.

When you are called to treat victims of sexual assault, you face many challenges that range from obvious medical concerns to serious psychologic and legal matters. Be professional and sensitive at all times.

You should expect she will not want to talk about the details of what happened. Do not force the victim to talk about her experience if she does not want to talk.

Whenever possible, a female sexual assault victim should be assessed and treated by a female EMT. If this is not an option, ask the patient if there is a female friend that you can call; if there is, she should be present during your assessment and treatment of the patient. Another option is to request a female police officer, if available, to respond to the scene.

3. What immediate medical treatment, if any, does this patient require?

Your primary assessment has not revealed any obvious immediately life-threatening injuries or conditions; therefore, immediate emergency medical treatment is not indicated *at this point*.

The patient is conscious and alert, although she is emotionally distressed. Her airway is patent, and her breathing is adequate. Her radial pulses are strong and a normal rate. There is no obvious bleeding that requires your attention, and her skin is pink, warm, and moist.

4. On the basis of the police officer's report, what should you suspect regarding the events that preceded the patient's assault?

Sexual assault is an acutely overwhelming emotional and dramatic event, and some patients experience amnesia as an involuntary emotional protective reflex. However, this type of amnesia is typically limited to the sexual assault itself, not several hours before the assault occurred. It is now 0555 hours, and the patient has absolutely no recollection of the events that occurred after 2100 hours the night before. You should be suspicious that the patient was unknowingly given a drug by the person who perpetrated this crime; this may have been the young man she met at the nightclub or a random person—man or woman.

5. What additional assessment should you perform on this patient?

As with any patient, the extent of your secondary assessment is based on your suspicion of injuries or conditions that may not have been grossly apparent during the primary assessment. In sexual assault victims, it is unlikely patients will consent to a physical examination of their entire body. Therefore, you should limit any physical examination of the patient to a brief survey for life-threatening injuries.

The patient in this scenario reports vaginal pain but denies vaginal bleeding. The external genitalia should not be exposed and examined—whether the EMT is a man or woman—unless there is evidence of severe bleeding that requires immediate treatment. Asking the patient questions rather than performing a hands-on examination will be enough for your assessment.

6. How should you respond to the patient's request to take a shower, change her clothes, and use the washroom?

It is very common for victims of sexual assault to want to take a shower, change their clothes, rinse their mouth out, or douche. These actions stem from the desire to "wash away" the humiliation and embarrassment of the assault.

However, remember that valuable evidence may be lost if the patient takes any measures to clean up; therefore, you should discourage—*not disallow*—her from doing so. The patient should also be discouraged from urinating or moving her bowels; doing so may destroy any DNA evidence that may remain from vaginal or anal penetration. Make every attempt to explain to the patient that she has potential evidence on or inside of her body that may be used to identify the perpetrator. If, despite your best efforts, you cannot convince the patient not to clean herself, you must respect her feelings and avoid forcing the issue.

7. How should you respond to the patient's refusal to go to the hospital?

In many cases, sexual assault victims will refuse EMS transport, and some of them will refuse *any and all* assessment and treatment. Provided the patient has decision making capacity, she has the legal right to refuse transport.

If the patient refuses EMS transport, do not simply accept the refusal and leave. You must still ensure she is aware of the potential consequences of refusing treatment. She reports vaginal pain; this could indicate a significant internal injury that could be potentially fatal. She *must* be made aware of this fact.

Although the patient in this case does not recall being sexually assaulted, her signs and symptoms (eg, vaginal pain) and the way she presents—torn shirt and nude from the waist down—are clear indicators that she was sexually assaulted. Patients who recall being sexually assaulted often benefit from being removed from the scene where the assault occurred because it keeps them from having to be subjected to the environment where the assault occurred. The best way to do this is to convince her to go to the hospital; doing so will remove her from the scene *and* allow her to be examined by a physician.

8. Whose responsibility is it to determine why the patient was sexually assaulted?

It is law enforcement's responsibility to investigate the incident, arrest the perpetrator, and see justice served. Police officers will want to ask questions pertaining to the incident; however, the prehospital setting is not the appropriate place for this. As an EMT, your role is to address the physical and emotional needs of the patient and to serve as a patient advocate.

9. Why is it important to transport a sexual assault victim to the hospital, even if she does not have any obvious injuries?

Sexual assault victims should be transported to the hospital for several reasons. First, the patient should have a medical examination by a physician to rule out injuries or conditions that were not detected or not present in the field. Injuries such as internal abdominal bleeding can have a delayed onset of symptoms for up to several hours. Furthermore, the patient will need initial and follow-up screening for any sexually transmitted diseases.

Narrative

Medic 86 was requested by law enforcement to respond to a residence for a young woman who was assaulted. While en route to the scene, law enforcement informed that the patient had evidently been sexually assaulted. Arrived on scene and found the patient, a 25-year-old woman, sitting on the ground next to her car with a blanket wrapped around her. She was conscious and alert, although clearly emotionally upset. Her airway was patent, her breathing was adequate, and no obvious bleeding was noted. Prior to EMS arrival, the patient informed law enforcement personnel she did not recall the events that occurred after 2100 the night before, when she was at a nightclub with her friends. She was found with her shirt torn and was nude from the waist down, so law enforcement personnel wrapped her with a blanket before EMS arrival. The patient reports vaginal pain but denies vaginal bleeding. The only obvious injuries noted were several small abrasions to her forearms. The patient would not consent to a secondary assessment or treatment; she would allow only assessment of her vital signs. She denied significant medical history and medication allergies. The patient stated she did not want to go to the hospital, via EMS or any other method of transportation. She further stated she wanted to take a shower and change her clothes. Advised patient this was not recommended because of the possibility of destroying potential evidence; however, she stated she did not care and only wanted to clean herself. Further advised the patient of the need for a physical examination at the hospital because hidden injuries, some of which could be life threatening, could not be ruled out in the prehospital setting. The patient requested law enforcement to summon a friend of hers to the scene. After talking to her friend, she consented only to EMS transport; she further requested her friend accompany her in the back of the ambulance. Began transport to the hospital and monitored the patient en route. She remained conscious and alert, and her vital signs remained stable. Provided emotional support, with the assistance of her friend, until delivery at the emergency department. Delivered patient to hospital and gave verbal report to staff nurse. Medic 86 cleared the hospital and returned to service at 0650.**End of report**

Prep Kit

Ready for Review

- A woman's body is uniquely formed to conceive and give birth. This difference makes women susceptible to a number of conditions that do not occur in men.
- If fertilization of the ovum does not occur within about 14 days of ovulation, the lining of the uterus begins to separate, and menstruation occurs and lasts for about 1 week.
- When a girl reaches puberty, she begins to ovulate and experience menstruation.
- Women continue to experience the cycle of ovulation and menstruation until they reach menopause.
- The causes of gynecologic emergencies are varied and range from sexually transmitted diseases to trauma.
- Pelvic inflammatory disease is an infection of the upper female reproductive organs: the uterus, ovaries, and fallopian tubes. PID can lead to an ectopic pregnancy or an abscess, which can cause death.
- Sexually transmitted diseases can lead to more serious conditions, such as pelvic inflammatory disease.
- Because menstrual bleeding occurs every month in most women, vaginal bleeding that is the result of other causes may initially be overlooked. Some possible causes of vaginal bleeding include abnormal menstruation, vaginal trauma, ectopic pregnancy, spontaneous abortion, cervical polyps, ectopic pregnancy, miscarriage, and even cancer.
- There are very few interventions that can or should be done in the prehospital setting to treat a gynecologic emergency.
- Whenever you deal with patients who have a gynecologic emergency, you must maintain the patients' privacy as much as possible.
- EMTs called to treat a victim of sexual assault, sexual abuse, or actual or alleged rape face many challenges, ranging from obvious medical ones to serious psychologic and legal issues. You may be the victim's first contact after the encounter, and how the situation is managed from first contact throughout treatment and transport may have lasting effects for the patient and you. It is very important to always be professional, sensitive, and kind.

Vital Vocabulary

bacterial vaginosis An overgrowth of bacteria in the vagina; characterized by itching, burning, or pain, and possibly a "fishy" smelling discharge.

cervix The lower third, or neck, of the uterus.

chlamydia A sexually transmitted disease caused by the bacterium *Chlamydia trachomatis*.

fallopian tubes The tubes that connect each ovary with the uterus and are the primary location for fertilization of the ovum.

gonorrhea A sexually transmitted disease caused by *Neisseria gonorrhoeae*.

labia majora Outer fleshy "lips" covered with pubic hair that protect the vagina.

labia minora Inner fleshy "lips" devoid of pubic hair that protect the vagina.

ovaries The primary female reproductive organs that produce an ovum, or egg, that, if fertilized, will develop into a fetus.

ovulation The process in which an ovum is released from a follicle.

pelvic inflammatory disease (PID) An infection of the fallopian tubes and the surrounding tissues of the pelvis.

perineum The area of skin between the vagina and the anus.

rape Sexual intercourse forcibly inflicted on another person, against that person's will.

sexual assault An attack against a person that is sexual in nature, the most common of which is rape.

uterus The muscular organ where the fetus grows, also called the womb; responsible for contractions during labor.

vagina The outermost cavity of a woman's reproductive tract; the lower part of the birth canal.

You respond to the home of a married 27-year-old woman reporting abdominal pain and vaginal bleeding. The bleeding is moderately heavy and she had her regular menstrual period 2 weeks prior. She denies trauma and has a history of miscarriage. She has soaked three sanitary pads in the past 2 hours.

Her airway is patent and she is alert and oriented to person, place, time, and event, although she feels dizzy. She does not have a fever. You ask her to lie supine and obtain her vital signs. Her blood pressure is 104/62 mm Hg; pulse rate, 104 beats/min; and respirations, 16 breaths/min.

She agrees to go to the hospital but fears her husband will be upset because they do not have medical insurance.

1. What is an initial consideration specific to this case?

   A. Ensure the scene is safe.
   B. Don appropriate PPE.
   C. Call for a female EMT.
   D. Confirm police have been called.

2. The primary assessment of the patient should include:

   A. quickly identifying any life-threatening injuries.
   B. an extensive trauma examination.
   C. an extensive medical examination.
   D. an extensive trauma and a medical examination.

3. The husband arrives and is very upset that you are considering transport. What is the best thing you can do?

   A. Call for police backup.

B. Inform him his wife has a potentially life-threatening condition.
C. Ignore him because the patient gave you legal consent.
D. Obtain on-line medical consultation for assistance.

4. What is your primary impression of this patient's emergency?

A. Pelvic inflammatory disease
B. Ectopic pregnancy
C. Sexually transmitted disease
D. Bleeding of unknown origin

5. The patient tells you she feels blood coming from her vaginal area. She gives you permission to look and you observe moderate bleeding from the vagina. What should you do to manage the bleeding?

A. Apply direct pressure using trauma dressings.
B. Pack the vagina with trauma dressings.
C. Ask the patient to insert a tampon.
D. Place a sanitary pad over the vaginal opening.

6. What is your most important treatment option?

A. Low-flow oxygen
B. Psychologic support
C. Transport to the hospital
D. Supine positioning

7. Careful documentation is always important. What information should NOT be included in your patient care report?

A. Patient condition
B. Description of the scene
C. Interventions performed
D. Diagnosis

8. What further assessment or treatment would you perform en route to the hospital?v

A. Distract her from the pain.
B. Administer high-flow oxygen.
C. Reassess vital signs and primary assessment.
D. Start an IV line.

9. Other than trauma, what are some of the causes of vaginal bleeding?

10. What are important parts of an assessment for abdominal pain?

Trauma

CHAPTER
24

Trauma Overview

© Jack Dagley Photography/ShutterStock.

National EMS Education Standard Competencies

Trauma

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

Trauma Overview

Pathophysiology, assessment, and management of the trauma patient
› Trauma scoring (p 869)
› Rapid transport and destination issues (pp 867–869)
› Transport mode (p 867)

Multisystem Trauma

Recognition and management of
› Multisystem trauma (p 864)

Pathophysiology, assessment, and management of
› Multisystem trauma (p 864)
› Blast injuries (pp 862–864)

Knowledge Objectives

1. Define the terms mechanism of injury (MOI), blunt trauma, and penetrating trauma. (pp 847, 850)
2. Explain the relationship of the MOI to potential energy, kinetic energy, and work. (pp 847–849)
3. Provide examples of the MOI that would cause blunt and penetrating trauma to occur. (pp 850–861)
4. Describe the five types of motor vehicle crashes, the injury patterns associated with each one, and how each relates to the index of suspicion of life-threatening injuries. (pp 853–856)
5. Discuss the three specific factors to consider during assessment of a patient who has been injured in a fall, plus additional

considerations for pediatric and geriatric patients. (pp 858–859)
6. Discuss the effects of high-, medium-, and low-velocity penetrating trauma on the body and how an understanding of each type helps EMTs form an index of suspicion about unseen life-threatening injuries. (pp 859–861)
7. Discuss primary, secondary, tertiary, and miscellaneous blast injuries and the anticipated damage each one will cause to the body. (pp 862–864)
8. Describe multisystem trauma and the special considerations that are required for patients who fit this category. (p 864)
9. Explain the major components of trauma patient assessment; include considerations related to whether the method of injury was significant or nonsignificant. (p 865)
10. Discuss the special assessment considerations related to a trauma patient who has injuries in each of the following areas: head, neck and throat, chest, and abdomen. (pp 865–866)
11. Explain a general overview of multisystem trauma patient management. (pp 867, 869)
12. Explain trauma patient management in relation to scene time and transport selection. (p 867)
13. List the Association of Air Medical Services criteria for the appropriate use of emergency air medical services. (p 867)
14. List the American College of Surgeons' Committee on Trauma classification of trauma centers. (pp 867–868)
15. Explain the American College of Surgeon's Committee on Trauma and the Centers for Disease Control and Prevention field triage decision scheme as it relates to making an appropriate destination selection for a trauma patient. (pp 869–870)

Skills Objective

There are no skills objectives for this chapter.

Introduction

According to the National Center for Injury Prevention and Control, traumatic injuries and unintentional injuries are the leading causes of death in the United States among people younger than age 44. Proper prehospital evaluation and care has the ability to reduce a patient's suffering, long-term disability, and death from trauma. As discussed in Chapter 14, *Medical Overview*, patients who need EMS assistance are generally categorized as either a medical or trauma emergency, although one may result from the other or both may exist.

Trauma emergencies occur as a result of physical forces applied to the body. **Medical emergencies** include illnesses or conditions; these are not caused by an outside force. Traumatic injuries may be caused by underlying medical conditions (a patient has a stroke and veers off the road, striking a tree). Similarly, medical illnesses may result from recent or remote traumatic injuries (pneumonia develops in a patient a few days after a fall that fractures the patient's ribs). This chapter introduces the basic physical concepts that dictate how traumatic injuries occur and how they affect the human body. When you understand these concepts, you will be better prepared to size up a vehicular crash scene and assess a patient.

This chapter begins with a basic discussion of energy and trauma. Next, different types of vehicle crashes and their impact on the body are explained. By assessing a vehicle that has crashed, you can often determine what happened to the passengers at the time of impact, which may allow you to predict what injuries the passengers sustained at the time of impact. Evaluation of the mechanism of injury (MOI) for the trauma patient will provide you with an index of suspicion for different types of serious and/or life-threatening underlying injuries. Certain injury patterns occur with certain types of injury events. The **index of suspicion** is your awareness and concern for potentially serious underlying and unseen injuries.

Energy and Trauma

Traumatic injury occurs when the body's tissues are exposed to energy levels beyond their tolerance **Figure 24-1**. The **mechanism of injury (MOI)** is the way in which traumatic injuries occur; it describes the forces (or energy transmission) acting on the body that cause injury. Three concepts of energy are typically associated with injury (not including thermal energy, which causes burns): potential energy, kinetic energy, and the energy of work. When considering the effects of energy on the human body, it is important to remember that energy can be neither created nor destroyed, but can only be converted or transformed. It is not the objective of this section to help you reconstruct the scene of a motor vehicle crash. Rather, you should have a sense of the effects of the event on the human body and understand, in a broad sense, how that event is related to potential and kinetic energy.

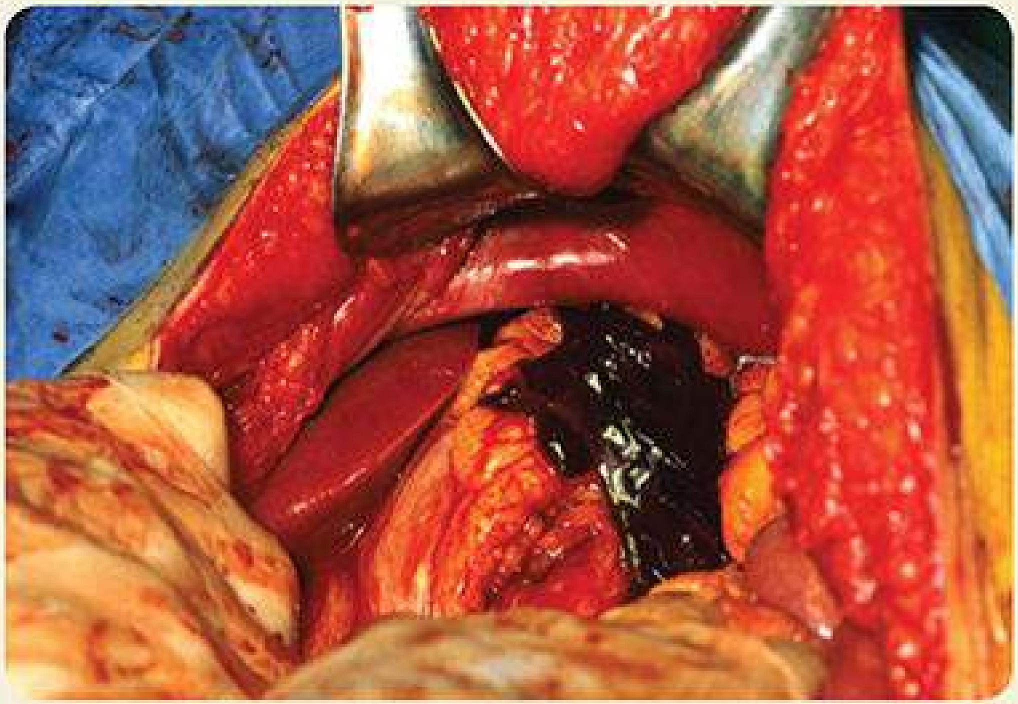

Figure 24-1 Traumatic injury occurs when the body's tissues are exposed to energy levels beyond their tolerance. This photo shows a ruptured spleen.

© M. English, MD/CMSP.

YOU are the Provider PART 1

At 1520 hours, you and your partner are dispatched to a motor vehicle crash, in which a passenger vehicle reportedly struck a tree head-on at an unknown rate of speed. The dispatch operator reports that the patient is still in the vehicle, but it is unknown if the person is trapped. Law enforcement personnel and two engine companies have also been dispatched to the scene. Your response time is 8 minutes, the weather is clear, and the traffic is heavy.

1. On the basis of the information provided by the dispatch operator, can you predict the potential types of injuries the patient may have? If so, how?
2. Why is it important to determine the speed at which a vehicle was traveling at the time of impact?

For example, when assessing a patient who fell, you need not calculate the speed at which the person hit the ground. Instead, focus on the factors of the impact and how those relate to the potential for injury. For example, it is important to estimate the height from which the patient fell, as well as the surface he or she landed on, to fully appreciate the injury potential of the fall.

Work is defined as force acting over a distance. For example, the force needed to bend metal multiplied by the distance over which the metal is bent is the work that crushes the front end of a vehicle that is involved in a frontal impact. Similarly, forces that bend, pull, or compress tissues beyond their inherent limits result in the work that causes injury.

The energy of a moving object is called **kinetic energy**. Kinetic energy reflects the relationship between the mass (weight) of the object and the velocity (speed) at which it is traveling. Kinetic energy is expressed as:

Kinetic energy = ½ mass × velocity^2 or, $KE = \frac{1}{2} m \times v^2$

Remember, energy cannot be created or destroyed, only converted. In the case of a motor vehicle crash, the kinetic energy of the speeding vehicle is converted into the work of stopping the vehicle, usually by crushing the vehicle's exterior **Figure 24-2**. Similarly, the passengers of the vehicle have kinetic energy because they were traveling at the same speed as the vehicle. Their kinetic energy is converted to the work of bringing them to a stop. It is this work on the passengers that results in injury. Notice that, according to the equation for kinetic energy, the energy that is available to cause injury *doubles* when an object's weight doubles but *quadruples* when its speed doubles. When a car's speed increases from 50 to 70 mph, the energy that is available to cause injury doubles. This point is even clearer when considering gunshot wounds. The speed of the bullet (high-velocity compared with low-velocity) has a greater impact on producing injury than the mass (size) of the bullet. This is why it is so important to report to the hospital the type of firearm that was used in a shooting. The amount of kinetic energy that is converted to do work on the body dictates the severity of the injury. High-energy injuries often produce such severe damage that patients require immediate transport to an appropriate facility to have any hope of survival.

Words of Wisdom

Newton's Laws

Newton's First Law

Newton's first law states that objects at rest tend to stay at rest and objects in motion tend to stay in motion unless acted on by some force. The first part of the law is fairly clear. An object such as an empty soda can will not move spontaneously unless some force, such as a gust of wind, acts on it. An example will help to illustrate the second part. In a car going 30 mph, the passengers and the car are moving at 30 mph. The passengers do not feel as though they are moving because they are not moving relative to the car. However, when the car strikes a concrete barrier and comes to a sudden stop, the passengers continue to travel at 30 mph. They stay in motion until they are acted on by an external force—most likely the windshield, steering wheel, or dashboard. To appreciate the severity of the impact, think of the driver as sitting motionless while a steering wheel rams into his or her chest at 30 mph. Now consider that the same thing happens to the driver's internal organs. They also are in motion, traveling at 30 mph relative to the ground, until they are acted on by an external force, in this case the sternum, rib cage, or other body structure. This scenario illustrates the three collisions that are associated with blunt trauma.

Newton's Second Law

Newton's second law states that force (F) equals mass (M) times acceleration (A), that is, $F = M \times A$, in which acceleration is the change in velocity (speed) that occurs over time. Therefore, it is not so much that "speed kills" but that the change in velocity with respect to time generates the forces that cause injury. Simply put, it is not the fall, but the sudden stop at the bottom, that causes the injury.

In the example of the car traveling at 30 mph, it takes about 3 seconds for the car to decrease its speed from 30 mph to 0 mph when the driver applies the brakes smoothly. If he or she is properly restrained by well-adjusted seat belts, the driver slows, or decelerates, at the same rate as the car. But if the car is stopped not by braking but by hitting a large tree and the driver is not restrained, his or her body will continue to stay in motion at 30 mph until it is stopped by an external force, in this case, the steering wheel. Although the change in the body's velocity is the same as when the car was braking smoothly in 3 seconds (30 to 0 mph), that change now takes place in about 0.01 second. Because the period of deceleration is 300 times less, the average force of impact is 300 times greater. This means that the force is approximately 150 times the force of gravity. Imagine a force 150 times your body weight slamming into your chest.

Now consider the same car striking the same tree, but this time, the driver is restrained with a shoulder and lap belt. The driver is essentially tied to the car and stops during the same period the car stops. It takes some time, although brief, to crush the front of the car and bring it to a halt. The car comes to a stop in approximately 0.05 second. The change in the driver's velocity is the same (30 to 0 mph), but the longer period of deceleration results in a g force of 30 times that of gravity (one g force is the normal acceleration due to gravity). This is still a substantial force, but it is much less than the force experienced by the unrestrained driver. More to the point, it is survivable.

In a final example, the car and driver, as before, are traveling at 30 mph, and the driver is properly restrained with a three-point seat belt. In this case, however, the car is also equipped with an air bag. When the car hits the tree and suddenly stops, the driver's upper body initially continues forward at 30 mph. The body is partially slowed by the lap and shoulder belts but is finally brought to rest by the air bag. The upper body compresses the air bag, which stops the body's forward motion in about 0.1 second. Thus, the air bag stretches the duration of impact by 0.05 second, buying the body even more time, and the force on the upper body drops to approximately 15 times that of gravity.

The air bag has another advantage. The force of its impact is applied over a much larger area than the area affected by the steering wheel or the shoulder belt, shrinking the force per unit area. This point can be illustrated by an analogy. A person standing on one toe on a sheet of ice applies a concentrated load in a very small area, thus breaking the ice and falling through. If the person lies flat on the ice, he or she greatly expands the contact area and reduces the stress on the ice, which, depending on conditions, should not break. The dual action of the air bag (distributing the force of impact over a greater area and increasing the duration of impact) results in less severe injuries.

Newton's Third Law

Newton's third law states that for every action, there is an equal and opposite reaction. Therefore, if you push on a door, the door pushes back (reacts) with an equal force but in the opposite direction. In the case of a dented A-pillar, the force of the driver's head was sufficient to dent the strong metal. But in terms of patient assessment, the more important point is the reaction force of the pillar on the head. Newton's third law states that the two forces are equal but occur in opposite directions. In other words, the head was essentially hit by an A-pillar traveling at 30 mph. Similarly, it takes a substantial force to collapse a steering wheel. When you notice a collapsed steering wheel during scene size-up, suspect serious chest injuries even if the driver initially has no visible signs of chest injury. Often, reading the scene and understanding the basic principles of energy transfer will give you as clear a picture of the patient's potential injuries and injury severity as the actual physical patient assessment.

Figure 24-2 The kinetic energy of a speeding car is converted into the work of stopping the car, usually by crushing the car's exterior and damaging the point of impact.

Courtesy of Mark Woolcock.

Words of Wisdom

Constantly and consistently reevaluate the MOI to rule out the possibility that the patient has a more significant injury than initially suspected or identified during the initial phases of care provided at the scene.

Potential energy is the product of mass (weight), force of gravity, and height and is mostly associated with the energy of falling objects. A worker on a scaffold has potential energy because he or she is some height above the ground. If the worker falls, potential energy is converted into kinetic energy. As the worker hits the ground, the kinetic energy is converted into work, that is, the work of bringing the body to a stop and thereby fracturing bones and damaging tissues.

Mechanism of Injury Profiles

Different types of MOIs will produce many types of injuries. Examples of nonsignificant injuries include injury to an isolated body part or a fall without the loss of consciousness. Examples of significant MOIs include injury to more than one body system (**multisystem trauma**), falls from heights, motor vehicle and motorcycle crashes, car versus pedestrian (or bicycle or motorcycle), gunshot wounds, and stabbings. Whether one body system or more than one system is involved, maintain a high index of suspicion for serious unseen injuries.

Blunt and Penetrating Trauma

Traumatic injuries can be considered in two categories: blunt trauma and penetrating trauma. **Blunt trauma** is the result of force (or energy transmission) to the body that causes injury without anything penetrating the soft tissues or internal organs and cavities. **Penetrating trauma** results in injury by objects that pierce and penetrate the surface of the body and injure the underlying soft tissues, internal organs, and body cavities. Either type of trauma may occur from a variety of MOIs. It is important to consider unseen as well as visible, obvious injuries with either type of trauma. Damage to the underlying deeper tissues is often more significant.

Words of Wisdom

According to the Centers for Disease Control and Prevention (CDC), in the United States, nearly 180,000 people die from violence and injuries each year. That means one person dies as a result of trauma almost every 3 minutes.

Blunt Trauma

Blunt trauma results from an object making contact with the body. Any object, for example a baseball bat, can cause blunt trauma if it is moving fast enough. Motor vehicle crashes and falls are two of the most common MOIs for blunt trauma. When providing care for your patient, be alert to signs of skin discoloration or reports of pain because these may be the only signs of blunt trauma. During assessment, maintain a high index of suspicion for hidden (internal) injuries in patients with blunt trauma.

Vehicular Crashes

Motor vehicle crashes are classified traditionally as frontal (head-on), rear-end, lateral (T-bone), rollovers, and rotational (spins). The principal difference among these crash types is the direction of the force of impact; also, with spins and rollovers, there is the possibility of multiple impacts. Motor vehicle crashes typically consist of a series of three collisions. Understanding the events that occur during each one of these three collisions will help you be alert for certain types of injury patterns.

Words of Wisdom

Even though today’s cars are designed and built to crumple upon impact, in the presence of vehicle damage, you should maintain a high index of suspicion that the patient’s MOI was substantial.

The three collisions in a typical impact are as follows:

1. The collision of the car against another car, a tree, or some other object. Damage to the car is perhaps the most dramatic part of the collision, but it does not directly affect patient care, except possibly to make extrication difficult **Figure 24-3**. However, it does provide information about the severity of the collision and, therefore, has an indirect effect on patient care. The greater the damage to the car, the greater the energy that was involved and, therefore, the greater the potential to cause injury to the patient. By assessing the vehicle that has crashed, you can often determine

the MOI, which may allow you to predict what injuries may have happened to the passengers at the time of impact according to forces that acted on their bodies. When you arrive at the crash scene and perform your scene size-up, quickly inspect the severity of damage to the vehicle(s). If there is significant damage to a vehicle, your index of suspicion for the presence of life-threatening injuries should automatically increase. A great amount of force is required to crush and deform a vehicle, cause intrusion into the passenger compartment, tear seats from their mountings, and collapse steering wheels. Such damage suggests the presence of high-energy trauma.

Figure 24-3 The first collision in a typical impact is that of the vehicle against another object (in this case, a utility pole). The appearance of the vehicle can provide you with critical information about the severity of the crash. The greater the damage to the vehicle, the greater the energy that was involved.

© Jack Dagley Photography/ShutterStock.

2. The collision of the passenger against the interior of the car. Just as the kinetic energy produced by the vehicle's mass and velocity is converted into the work of bringing the vehicle to a stop, the kinetic energy produced by the passenger's mass and velocity is converted into the work of stopping his or her body **Figure 24-4**. Just like the obvious damage to the exterior of the car, the injuries that result are often dramatic and usually immediately apparent during your scene size-up or primary assessment. Common passenger injuries include lower extremity fractures (knees into the dashboard), rib fractures (rib cage into the steering wheel), and head trauma (head into the windshield). Such injuries occur more frequently if the passenger is not restrained. But even when the passenger is restrained with a properly adjusted seat belt, injuries can occur, especially in lateral and rollover impacts.
3. The collision of the passenger's internal organs against the solid structures of the body. The injuries that occur during the third collision may not be as obvious as external injuries, but they are often the most life threatening. For example, as the passenger's head hits the windshield, the brain continues to move forward until it comes to rest by striking the inside of the skull. This results in a compression injury (or bruising) to the anterior portion of the brain and stretching (or tearing) of the posterior portion of the brain **Figure 24-5**. This is an example of a **coup-contrecoup brain injury** **Figure 24-6**. Similarly, in the thoracic cage, the heart may slam into the sternum, which may rupture the aorta and cause fatal bleeding.

Figure 24-4 The second collision in a typical impact is that of the passenger against the interior of the car. The appearance of the interior of the car can provide you with information about the severity of the patient's injuries.

Courtesy of Rhonda Hunt.

Understanding the relationship among the three collisions will help you make the connections between the amount of damage to the exterior of the vehicle and potential injury to the passenger. For example, in a high-speed crash that results in massive damage to the vehicle, you should suspect serious injuries to the passengers, even if the injuries are not readily apparent. A number of potential physical problems may develop as a result of traumatic injuries. Your initial general impression of the patient and evaluation of the MOI can help direct lifesaving care and provide critical information to the hospital staff. Therefore, if you see a contusion on the patient's forehead and the windshield is starred and pushed out, you should strongly suspect an injury to the brain. After you inform medical control about the damage to the windshield, hospital staff can prepare for the patient by being ready to perform a CT scan of the brain. Without your input, the physician might have found the brain injury anyway, but it might not have been detected until the brain had swollen sufficiently to cause clinical signs of the injury. Whenever there is a significant impact to the head, also suspect a spinal injury and take cervical spine precautions if indicated.

Figure 24-5 The discolored spots show injuries (contusions) in this brain.

Figure 24-6 The third collision in a typical impact is that of the passenger's internal organs against the solid structures of the body. A coup-contracoup injury occurs when the brain continues its forward motion and strikes the inside of the skull, resulting in a compression injury to the anterior portion of the brain and stretching of the posterior portion.

Words of Wisdom

When you are assessing trauma incidents, the MOI is a crucial element of history taking. Be alert to the extent of damage to the interior and exterior of the vehicles involved in crashes. Use this observation to paint a picture of the scene in written and verbal communication.

The amount of damage considered significant varies, depending on the type of crash, but any substantial deformity of the vehicle should be enough cause for you to consider transporting the patient to a trauma center. Significant mechanisms of injury are suggested by the following findings:

- Death of an occupant in the vehicle
- Severe deformity of the vehicle or intrusion into the vehicle
  - Severe deformities of the frontal part of the vehicle, with or without intrusion into the passenger compartment
  - Moderate intrusions from a lateral (T-bone) type of accident
  - Severe damage from the rear
  - Crashes in which rotation is involved (rollover and spins)
- Ejection from the vehicle

Damage to the vehicle that was involved and information obtained during the scene size-up are not the only clues you can use to determine crash severity. Clearly, if one or more of the passengers are dead, you should suspect that the other passengers have sustained serious injuries, even if the injuries are not obvious. Therefore, focus on treating life-threatening injuries and providing rapid transport to a trauma center, because these passengers have likely experienced the same amount of force that caused the death of the others. Digital photos of the crash scene may provide valuable information to the staff and treating physicians at the trauma center; however, photos should never be shared over social media. Photos containing patient images or other identifiable patient information may become part of the medical record or may need to be deleted after review by the receiving health care providers, depending on policies.

Words of Wisdom

Items in the passenger compartment (including unrestrained passengers) can become flying objects during a crash and have the potential to cause injury to the patient, resulting in injury patterns that do not match the expected MOI.

Frontal Crashes

Understanding the MOI after a frontal crash first involves evaluation of the supplemental restraint system, including seat belts and air bags. Determine whether the passenger was restrained by a full and properly applied three-point restraint. Also determine whether the air bag was deployed. Identifying the types of restraints used and whether air bags were deployed will help you identify injury patterns related to the supplemental restraint systems.

When properly applied, seat belts are successful in restraining the passengers in a vehicle and preventing a second collision inside the motor vehicle. According to the CDC, between the years 1975 and 2008 seat-belt use saved an estimated 255,000 lives. Seat belts may also decrease the severity of the third collision, that of the passenger's organs with the chest or abdominal wall. The protective abilities of seat belts are further enhanced by deployment of the air bags. Air bags provide the final capture point of the passengers and decrease the severity of **deceleration** injuries by allowing seat belts to be more compliant and by gently cushioning the occupant as the body slows, or decelerates.

Remember that air bags decrease injury to the chest, face, and head very effectively. However, you should still suspect that other serious injuries to the extremities (resulting from the second collision) and to internal organs (resulting from the third collision) have occurred. Most new motor vehicles are manufactured with air bag safety systems. These safety devices enhance the safety and survival of forward-facing occupants inside the vehicle during a crash. In an emergency braking event, or crash, the air bag inflates very quickly. Because a rear-facing car seat is in proximity to the dashboard, rapid inflation of the air bag could cause serious injury or death to an infant. All children who are shorter than 4 feet 9 inches (145 cm) should ride in the rear seat or, in the case of a pickup truck or other single-seated vehicle, the air bag should be turned off.

When providing care to an occupant inside a motor vehicle, it is important to remember that if the air bag did not inflate during the accident, it may deploy during extrication. If this occurs, you may be seriously injured. Extreme caution must be used when extricating a patient in a vehicle with an air bag that has not deployed.

YOU are the Provider — PART 2

When you arrive at the scene, fire and law enforcement personnel are already present. An air transport helicopter has been placed on standby. The front of the vehicle has been crushed all the way up to the windshield. The driver, a young man, was unrestrained and is still in the driver's seat; he appears to be unconscious and his face is covered with blood. As your partner accesses the patient from the backseat and manually stabilizes his head, you perform a primary assessment.

Recording Time: 0 Minutes	
Appearance	Bleeding from the head, face, and mouth; pale skin; labored breathing
Level of consciousness	Responsive only to pain
Airway	Blood in the nasopharynx and oropharynx
Breathing	Rapid and labored
Circulation	Radial pulses, weak and rapid; skin is cool, pale, and clammy

Despite the severity of exterior damage to the vehicle, the patient is not entrapped and there is no interior intrusion into the passenger compartment. You suction the patient's mouth, apply a cervical collar, and prepare to rapidly extricate him from the vehicle. Responders from one of the engine companies have prepared a backboard, straps, and a lateral head immobilizer.

3. Where will you most likely find damage to the vehicle's interior based on the patient's signs and symptoms?

Supplemental restraint systems can also cause harm whether they are used properly or improperly. For example, some older vehicle models have seat belts that buckle automatically at the shoulder but require the passengers to buckle the lap portion; these can cause the occupant to travel down and under the shoulder strap as the body continues forward, resulting in the lower body striking the dashboard. This movement of the body can cause the lower extremities and the pelvis to crash into the dashboard because that part of the body is unrestrained. Seat belts may also cause unseen abdominal injuries, particularly in pediatric patients. Seat belts are designed to be worn over the iliac crests of the pelvis to distribute the force over the bony surface. Hip dislocations may result if seat belts are worn too low. Internal injuries can occur when the belt is worn too high, resulting in damage to abdominal organs **Figure 24-7**. Lumbar spine fractures are also possible, particularly in children and older patients.

When passengers are riding in vehicles equipped with air bags but are not restrained by seat belts, they are often thrown forward in the act of emergency braking. As a result, they come into contact with the air bag and/or the doors at the time of deployment. This MOI is also responsible for some severe injuries to children who are riding unrestrained in the front seats of vehicles, unrestrained passengers, and those sitting too close to the air bag. Today's motor vehicles often have multiple air bags and side curtains. These are designed to protect the occupants of the vehicle, but can also alter injury patterns. Certain areas of a vehicle's body may have air bags that will deploy when impacted. Pushing on or using extrication tools in those areas may cause air bags to unexpectedly deploy. This can happen even after the car battery has been disengaged.

In addition, some passengers may pass out before impact, and you may find them lying against the deployed air bag. When you encounter these types of situations, look for abrasions and/or traction-type injuries on the face, lower part of the neck, and chest **Figure 24-8**.

Contact points are often obvious as you perform a simple quick evaluation of the interior of the vehicle. If there is no intrusion into the passenger compartment, you might see that an unrestrained front-seat passenger in a frontal crash has come into contact with the dashboard or the instrument panel at the knees, thus transferring loads from the knees through the femur to the pelvis and hip joint **Figure 24-9A**. The chest and/or abdomen may also hit the steering wheel **Figure 24-9B**. In addition, the passenger's face often hits the steering wheel, or the passenger may launch forward and up, hitting the windshield and/or the roof header in the area of the visors **Figure 24-9C**. Signs of most of these injuries can be found by inspecting the interior of the vehicle during extrication of the patient.

Figure 24-7 Injuries can result if the seat belt is worn too high or too low across the waist. Although less common, they can also result from seat belts worn in the correct position across the torso.

Courtesy of ED, Royal North Shore Hospital/NSW Institute of Trauma & Injury.

Figure 24-8 Air bags can cause injury in frontal crashes, specifically, abrasions, contusions, and traction-type injuries to the face, neck, chest, and inner arms.

Figure 24-9 Mechanism of injury and condition of the vehicle interior suggest likely areas of injury. **A.** The knees can strike the dashboard, resulting in a hip fracture or dislocation. **B.** Serious chest and abdominal injuries can result from striking the steering wheel. **C.** Head and spinal injuries can result when the face and head strike the windshield.

Rear-End Crashes

Rear-end impacts are known to cause whiplash injuries, particularly when the passenger's head and/ or neck is not restrained by an appropriately placed headrest **Figure 24-10**. On impact, the passenger's body and torso move forward. As the body is propelled forward, the head and neck are left behind because the head is relatively heavy, and they appear to be whipped back relative to the torso. As the vehicle comes to rest, the unrestrained passenger moves forward, striking the dashboard. In this type of crash, the cervical spine and surrounding area may be injured. The cervical spine is less tolerant of damage when it is bent back. Headrests decrease extension of the head and neck during a crash and, therefore, help reduce injury. Other parts of the spine and the pelvis may also be at risk for injury. In addition, the patient may sustain an acceleration injury to the brain, that is, the third collision of the brain within the skull. Passengers in the backseat wearing only a lap belt might have a higher incidence of injuries to the thoracic and lumbar spine.

Lateral Crashes

Lateral or side impacts (commonly called T-bone crashes) are a very common cause of death associated with motor vehicle crashes. When a vehicle is struck from the side, it is typically struck above its center of gravity and begins to rock away from the side of the impact. This results in the passenger sustaining a lateral whiplash injury **Figure 24-11**. The movement is to the side, and the passenger's shoulders and head whip toward the intruding vehicle. This action may thrust the shoulder, thorax, and upper extremities, and, more important, the skull against the doorpost or the window. The cervical spine has little tolerance for lateral bending.

Figure 24-10 Rear-end impacts often cause whiplash injuries, particularly when the head and/ or neck is not restrained by a headrest.

© Crystalcraig/Dreamstime.com.

Figure 24-11 In a lateral crash, the car is typically struck above its center of gravity and begins to rock away from the side of impact. This causes a type of lateral whiplash in which the passenger's shoulders and head whip toward the intruding vehicle.

If there is substantial intrusion into the passenger compartment, suspect your patient to have lateral chest and abdomen injuries on the side of the impact, as well as possible fractures of the lower extremities, pelvis, and ribs. In addition, the organs within the abdomen are at risk because of a possible third collision. According to the Journal of Safety Research, lateral crashes cause approximately 25% of all severe injuries to the aorta and approximately 30% of all fatalities that occur in motor vehicle crashes.

Rollover Crashes

Certain vehicles, such as large trucks and some sport utility vehicles, are more prone to rollover crashes because of their high center of gravity. Injury patterns that are commonly associated with rollover crashes differ, depending on whether the passenger was restrained or unrestrained. The most unpredictable types of injuries are caused by rollover crashes in which an unrestrained passenger may have sustained multiple strikes within the interior of the vehicle as it rolled one or more times. The most common life-threatening event in a rollover is ejection or partial ejection of the passenger from the vehicle **Figure 24-12**. Passengers who have been ejected may have struck the interior of the vehicle many times before ejection. The passenger may also have struck several objects, such as trees, a guardrail, or the vehicle's exterior, before landing. Passengers who have been partially ejected may have struck both the interior and exterior of the vehicle and may have been sandwiched between the exterior of the vehicle and the environment as the vehicle rolled. Ejection and partial ejection are significant mechanisms of injury; in these cases, prepare to care for life-threatening injuries.

Figure 24-12 Passengers who have been ejected or partially ejected may have struck the interior of the car many times before ejection.

Even when restrained, passengers can sustain severe injuries during a rollover crash, although the patterns of injury tend to be more predictable, and when the restraint system is properly used, ejection from the vehicle is prevented. A passenger on the outboard side of a vehicle that rolls over is at high risk for injury because of the centrifugal force (the patient is pinned against the door of the vehicle). Rollover crashes can also cause injury when the roof of the vehicle hits the ground during the rollover; a passenger who is restrained can still move far enough toward the roof to make contact and sustain a spinal cord injury. Therefore, rollover crashes are dangerous for both restrained and, to a greater degree, unrestrained passengers because these crashes provide multiple opportunities for second and third collisions.

Rotational Crashes

Rotational crashes (spins) are conceptually similar to rollovers. The rotation of the vehicle as it spins provides opportunities for the vehicle to strike objects such as utility poles. For example, as a vehicle spins and strikes a pole, the passengers experience not only the rotational motion, but also a lateral impact.

Car Versus Pedestrian

Car-versus-pedestrian crashes often result in patients who have graphic and apparent injuries, such as broken bones; however, this type of crash can cause serious unseen injuries to underlying body systems. Therefore, you must maintain a high index of suspicion for unseen injuries. A thorough evaluation of the MOI is critical. First, estimate the speed of the vehicle that struck the patient; next, determine whether the patient was ejected, what surface the patient landed on, and at what distance or whether the patient was struck and pulled under the vehicle. Evaluate the vehicle that struck the patient for structural damage that might indicate contact points with the patient and alert you to potential injuries. Multisystem injuries are common after this type of event. Summon advanced life support (ALS) backup for any patients who have or are thought to have sustained a significant MOI.

Car Versus Bicycle

In a car-versus-bicycle crash, evaluate the MOI in much the same manner as car-versus-pedestrian crashes. However, additional evaluation of damage to and the position of the bicycle is warranted. If the patient was wearing a helmet, inspect the helmet for damage and suspect potential injury to the head **Figure 24-13**. Presume that the patient has sustained an injury to the spinal column, or spinal cord, until proven otherwise at the hospital. Initiate and maintain spinal immobilization during the encounter. When practical, roll the patient on to his or her side to allow for an appropriate assessment of the posterior side of the body.

Figure 24-13 If the patient's bike helmet is damaged, suspect head and spine injuries.

Car Versus Motorcycle

In a motorcycle crash, any structural protection afforded to the victim is not derived from a steel cage, as is the case in an automobile, but from protective devices worn by the rider, that is, helmet, leather or abrasion-resistant clothing, and boots. While helmets are designed to protect against impact forces to the head, they do not protect from cervical injury. Patients who have experienced a motorcycle crash should undergo cervical spine assessment and have cervical collars placed if indicated. Leather and synthetic gear worn over the body was initially designed to protect professional riders in competition, where falls tend to be controlled and result in long sliding mechanisms on hard surfaces rather than multiple collisions against road objects and other vehicles. Leather clothing will protect mostly against road abrasion but offers no protection against blunt trauma from secondary impacts. In a street crash, collisions usually occur against other larger vehicles or stationary objects.

When assessing the scene of a motorcycle crash, look for deformity of the motorcycle, the side of most damage, the distance of skid in the road, the deformity of stationary objects or other vehicles, and the extent and location of deformity in the helmet. These findings can be helpful in estimating the extent of trauma in a patient.

Words of Wisdom

If possible bring the helmet to the hospital for the trauma staff to see. This will provide them with critical information as to the type and extent of potential head injury.

There are four types of motorcycle impacts.

- **Head-on crash:** The motorcycle strikes another object and stops its forward motion while the rider and parts of the motorcycle that are broken off continue their forward motion until stopped by an outside force, such as drag from the road or another opposing force from a secondary collision.
- **Angular crash:** The motorcycle strikes an object or another vehicle at an angle so that the rider sustains direct crushing injuries to the lower extremity between the object and the motorcycle. This usually results in severe open and comminuted lower extremity injuries with severe neurovascular compromise, often requiring surgical amputation.
- **Ejection:** The rider will travel at high speed until stopped by a stationary object, another vehicle, or by road drag. Severe abrasion injuries (road rash) down to bone can occur with drag. An unpredictable combination of blunt injuries can occur from secondary collisions.
- **Controlled crash:** A technique used to separate the rider from the body of the motorcycle and the object to be hit is referred to as laying the bike down. It was developed by motorcycle racers and adapted by street bikers as a means of achieving a controlled crash. As a crash approaches, the motorcycle is turned flat and tipped sideways at 90 degrees to the direction of travel so that one leg is dropped to the grass or asphalt. This slows the occupant faster than the motorcycle, allowing the rider to become separated from the motorcycle. If properly protected with leather or synthetic abrasion-resistant gear, injuries should be limited to those sustained by rolling over the pavement and any secondary collision that may occur. When executed properly, this maneuver prevents the rider from being trapped between the bike and the object. However, a rider unable to clear the bike will continue into the vehicle, often with devastating results.

Falls

The injury potential of a fall is related to the height from which the patient fell. Falls are common MOIs for blunt trauma. The greater the height of the fall, the greater the potential for injury. A fall from more than 20 feet (6 m) is considered significant. The patient lands on the surface just as an unrestrained passenger smashes into the interior of a vehicle. The internal organs travel at the speed of the patient's body before it hits the ground and stop by smashing into the interior of the body. Again, as in a motor vehicle crash, it is these internal injuries that are the least obvious during assessment but pose the gravest threat to life. Therefore, suspect internal injuries in a patient who has fallen from a significant height, just as you would in a patient who has been in a high-speed motor vehicle crash. Always consider syncope or other underlying medical causes of the fall.

Patients who fall and land on their feet may have less severe internal injuries because their legs may have absorbed much of the energy of the fall Figure 24-14. However, as a result, they may have very serious injuries to the lower extremities and pelvic and spinal injuries from energy that the legs did not absorb. Patients who fall onto their heads, as in diving accidents, will likely have serious head and/or spinal injuries. In either case, a fall from a significant height is a serious event with great injury potential, and the patient should be evaluated thoroughly. Take the following factors into account:

Special Populations

When your patient is a child, the following constitute a significant MOI:

1. Falls of greater than 10 feet (3 m) (or 2 to 3 times the height of the child)
2. Medium- to high-speed vehicle crash (>25 mph)

Also note that young children are top-heavy, so they tend to land on their heads even from short falls. Triage children to a pediatric trauma center if possible.

Figure 24-14 When a patient falls and lands on his or her feet, the energy is transmitted to the spine, sometimes producing a spinal injury in addition to injuries to the legs and pelvis.

- The height of the fall
- The type of surface struck
- The part of the body that hit first, followed by the path of energy displacement

Many falls, especially those sustained by older patients, are not the result of high-energy trauma, even though broken bones may result. Older patients often have osteoporosis, a condition in which the musculoskeletal system can fail under relatively low stress because the bones are structurally weakened. Because of this condition, an older patient can sustain a fracture as a result of a fall from a standing position. These cases do not constitute true high-energy trauma unless the patient fell from a significant height.

Penetrating Trauma

Penetrating trauma is the second leading cause of trauma death in the United States after blunt trauma. In 2011, the CDC reported just over 32,000 deaths from firearms, which is just under the number of deaths related to motor vehicles. Low-energy penetrating trauma may be caused accidentally by impalement or intentionally by a knife, ice pick, or other weapon **Figure 24-15**. Many times it is difficult to determine entrance and exit wounds from **projectiles** in a prehospital setting. First determine the number of penetrating injuries and then combine that information with the important things you already know about the potential pathway of penetrating projectiles to form an index of suspicion about unseen life-threatening injuries. With low-energy penetrations, injuries are caused by the sharp edges of the object moving through the body and are, therefore, close to the object's path. Weapons such as knives, however, may have been deliberately moved around internally, causing more damage than the external wound might suggest. Try to determine the length of the penetrating object.

Special Populations

Many older patients are seriously injured from falls. Completely assess older patients for all possible injuries, even from low-impact falls.

In medium- and high-velocity (speed) penetrating trauma, the path of the projectile (usually a bullet) may not be as easy to predict. This is because the bullet may flatten out, tumble, or even ricochet within the body before exiting. The path the projectile takes is referred to as a **trajectory**. Fragmentation, especially frangible bullets that are designed to disintegrate into tiny particles on impact, will increase damage as multiple fragments increase the likelihood of multiple organs/ vessels sustaining injury. Full metal jacket bullets cause less damage than fragmented rounds because of their tendency to pass through the body's tissues. The bullet's speed is another factor in the resulting injury pattern; there is often additional damage caused by the object moving inside the body, but not along the suspected pathway. This phenomenon, called **cavitation**, which results from the rapid changes in tissue and fluid pressure that occur with the passage of the projectile, can result in serious injury to internal organs distant to the actual path of the bullet **Figure 24-16**. Consequences of cavitation can be temporary or permanent. Temporary cavitation injury results from a stretching of the tissues that occurs with the pressure changes. Permanent cavitation injury results closer to the bullet path where the pressure fluctuations are greatest and remains after the projectile has passed through the tissue. Remain alert during assessment because patients will exhibit various signs and symptoms depending on the organ(s) affected.

YOU are the Provider — PART 3

The patient is removed from the vehicle onto the backboard, and you perform a quick secondary assessment. Your partner applies high-flow oxygen via a nonrebreathing mask while one of the EMTs from one of the engine companies obtains the patient's vital signs.

Recording Time: 5 Minutes	
Respirations	22 breaths/min; labored
Pulse	120 beats/min; weak radial pulses
Skin	Cool, clammy, and pale
Blood pressure	84/64 mm Hg
Oxygen saturation (Spo_2)	97% (with supplemental oxygen)

The patient's level of consciousness is still markedly decreased; he only responds to pain. He has a large hematoma and laceration to his forehead, which is covered with a sterile dressing. He also has crepitus and bruising to his chest. A Level I trauma center is 30 miles away, but there is a Level III trauma center only 15 miles away.

4. Should the patient be transported to the Level I trauma center or the Level III trauma center? Why?
5. What other transport factors should you consider with this patient?

Words of Wisdom

Do not waste time trying to determine whether a penetrating wound is an entrance or exit wound; this can be difficult. Instead, focus on finding all of the wounds and providing appropriate care.

Figure 24-15 Injuries from low-energy penetrations, such as a stab wound, are caused by the sharp edges of the object moving through the body.
Andrew Pollak, MD. Used with permission.

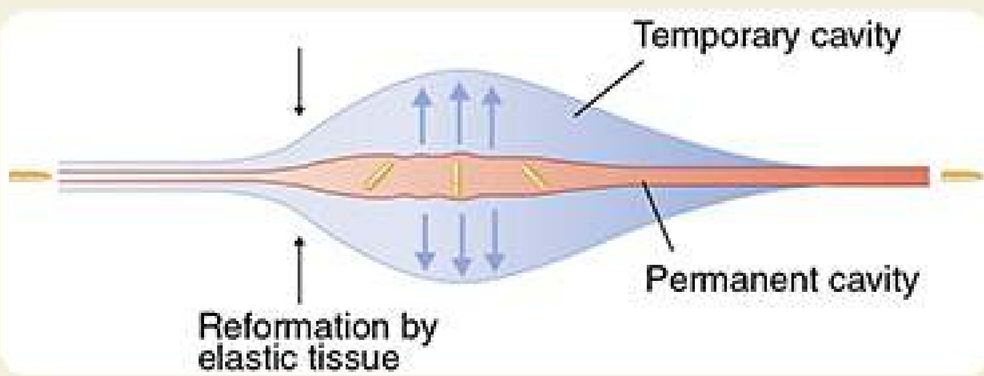

Figure 24-16 There are two types of injury caused by cavitation—temporary and permanent.
© Jones & Bartlett Learning.

Figure 24-17 The area damaged by high-velocity projectiles, such as bullets, can be many times larger than the diameter of the projectile itself.

© D. Willoughby/Custom Medical Stock Photo.

The relationship between distance and the severity of injury varies depending on the type of weapon involved, such as a rifle, pistol, or shotgun. Air resistance, often referred to as **drag**, slows the projectile, decreasing the depth of penetration and energy of the projectile and thus reducing damage to the tissues. Much like a boat moving through water, the bullet disrupts not only the tissues that are directly in its path but also those in its wake. Therefore, the area that is damaged by medium- and high-velocity projectiles is typically many times larger than the diameter of the projectile itself **Figure 24-17**. This is one reason that exit wounds are often many times larger than entrance wounds. As with motor vehicle crashes, the energy available for a bullet to cause damage is more a function of its speed than its mass (weight). If the mass of the bullet is doubled, the energy that is available to cause injury is doubled. If the velocity of the bullet is doubled, the energy that is available to cause injury is quadrupled. For this reason, it is important for you to try to determine the type of weapon that was used. Although it is not necessary (or always possible) for you to distinguish between medium- and high-velocity injuries, any information regarding the type of weapon that was used should be relayed to medical control. Medium-velocity injuries may be caused by handguns and some rifles, whereas high-velocity injuries may be caused by a military weapon. Police at the scene may be a useful source of information regarding the caliber of weapon. The majority of civilian gunshot wound injuries in the United States are the result of low-velocity weapons.

Table 24-1 summarizes how to recognize developing problems in trauma patients.

Table 24-1 Recognizing Developing Problems in Trauma Patients

Mechanism of Injury	Signs and Symptoms	Index of Suspicion
Blunt or penetrating trauma to the neck	▪ Noisy or labored breathing ▪ Increased respiratory rate ▪ Swelling of the face or neck ▪ Altered gag reflex ▪ Decreasing/low Glasgow Coma Scale (GCS); <9 is severe ▪ Decreasing/low Spo_2 ▪ Rapid, weak pulse ▪ Decreasing/low blood pressure	▪ Significant bleeding or foreign bodies in the upper or lower airway, causing obstruction ▪ Be alert for airway compromise
Significant chest wall blunt trauma from motor vehicle crashes, car-versus-pedestrian, and other crashes; penetrating trauma to the chest wall	▪ Significant chest pain ▪ Shortness of breath ▪ Increased respiratory rate ▪ Asymmetric chest wall movement ▪ Subcutaneous emphysema ▪ Decreasing GCS (<9 is severe) ▪ Decreasing/low Spo_2 ▪ Presence of jugular vein distention ▪ Rapid, weak pulse ▪ Decreasing/low blood pressure ▪ Loss of peripheral pulses during inspiration ▪ Narrowing pulse pressures	▪ Cardiac or pulmonary contusion ▪ Pneumothorax (accumulation of air or gas in the pleural cavity) or hemothorax (accumulation of blood in the pleural cavity) ▪ Broken ribs, causing respiratory compromise
Any significant blunt force trauma from motor vehicle crashes or penetrating injury	▪ Blunt or penetrating trauma to the neck, chest, abdomen, or groin ▪ Blows to the head sustained during motor vehicle crashes, falls, or other incidents, producing loss of consciousness, altered mental status, inability to recall events, combativeness, or changes in speech patterns ▪ Difficulty moving extremities; headache, especially with nausea and vomiting ▪ Decreasing GCS (<9 is severe) ▪ Decreasing/low Spo_2 ▪ Rapid, weak pulse ▪ Decreasing/low blood pressure or increasing blood pressure with slow pulse	▪ Injuries in these regions may tear and cause damage to the large blood vessels located in these body areas, resulting in significant internal and external bleeding ▪ Be alert to the possibility of bruising to the brain and bleeding in and around the brain tissue, which may cause the development of excess pressure inside the skull around the brain
Any significant blunt force trauma, falls from a significant height, or penetrating trauma	▪ Severe back and/or neck pain, history of difficulty moving extremities, loss of sensation or tingling in the extremities ▪ Decreasing GCS (<9 is severe) ▪ Rapid, weak pulse or slow pulse	▪ Injury to the bones of the spinal column or to the spinal cord

Blast Injuries

Although most commonly associated with military conflict, blast injuries are also seen in civilian practice in mines, shipyards, chemical plants, and, increasingly, in association with terrorist activities. As with any explosion there is a risk of contamination of patients from environmental contaminants, toxic chemicals, or dirty bombs. People who are injured in explosions may be injured by any of four different mechanisms Figure 24-18.

- **Primary blast injuries.** These injuries are due entirely to the blast itself; that is, damage to the body is caused by the pressure wave generated by the explosion. When the victim is close to the blast, the blast wave may cause disruption of major blood vessels and rupture of eardrums and major organs, including the lungs. Hollow organs are the most susceptible to the pressure wave. In some cases, pressure wave injuries can amputate limbs.

- **Secondary blast injuries.** Damage to the body results from being struck by flying debris, such as shrapnel from the device or from glass or splinters, which have been set in motion by the explosion. Objects are propelled by the force of the blast wave and strike the victim, causing injury. These objects can travel great distances and be propelled at tremendous speeds, up to nearly 3,000 mph for conventional military explosives.
- **Tertiary blast injuries.** These injuries occur when the patient is hurled by the force of the explosion against a stationary object. A blast wind (sudden change in the surrounding atmosphere) creates a pressure wave. This can cause the patient's body to be hurled or thrown, resulting in further injury. This physical displacement of the body is also referred to as ground shock when the body impacts the ground.
- **Quaternary blast injuries.** This category of miscellaneous injuries includes burns from hot gases or fires started by the blast; respiratory injury from inhaling toxic gases; suffocation; poisoning; medical emergencies incurred as a result of the explosion; crush injuries from the collapse of buildings; contamination of wounds from environmental, chemical, or toxic substances; and mental health emergencies.

Most patients who survive an explosion will have some combination of the four types of injuries mentioned. The discussion here will be confined to primary blast injuries because these injuries are the ones that are most easily overlooked.

Tissues at Risk

Organs that contain air, such as the middle ear, lung, and gastrointestinal tract, are most susceptible to pressure changes. The junction between tissues of different densities and exposed areas such as head and neck tissues are prone to injury as well. The ear is the organ system that is most sensitive to blast injuries. The **tympanic membrane** evolved to detect minor changes in pressure and will rupture at pressures of 5 to 7 pounds per square inch above atmospheric pressure. Thus, the tympanic membranes are a sensitive indicator that you can use to help determine the possible presence of other blast injuries. The patient may report ringing in the ears, pain in the ears, or some loss of hearing, and blood may be visible in the ear canal. Dislocation of structural components of the ear, such as the ossicles conforming the inner ear, may occur. Permanent hearing loss is possible. These findings can be used to assist in triaging patients as they indicate risk of pressure injuries to the lungs.

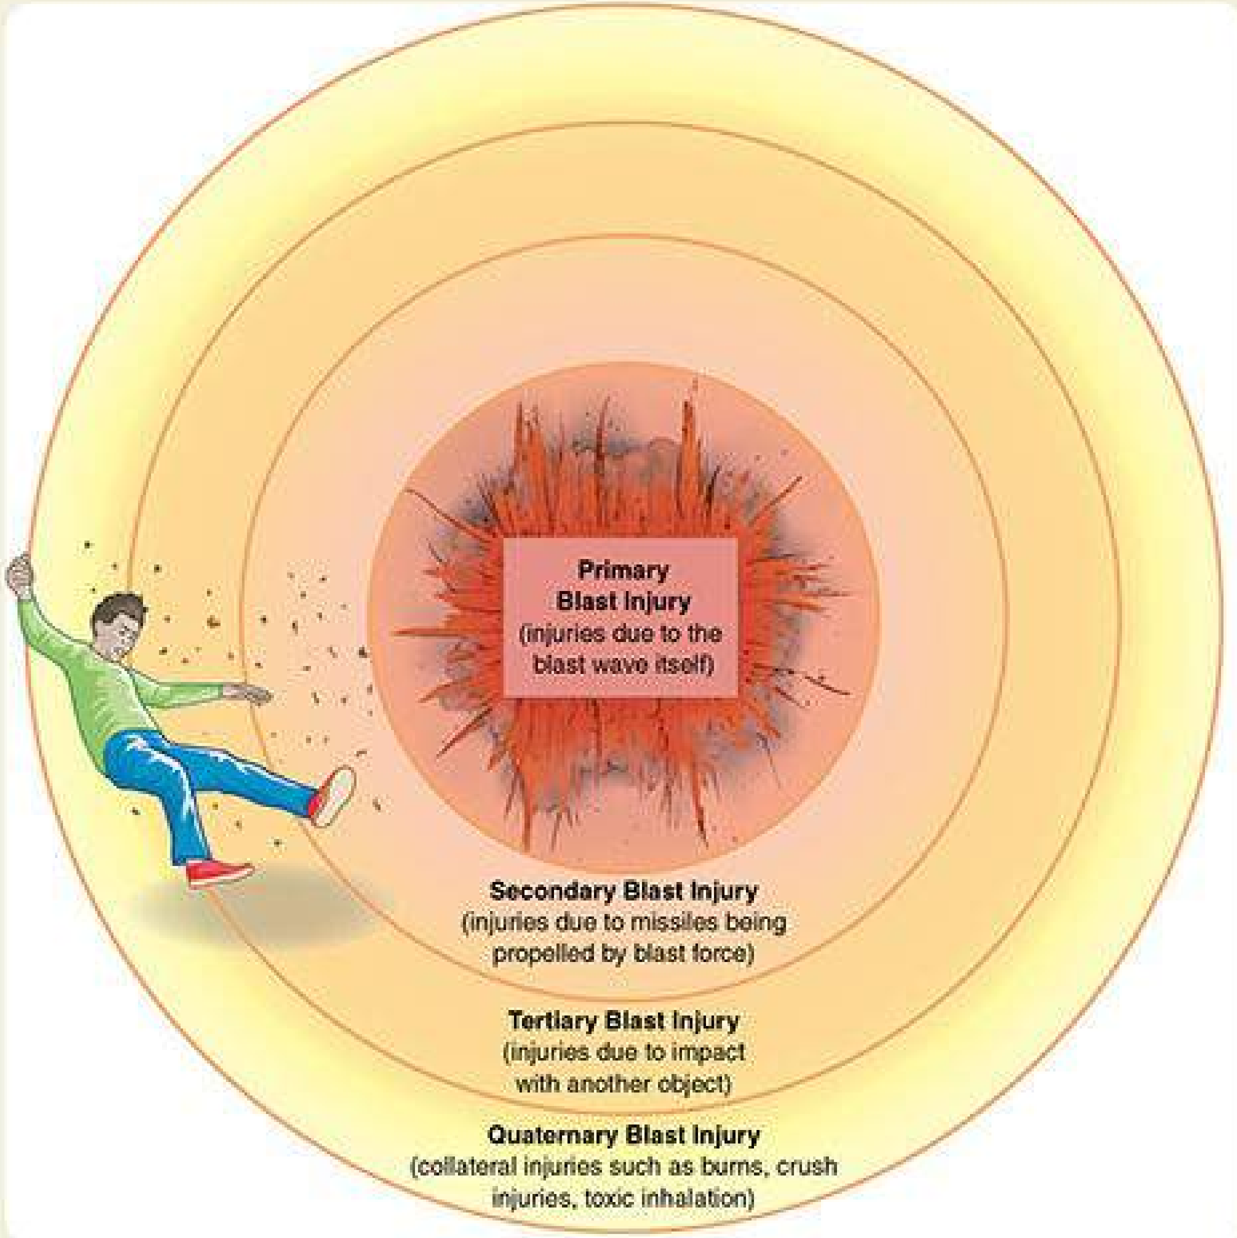

Figure 24-18 The mechanisms of blast injuries.

Pulmonary blast injuries are defined as pulmonary trauma (consisting of contusions and hemorrhages) that results from short-range exposure to the detonation of explosives. When the explosion occurs in an open space, both lungs are usually injured. Primary blast injury is often characterized by a lack of external visible injuries and thus can go unrecognized. The patient may report tightness or pain in the chest and may cough up blood and have tachypnea or other signs of respiratory distress. Subcutaneous emphysema (crackling under the skin) can be detected over the chest through the use of palpation, indicating air in the thorax. Pneumothorax is a common injury and may require emergency decompression (which is covered in Chapter 29, *Chest Injuries*) in the field for your patient to survive. Pulmonary edema may ensue rapidly. If there is any reason to suspect lung injury in a blast victim (even just the presence of a ruptured eardrum), administer oxygen. Avoid giving oxygen under positive pressure, however (that is, by demand valve), because that may simply increase the damage to the lung. Be cautious as well with intravenous fluids, which may be poorly tolerated in patients with this type of lung injury and result in pulmonary edema.

One of the most concerning pulmonary blast injuries is **arterial air embolism**, which occurs on alveolar disruption with subsequent air embolization into the pulmonary vasculature. Even small air bubbles can enter a coronary artery and cause myocardial injury. Air embolisms to the cerebrovascular system can produce disturbances in vision, changes in behavior, changes in state of consciousness, and a variety of other neurologic signs.

Solid organs are relatively protected from shock wave injury but may be injured by secondary missiles or a hurled body. Hollow organs, however, may be injured by the same mechanisms that damage lung tissue. Petechiae, or pinpoint reddish-purple hemorrhages that show up on the skin, to large hematomas may be found. Perforation or rupture of the bowel and colon is a risk. Underwater explosions result in the most severe abdominal injuries.

Neurologic injuries and head trauma are the most common causes of death from blast injuries. Subarachnoid (beneath the arachnoid layer covering the brain) and subdural (beneath the outermost covering of the brain) hematomas are often seen. Permanent or transient neurologic deficits may be secondary to concussion, intracerebral bleeding, or air embolism. Instant but transient unconsciousness, with or without retrograde amnesia, may be initiated not only by head trauma, but also by cardiovascular problems. Bradycardia and hypotension are common after an intense pressure wave from an explosion.

YOU are the Provider — PART 4

The decision is made to transport the patient by air based on his injuries and the news of heavy traffic causing a lengthy delay in transporting him to the Level I trauma center. After full spinal immobilization is employed, the patient is loaded into the ambulance and immediately reassessed.

Recording Time: 10 Minutes	
Level of consciousness	Responds only to pain
Respirations	30 breaths/min; extremely labored
Pulse	130 beats/min; absent radial pulses
Skin	Cool, clammy, and pale
Blood pressure	80/50 mm Hg
Spo_2	89% (supplemental oxygen)

Your partner begins assisting the patient's ventilations with a bag-valve mask (BVM) and high-flow oxygen, and oral suctioning is performed as needed to keep the patient's airway clear of blood. The patient flexes his arms in response to pain, but does not open his eyes or respond verbally when you talk to him. An EMT from one of the engine companies drives the ambulance to the landing zone, which is about a mile away.

6. What trauma scoring systems are commonly used to assess the severity of a trauma patient's condition? How would you apply them to this patient?

Extremity injuries, including traumatic amputations, are common. Patients with traumatic amputation by postblast wind are likely to sustain fatal injuries secondary to the blast. In present day combat, improved body armor has increased the number of survivors of blast injuries from shrapnel wounds to the torso. The number of severe orthopaedic and extremity injuries, however, has increased. In addition, whereas body armor may limit or prevent shrapnel from entering the body, it also "catches" more energy from the blast wave, possibly resulting in the victim being thrown backward, thus increasing the potential for spine and spinal cord injury.

Although blast injuries have usually been the domain of military surgeons, they often occur in industrial settings and are, unfortunately, more common today owing to the increased use of explosives as a tool for urban terrorism and, in the United States, from methamphetamine laboratory explosions. Although civilian blast injuries in an industrial or mining setting used to be mostly characterized by blast injuries and burns, terrorist bombs often contain shrapnel. As an EMT, you and other EMS and trauma services personnel should be fully educated and aware of what to expect in these scenarios.

Multisystem Trauma

Multisystem trauma is a term that describes a person who has been subjected to multiple traumatic injuries involving more than one body system such as head and spinal trauma, chest and abdominal trauma, or chest and multiple extremity trauma. You must recognize patients who fit into this classification and provide rapid treatment and transportation, and alert medical control as to the nature of the patient's injuries so that the trauma center is prepared prior to your arrival. Multisystem trauma patients have a high level of morbidity and mortality; therefore, they require teams of physicians to treat their injuries. These teams may include specialists such as neurosurgeons, thoracic surgeons, and orthopaedic surgeons.

Golden Principles of Prehospital Trauma Care

As with any EMS call, your main priority in managing multisystem trauma is to ensure your safety and the safety of your crew and patient. Next, you must determine the need for additional personnel or equipment, evaluate the MOI, and identify and appropriately manage life threats. Once these steps have been completed, you can focus on patient care. Begin by assessing and managing the airway, including ventilatory support and high-flow oxygen while maintaining cervical spine immobilization. Ensure that basic shock therapy, such as controlling hemorrhages, stopping arterial bleeding, and keeping the patient warm, is completed. If bleeding cannot be controlled rapidly by direct pressure, use a tourniquet. If the patient is bleeding profusely, this must be controlled to ensure sufficient perfusion of organs and tissues.

Once threats to the ABCs are corrected, protect the patient's cervical spine and rapidly proceed with spinal immobilization if indicated. If the patient is entrapped, consider the use of rapid extrication techniques. In most patients with multisystem trauma, definitive care requires surgical intervention; therefore, on-scene time should be limited to 10 minutes or less. This is referred to as the platinum 10 minutes. During transport, obtain a SAMPLE history and complete a secondary assessment. Most care can be provided in transport. However, keep in mind that your patient has sustained multisystem trauma, and the order in which you usually provide treatment and care may need to be adjusted depending on the needs of the patient. For critically injured patients, consider ALS intercept and/or air medical transportation. Regardless of the mode of transport, ensure that the patient is transported to an appropriate facility and that the facility is notified as soon as possible. Specific standards of care in regard to multisystem trauma are addressed in detail in respective chapters.

Words of Wisdom

Rapid transport decisions are needed for patients who have sustained significant trauma. After the first 60 minutes, the body has increasing difficulty in compensating for shock and traumatic injuries. This is referred to as the Golden Hour. Because many injured patients require definitive care in less than an hour, this is also referred to as the Golden Period.

Patient Assessment

Identifying life-threatening illnesses and injuries as soon as possible has proven to improve patient outcomes. As an EMT, you must apply this knowledge as well as the appropriate assessment skills to assess, triage, manage, and transport patients with traumatic injuries to the most appropriate facility. The major components of patient assessment include the following:

- Scene size-up
- Primary assessment
- History taking
- Secondary assessment
- Reassessment

When you are caring for a patient who has experienced a significant MOI and the patient is considered to be in serious or critical condition, you should rapidly perform a physical examination. With a patient who has experienced a nonsignificant MOI, focus on the chief complaint while assessing the patient as a whole. The human body is divided into areas (or systems) based on body function, and its internal organs are subject to unseen injuries when force is applied to the body. For example, the brain may have bruising, the heart and lungs may have bruising or unseen bleeding, and the organs of the abdomen may have life-threatening bleeding. The following sections discuss the assessment of various body systems.

Injuries to the Head

The brain lies well protected within the skull. However, when the head is injured from trauma, disability and unseen injury to the brain may occur. The brain itself may tear or become bruised, causing bleeding. The blood vessels around the brain may also tear and produce bleeding. Bleeding or swelling inside the skull from brain injury is often life threatening; therefore, your assessment must include conducting frequent neurologic examinations. Neurologic assessments coupled with the patient's level of consciousness will often provide details on subtle changes in the patient's condition. Some patients will not have obvious signs or symptoms, such as changes in pupillary size and reactivity, of unseen brain injury until minutes or hours after the injury has occurred.

Injuries to the Neck and Throat

The neck and throat contain many structures that are susceptible to injuries from trauma that could be serious or deadly to your patients. In this region of the human body, the trachea (or windpipe) may become torn or swell after an injury to the neck or deviate after an injury to the lungs. These types of injuries may result in an airway problem that could quickly become a serious life threat because they interfere with the patient's ability to breathe; therefore, your assessment must include frequent physical examination looking for DCAP-BTLS in the neck region. In addition, you should also assess for jugular venous (vein) distention and tracheal deviation (late sign of injury).

The neck also contains large blood vessels that supply the brain with oxygen-rich blood. When a neck injury occurs, swelling may prevent blood flow to the brain and cause injury to the central nervous system, even though the brain may not have been directly affected by the initial force that caused the injury to the neck. If a penetrating injury to the neck results in an open wound, the patient may have significant bleeding, or air may be drawn into the circulatory system. If air enters the veins, this may result in air embolism, which may lead to cardiac arrest if the air enters the heart. Occlusive dressings must be used to keep this from happening. A crushing injury to the upper part of the neck may cause the cartilages of the upper airway and larynx to fracture. This can lead to the leakage of air into the soft tissue of the neck. When air is trapped in subcutaneous tissue (subcutaneous emphysema), it produces a crackling sound or feeling when palpated, called subcutaneous crepitation. Either air in the circulation or an airway cartilage fracture may cause rapid death.

Injuries to the Chest

The chest contains the heart, the lungs, and the large blood vessels of the body. When injury occurs to this area of the body, many life-threatening injuries may occur. For example, blunt trauma to the chest can fracture ribs or the sternum. When ribs are broken and the chest wall does not expand normally during breathing, this interferes with the body's ability to obtain sufficient amounts of oxygen for the cells. Bruising may occur to the heart and cause an irregular heartbeat. Depending on the severity of the trauma, the large vessels of the heart may be torn inside the chest, causing massive unseen bleeding that can quickly kill the trauma patient. In some chest injuries the lungs become bruised, thus interfering with normal oxygen exchange in the body.

Some chest injuries result in air collecting between the lung tissue and the chest wall. As air accumulates in this space, the lung tissue becomes compressed, again interfering with the body's ability to effectively exchange oxygen. This injury is called a *pneumothorax*. If left untreated or unrecognized, the lung tissue becomes squeezed under pressure until the heart is also squeezed and can no longer pump blood. This condition is called a tension pneumothorax and is a life-threatening emergency. In some patients bleeding in this portion of the chest develops. Instead of air collecting in this space, blood collects here and causes interference with breathing. This condition is called a *hemothorax* and it also poses a threat to the patient's life.

A penetration or perforation of the integrity of the chest is called an open chest wound. As air enters the chest cavity, the natural pressure balance within the chest cavity is no longer equal. If left untreated, shock and/or death will result. Regardless of the particular injury, it is imperative that you reassess a trauma patient's chest region every 5 minutes. The assessment should include DCAP-BTLS, lung sounds, and chest rise and fall. Some patients will not have obvious signs or symptoms such as absent breath sounds or respiratory difficulty immediately.

Injuries to the Abdomen

The abdomen is an area of the human body that contains many organs vital to body function. These organs also require a very high amount of blood flow so they can perform the functions necessary for life. The organs of the abdomen and retroperitoneum (the space immediately behind the true abdomen) can be classified into two simple categories: solid and hollow. The solid organs include the liver, spleen, pancreas, and kidneys. The hollow organs include the stomach, large and small intestines, and urinary bladder.

When injuries from trauma occur in this region of the body, serious and life-threatening problems may occur. The solid organs may tear, lacerate, or fracture. This causes serious bleeding into the abdomen that can quickly cause death. Be alert for a trauma patient who reports abdominal pain—it may be a symptom of abdominal bleeding. Also be alert to vital signs that begin to worsen; this can be a sign of serious, unseen bleeding inside the abdominal region of the body.

When the hollow organs of the body have been injured, they may rupture and leak toxic chemicals used for digestion into the abdomen. This not only causes pain, but a life-threatening infection also may eventually develop.

The abdomen also contains large blood vessels that supply the organs of this region and the lower extremities with oxygen-rich blood. Occasionally these vessels rupture or tear and cause serious unseen bleeding that may cause death. Some patients, particularly healthy young adults, are able to compensate longer than others from blood loss; therefore, you should always maintain a high index of suspicion when the MOI suggests injury to the abdominal region. This is best accomplished by reassessing the abdominal region using DCAP-BTLS.

YOU are the Provider — PART 5

The air transport helicopter arrives at the landing zone approximately 5 minutes after your unit. After reassessing the patient, you give your verbal report to the flight paramedic and transfer patient care.

Recording Time: 15 Minutes	
Level of consciousness	Responds only to pain
Respirations	30 breaths/min; extremely labored
Pulse	140 beats/min; absent radial pulses
Skin	Cool, clammy, and pale
Blood pressure	74/50 mm Hg
Spo_2	95% (supplemental oxygen)

After further assessment and treatment, the helicopter personnel load the patient into the aircraft and depart the scene. You later learn that the patient had intrathoracic and intracranial bleeding and multiple rib fractures. He was taken to surgery, and was in critical condition in the surgical intensive care unit.

7. How does the level of trauma care provided by the paramedic differ from that of the EMT?

Management: Transport and Destination

Caring for victims of traumatic injuries requires a solid understanding of the trauma system in the United States. You need a good working knowledge of the resources available to you, including the most optimal methods of rapid transport and trauma centers that can best provide definitive care. Call for ALS and helicopter assistance early, possibly even before you arrive on scene, to avoid delays in treatment and transport.

Scene Time

Because survival of critically injured trauma patients is time dependent, limit on-scene time to the minimum amount necessary to correct life-threatening injuries and package the patient. Optimally, on-scene time for critically injured patients should be less than 10 minutes—the platinum ten. The following criteria will help you identify a critically injured patient:

- Dangerous MOI
- Decreased level of consciousness
- Any threats to airway, breathing, or circulation. Patients who present with these criteria or who are very young or old or have chronic illnesses should also be considered to be high risk, thus requiring rapid treatment and transport.

Type of Transport

As discussed in Chapter 14, *Medical Overview*, modes of transport ultimately come in one of two categories: ground or air. Ground transportation EMS units are generally staffed by EMTs and paramedics. Air transportation EMS units or critical care transport units are often staffed by critical care transport professionals such as critical care nurses and paramedics.

You should be familiar with your local protocols defining indications for use of air medical transport. The Association of Air Medical Services and MedEvac Foundation International identified the following criteria in the 2006 white paper, *Air Medicine: Accessing the Future of Healthcare*, for consideration in deciding the appropriate use of emergency air medical services for trauma patients.

- There is an extended period required to access or extricate a remote (eg, injured hiker, snowmobiler, or boater) or trapped patient (eg, in a crashed car) which depletes the time window to get the patient to the trauma center by ground.
- Distance to the trauma center is greater than 20 to 25 miles.
- The patient needs medical care and stabilization at the ALS level, and there is no ALS-level ground ambulance service available within a reasonable time frame.
- Traffic conditions or hospital availability make it unlikely that the patient will get to a trauma center via ground ambulance within the ideal time frame for best clinical outcome.
- There are multiple patients who will overwhelm resources at the trauma center(s) reachable by ground within the time window.

- EMS systems require bringing a patient to the nearest hospital for initial evaluation and stabilization, rather than bypassing those facilities and going directly to a trauma center. This may add delay to definitive surgical care and necessitate air transport to mitigate the impact of that delay.
- There is a mass-casualty incident.

These recommendations are not to be understood as fully encompassing, but more as a guideline for local decision makers to develop more comprehensive protocols for the use of air medical transport. Always follow your local protocols when determining what type of patient transportation is appropriate.

Destination Selection

You will often be summoned to accident scenes to transport critically ill trauma patients to definitive care. For this reason, it is important for you to be familiar with how the American College of Surgeons' Committee on Trauma (ACS-COT) classifies trauma care. Trauma centers are classified into Levels I through IV, with Level I having the most resources followed by Levels II, III, and IV, respectively Table 24-2.

A Level I facility is a regional resource center and generally serves large cities or heavily populated areas. Level I facilities must be capable of providing every aspect of trauma care from prevention through rehabilitation; therefore, the facility must have adequate personnel and resources. Because of the extensive requirements, most Level I facilities are university-based teaching hospitals.

A Level II facility is typically located in less populated areas. Level II centers are expected to provide initial definitive care, regardless of injury severity. These facilities can be academic institutions or a public/private community facility. Because of its location and resources, a Level II trauma center may not be able to provide the same comprehensive care as a Level I trauma center.

Table 24-2 Key Elements for Trauma Centers

Level	Definition	Key Elements
Level I	A comprehensive regional resource that is a tertiary care facility; capable of providing total care for every aspect of injury—from prevention through rehabilitation	**1.** 24-hour in-house coverage by general surgeons **2.** Availability of care in specialties such as orthopaedic surgery, neurosurgery, anesthesiology, emergency medicine, radiology, internal medicine, and critical care **3.** Should also include cardiac, hand, pediatric, and microvascular surgery and hemodialysis **4.** Provides leadership in prevention, public education, and continuing education of trauma team members **5.** Committed to continued improvement through a comprehensive quality assessment program and organized research to help direct new innovations in trauma care
Level II	Able to initiate definitive care for all injured patients	**1.** 24-hour immediate coverage by general surgeons **2.** Availability of orthopaedic surgery, neurosurgery, anesthesiology, emergency medicine, radiology, and critical care **3.** Tertiary care needs such as cardiac surgery, hemodialysis, and microvascular surgery may be referred to a Level I trauma center **4.** Committed to trauma prevention and continuing education of trauma team members **5.** Provides continued improvement in trauma care through a comprehensive quality assessment program
Level III	Able to provide prompt assessment, resuscitation, and stabilization of injured patients and emergency operations	**1.** 24-hour immediate coverage by emergency medicine physicians and prompt availability of general surgeons and anesthesiologists **2.** Program dedicated to continued improvement in trauma care through a comprehensive quality assessment program **3.** Has developed transfer agreements for patients requiring more comprehensive care at a Level I or Level II trauma center **4.** Committed to continuing education of nursing and allied health personnel or the trauma team **5.** Must be involved with prevention and have an active outreach program for its referring communities
Level IV	Able to provide advanced trauma life support (ATLS) before transfer of patients to a higher level trauma center	**1.** Includes basic emergency department facilities to implement ATLS protocols and 24-hour laboratory coverage **2.** Transfer to higher level trauma centers follows the guidelines outlined in formal transfer agreements **3.** Committed to continued improvement of these trauma care activities through a formal quality assessment program **4.** Involved in prevention, outreach, and education within its community

Level III facilities serve communities that do not have access to Level I or II facilities. Level III facilities provide assessment, resuscitation, emergency care, and stabilization. A Level III facility must have transfer agreements with a Level I or II trauma center and must have protocols in place to transfer patients whose needs exceed the resources of the facility.

Level IV facilities are typically found in remote outlying areas where no higher level of care is available. These facilities provide advanced trauma life support prior to transfer to a higher level trauma center. Such a facility may be a clinic urgent care facility, with or without a physician.

Although an inclusive trauma system should leave no facility without a direct link to a Level I or II facility, all facilities are expected to provide the same high quality of initial care regardless of the classification level.

Trauma centers are categorized as either adult trauma centers or pediatric trauma centers, but not necessarily both. Pediatric trauma centers are not nearly as common as adult trauma centers. When transporting a pediatric trauma patient, you must be certain to transport your patient to a pediatric trauma center if there is one in your area; do not make the mistake of transporting a pediatric patient to an adult trauma center when a pediatric trauma center is available.

In 2011, the ACS-COT and the CDC published an updated field triage decision scheme **Figure 24-19**. These criteria are intended to help prehospital care providers recognize injured patients who are likely to benefit from transport to a trauma center compared with transport to an emergency department. It is not intended as a mass-casualty or disaster triage tool; it is only intended for individual patients.

Words of Wisdom

The **trauma score** calculates a number from 1 to 16, with 16 being the best possible score. It takes into account the **Glasgow Coma Scale (GCS) score**, respiratory rate, respiratory expansion, systolic blood pressure, and capillary refill **Table 24-3**. The GCS is an evaluation tool used to determine level of consciousness. It evaluates and assigns point values (scores) for eye opening, verbal response, and motor response; these scores are then totaled and help to effectively predict patient outcomes. Note that the lower the score, the more severe the extent of brain injury. The trauma score relates to the likelihood of patient survival. However, this scoring system does not accurately predict survivability in patients with severe head injuries because motor and verbal deficits make those criteria difficult to assess; in its place, the Revised Trauma Score (RTS), discussed next, is used.

Table 24-3 Glasgow Coma Scale

Test	Response	Score
Eye opening	Spontaneous	4
	Voice	3
	Pain stimulation	2
	None	1
Verbal	Oriented conversation	5
	Confused conversation	4
	Inappropriate words	3
	Incomprehensible sounds	2
	None	1
Motor	Obeys commands	6
	Localizes pain	5
	Withdraws from pain	4
	Abnormal flexion (decorticate)	3
	Abnormal extension (decerebrate)	2
	None	1

Score: 15 indicates no neurologic disabilities.
Score: 13–14 may indicate mild dysfunction.
Score: 9–12 may indicate moderate dysfunction.
Score: 8 or less is indicative of severe dysfunction.

Revised Trauma Score

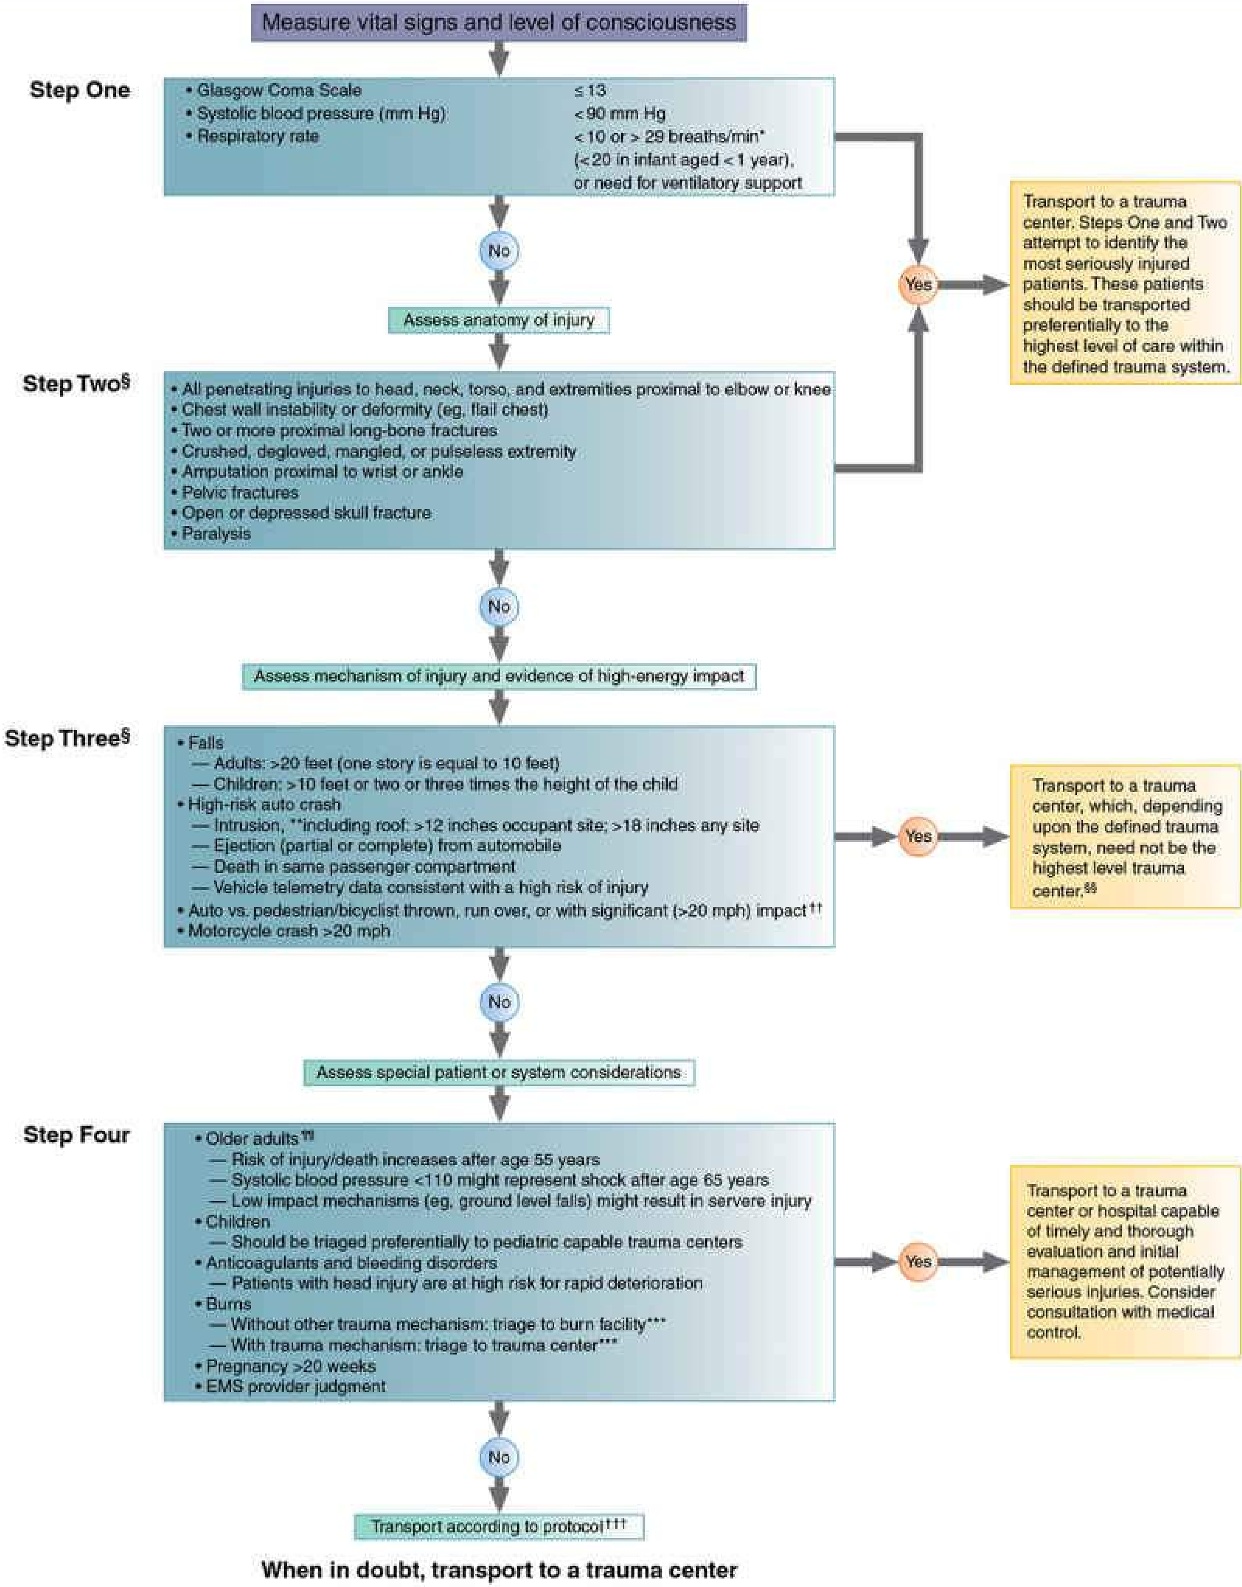
The numeric scoring of trauma patients for determining the severity of their injury is common practice in the health care profession. When the various scoring systems were created, it was thought that the implementation of the scoring system would assist in rapidly identifying the severity of the patient's injuries. There are several different trauma scoring systems. The Revised Trauma Score (RTS) is most commonly used for patients with head trauma because it is weighted to compensate for major head injury without multisystem injury or major physiologic changes.

The RTS is a physiologic scoring system that is also used to assess the severity of a trauma patient's injuries. Objective data used to calculate the RTS include the GCS score, systolic blood pressure (SBP), and respiratory rate (RR). In addition to assessing injury severity, the RTS has also demonstrated reliability in predicting survival in patients with severe injuries. The highest RTS a patient can receive is 12; the lowest is 0. The RTS is calculated as shown in

Table 24-4.

Table 24-4 The Revised Trauma Score

GCS	SBP	RR	Value
13 to 15	>89 mm Hg	10 to 29 breaths/min	4
9 to 12	76 to 89 mm Hg	>29 breaths/min	3
6 to 8	50 to 75 mm Hg	6 to 9 breaths/min	2
4 to 5	1 to 49 mm Hg	1 to 5 breaths/min	1
3	0	0	0



Abbreviation: EMS = emergency medical services.

* The upper limit of respiratory rate in infants is >29 breaths per minute to maintain a higher level of overtriage for infants.

§ Any injury noted in Step Two or mechanism identified in Step Three triggers a "yes" response.

¶ Age <15 years.

** Intrusion refers to interior compartment intrusion, as opposed to deformation, which refers to exterior damage.

†† Includes pedestrians or bicyclists thrown or run over by a motor vehicle or those with estimated impact >20 mph with a motor vehicle.

§§ Local or regional protocols should be used to determine the most appropriate level of trauma center within the defined trauma system; need not be the highest-level trauma center.

¶¶ Age >55 years.

*** Patients with both burns and concomitant trauma for whom the burn injury poses the greatest risk for morbidity and mortality should be transferred to a burn center. If the nonburn trauma presents a greater immediate risk, the patient may be stabilized in a trauma center and then transferred to a burn center.

††† Patients who do not meet any of the triage criteria in Steps One through Four should be transported to the most appropriate medical facility as outlined in local EMS protocols.

Figure 24-19 2011 decision scheme for field triage of injured patients.

Source: Adapted from Centers for Disease Control and Prevention, Morbidity and Mortality Weekly Report (MMWR), January 13, 2012.

Special Considerations

Because traumatic injuries are as varied as the mechanisms that cause them, it is almost impossible to prepare for every possible situation that you may face during your career. In all situations, you must remain calm, complete an organized assessment, correct life-threatening injuries, and do no harm. You should never hesitate to contact ALS backup or medical control for guidance.

YOU are the Provider — SUMMARY

1. On the basis of the information provided by the dispatch operator, can you predict the potential types of injuries the patient may have? If so, how?

Although you will not ultimately know the type and severity of injuries the patient has until you arrive at the scene, information provided by the dispatch operator can influence your index of suspicion.

En route to this scene, you know that the incident involves a head-on (frontal) crash with a tree, and the patient is still in the vehicle. What you do not know is the speed of the vehicle at the time of impact, whether or not the patient was restrained, or whether or not the air bags deployed. *Just because the patient is still in the vehicle does not indicate that he was restrained*. Until you arrive at the scene and gather more information, you should assume the worst.

The patient has experienced three collisions: collision of the vehicle against another object, collision of himself against the interior of the vehicle, and collision of his internal organs against the solid structures of the body.

Damage to the vehicle (the first collision) provides information about the severity of the collision. The greater the damage is to the vehicle, the greater the energy that was involved and, therefore, the greater the potential to cause injury. If there is significant damage to the vehicle, your index of suspicion for serious injury to the patient should increase, even if injuries are not immediately apparent.

Just like the obvious damage that occurs to the exterior of the vehicle during the first collision, the injuries that result from the second collision are often obvious during primary assessment. Common injuries that occur during the second collision include lower extremity and pelvic fractures (when the knees impact the dashboard), rib fractures, pneumothoraces (when the chest impacts the steering wheel), and head and neck trauma (when the head impacts the windshield).

The type of injury experienced by the unrestrained occupant depends on the path he or she took at the time of impact. There may be injuries to the abdomen, pelvis, and lower extremities if the patient's body took the down-and-under path causing the abdomen to impact the lower part of the steering wheel and the knees to impact the dashboard. Head, neck, or chest trauma may be present if the patient was propelled over the steering wheel. Blunt chest and/or abdominal trauma may result from direct impact with the steering wheel.

The injuries that occur during the third collision may not be as obvious as external injuries, but these injuries are usually the most life threatening. For example, if the chest impacts the steering wheel, the thoracic organs continue their forward motion until they collide with the inside of the chest cavity. As a result of these forces, shearing injuries of the great vessels (eg, aorta, vena cava) or injury to the heart as it impacts with the sternum may occur. If the occupant's head strikes the windshield, the brain continues its forward motion until it strikes the inside of the skull; this results in compression injuries to the anterior part of the brain and stretching or tearing of the posterior part of the brain.

2. Why is it important to determine the speed at which a vehicle was traveling at the time of impact?

A vehicle's speed affects the potential for injury to its occupant(s). According to the equation for kinetic energy ($KE = 1/2mv^2$), the energy available to cause injury doubles when the object's weight doubles, but *quadruples when the object's speed doubles*.

The relationship between a vehicle's speed and its deceleration is best described in these terms: The faster the vehicle is traveling and the quicker it stops, the greater the potential for serious injury to the occupant(s).

3. Where will you most likely find damage to the vehicle's interior based on the patient's signs and symptoms?

The patient's signs and symptoms indicate, at a minimum, injury to his head and chest. He is bleeding from the head, face, and mouth; his level of consciousness is markedly decreased; and his respirations are rapid and labored. Inspection of the interior of the vehicle in this incident will most likely reveal a deformed steering wheel (top, bottom, or both) that occurred when the patient's chest—and maybe abdomen—impacted it. You will also likely find an outward bulge of the windshield with a typical star-burst fracture where the patient's head and face made impact with it. You may also find some of the patient's hair caught in the windshield, and this is a clear indicator of patient impact. Keep in mind that these may not be the only contact points; they are simply the most likely areas based on the patient's injuries.

4. Should the patient be transported to the Level I trauma center or the Level III trauma center? Why?

You are caring for a multisystem trauma patient; that is, he has experienced trauma that affects more than one body system. The obvious trauma to his head and his level of consciousness indicate a traumatic brain injury, the bruising and crepitus to his chest and his labored breathing indicate intrathoracic trauma, and his vital signs indicate a general state of shock. He requires the highest level of trauma care available—a Level I trauma center if possible. There are several reasons you may consider the Level III center, however. If you are unable to achieve an adequate airway to be able to maintain ventilation throughout the time of transport to the Level I center, you should consider going to the Level III center first for stabilization prior to transfer to the Level I center. Similarly, if the patient's condition is otherwise sufficiently grave from the standpoint of his head injury or blood pressure, going to the Level III center first might be warranted. Be familiar with transport times and options to minimize those times (ie, aeromedical transport) in your area.

5. What other transport factors should you consider with this patient?

The patient should be transported to a Level I trauma center; however, the closest one is 30 miles away. Ground transport in heavy traffic will cause a delay in patient care. This situation requires you to make a decision as to how to best transport the patient to a Level I facility in the most expedient manner.

In this scenario, you are faced with two transport options: Try to coordinate a paramedic intercept and transport by ground to the Level I facility, or request air medical transport. Coordinating a paramedic intercept and transporting the patient by ground will get advanced life support (ALS) care to the patient quicker, but it will not get him to the Level I facility any quicker. Conversely, air medical transport via a helicopter will get ALS personnel (ie, paramedic, critical care nurse) to the patient *and* get him to the Level I facility in a shorter period of time. You should also be prepared for the situation where you are faced with the same patient but no access to aeromedical services for some reason such as bad weather. Your priorities remain the same, but the best option for achieving the fastest access to resuscitative care may be less obvious.

6. What trauma scoring systems are commonly used to assess the severity of a trauma patient's condition? How would you apply them to this patient?

The two most commonly used numeric trauma scoring systems are the Glasgow Coma Scale (GCS) and the Revised Trauma Score (RTS).

To assess the patient in this scenario, you must first calculate his GCS. The patient does not open his eyes, even when a painful stimulus is applied; therefore, he receives a 1 for eye opening. For verbal response, he also receives a 1 because he does not respond when you talk to him. For motor response, he receives a 3; he responds to pain by flexing his arms (decorticate posturing). Currently, the patient's GCS score is 5, which indicates a severe brain injury.

To calculate the patient's RTS, you will use his GCS, along with his systolic blood pressure and respiratory rate. He has already been assigned a GCS score of 5; therefore, he is assigned a numeric value of 1. His systolic blood pressure is 80 mm Hg; therefore, he is assigned a numeric value of 3. His respiratory value is 34 breaths/ min; therefore, he is assigned a numeric value of 3. On the basis of these parameters, the patient's RTS is 7.

Note that *a single assessment of a trauma patient's GCS and RTS scores cannot reliably capture his or her clinical progression*. Obtain baseline scores and then frequently (at least every 5 minutes) reassess them. Document all scores you obtained in the field, including the times they were obtained.

7. How does the level of trauma care provided by the paramedic differ from that of the EMT?

The level of trauma care you provide as an EMT versus personnel with a higher level of training, such as AEMTs and paramedics, differs mainly in the emergency treatment interventions that can be performed. For example, paramedics are trained to provide intravenous therapy and to administer certain emergency medications, among others. Although these additional skills can be of great benefit to the patient, they are not definitive care interventions. Paramedics cannot repair a lacerated liver or stop bleeding in the brain; therefore, their focus on trauma care should not be significantly different from yours. Trauma care is based on identifying injuries, stabilizing the patient, and rapid transport to the appropriate medical facility, in this case, a trauma center. In many cases, you will be called on to assist the paramedic in performing advanced level skills. Depending on local protocols, you may even be able to perform additional skills as deemed necessary by the EMS system medical director.

Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** Thermal management, suction, full spinal immobilization

Narrative

Dispatched for a motor vehicle versus tree head-on crash. Rescue assignment and law enforcement were dispatched as well. Arrived at the scene and noted that a small passenger vehicle made frontal impact with a large tree. Damage to the front of the vehicle was significant. The driver, a 20-year-old man, was still in the vehicle; however, he was unrestrained. Driver and passenger side air bags both deployed, and patient was not entrapped. Partner accessed patient through backseat and manually stabilized his head. Primary assessment revealed that the patient was responsive only to pain. He had blood in his oropharynx, a large hematoma and laceration with active bleeding to his forehead, and facial bleeding. His respirations were rapid and labored. Suctioned the patient's oropharynx, controlled the bleeding on his forehead, applied cervical collar, and rapidly extricated him from the vehicle. Due to the MOI and patient's clinical status, requested air transport. Applied oxygen @ 15 L/min via nonrebreathing mask and performed secondary assessment, which revealed diffuse bruising and crepitus to the chest. Breath sounds were diminished over the left side of the chest. Pelvis and upper and lower extremities were unremarkable for gross injury. Pupils were dilated to approximately 6 mm, and sluggish to react. Engine 3 fire fighter reported interior damage to the steering wheel and a starburst fracture to the windshield with evidence of human hair. Applied full spinal immobilization and a blanket for warmth, and loaded patient into the ambulance. Reassessment revealed that his respiratory rate had increased, his breathing effort was more labored, and his oxygen saturation had decreased. Began assisting his ventilations with a BVM and high-flow oxygen. Engine 3 EMT drove ambulance to landing zone (LZ) to meet with air transport helicopter. Continued to reassess patient every 3 to 5 minutes and noted no change in his clinical status. Contacted air medical helicopter via radio and provided patient status update. Continued to assist patient's ventilations and suctioned his oropharynx as needed to maintain airway patency. Vital signs were also reassessed, as noted above. After a 3-minute wait at the LZ, air transport helicopter arrived. Gave verbal report to flight paramedic, and transferred patient care to the flight crew. Helicopter departed the LZ at 1550, and EMS 3 returned to service at 1610.**End of report**

Prep Kit

Ready for Review

- Determine the mechanism of injury (MOI) as quickly as possible; this will assist you in developing an index of suspicion for the seriousness of your patient's unseen injuries.
- Three concepts of energy are typically associated with injury: potential energy, kinetic energy, and work.
- Traumatic injuries can be described as blunt trauma or penetrating trauma.
- Motor vehicle crashes are classified traditionally as frontal (head-on), lateral (T-bone), rear-end, rotational (spins), and rollovers.
- In every crash there are three collisions that occur:
  - The collision of the vehicle against some type of object
  - The collision of the passenger against the interior of the vehicle
  - The collision of the passenger's internal organs against the solid structures of the body
- Maintain a high index of suspicion for serious injury in the patient who has been involved in a motor vehicle crash with significant damage to the vehicle, has fallen from a significant height, or has sustained penetrating trauma to the body.
- Communicate MOI findings in the written patient care report and verbally to hospital staff; this will ensure that appropriate treatment of potential serious injuries continues for the patient at the hospital.
- People who are injured in explosions may have injuries that are classified as primary blast injuries, secondary blast injuries, tertiary blast injuries, and/or miscellaneous blast injuries.
- A patient who has sustained a significant MOI and is considered to be in serious or critical condition should receive a secondary assessment including a rapid examination of the entire body. Any patient who has sustained a non-significant MOI should receive an assessment more focused on the chief complaint while still assessing the patient as a whole.
- Caring for victims of traumatic injuries requires a solid understanding of the trauma system in the United States. This includes transport time, transport destination, and selection of type of transport.
- The criteria for transport to a trauma center vary from system to system. Key variables define the level rating of a trauma center. There are four categories of trauma centers. Your system may include a Level I trauma center, the highest-level trauma center.
- The field triage decision scheme from the American College of Surgeons' Committee on Trauma and the Centers for Disease Control and Prevention outlines criteria to help prehospital care providers recognize injured patients who are likely to benefit from transport to a trauma center.

Vital Vocabulary

arterial air embolism Air bubbles in the arterial blood vessels.

blunt trauma An impact on the body by objects that cause injury without penetrating soft tissues or internal organs and cavities.

cavitation A phenomenon in which speed causes a bullet to generate pressure waves, which cause damage distant from the bullet's path.

coup-contrecoup brain injury A brain injury that occurs when force is applied to the head and energy transmission through brain tissue causes injury on the opposite side of original impact.

deceleration The slowing of an object.

drag Resistance that slows a projectile, such as air.

Glasgow Coma Scale (GCS) score An evaluation tool used to determine level of consciousness, which evaluates and assigns point values (scores) for eye opening, verbal response, and motor response, which are then totaled; effective in helping predict patient outcomes.

index of suspicion Awareness that unseen life-threatening injuries may exist when determining the mechanism of injury.

kinetic energy The energy of a moving object.

mechanism of injury (MOI) The forces, or energy transmission, applied to the body that cause injury.

medical emergencies Emergencies that require EMS attention because of illnesses or conditions not caused by an outside force.

multisystem trauma Trauma that affects more than one body system.

penetrating trauma Injury caused by objects, such as knives and bullets, that pierce the surface of the body and damage internal tissues and organs.

potential energy The product of mass, gravity, and height, which is converted into kinetic energy and results in injury, such as from a fall.

projectile Any object propelled by force, such as a bullet by a weapon.

pulmonary blast injuries Pulmonary trauma resulting from short-range exposure to the detonation of explosives.

Revised Trauma Score (RTS) A scoring system used for patients with head trauma.

trajectory The path a projectile takes once it is propelled.

trauma emergencies Emergencies that are the result of physical forces applied to a patient's body.

trauma score A score calculated from 1 to 16, with 16 being the best possible score. It relates to the likelihood of patient survival with the exception of a severe head injury. It takes into account the Glasgow Coma Scale (GCS) score, respiratory rate, respiratory expansion, systolic blood pressure, and capillary refill.

tympanic membrane The eardrum; a thin, semi-transparent membrane in the middle ear that transmits sound vibrations to the internal ear by means of auditory ossicles.

work The measure of force over distance.

Assessment *in Action*

You are dispatched to a motor vehicle crash on a rural road. On arrival you see a single vehicle in an embankment. The scene appears to be safe. The car has front-end damage and a starred windshield. You find an unrestrained driver sitting in the driver's seat. He opens his eyes when you speak to him; however; he is confused and unable to tell you what happened, but he follows your commands. Examination reveals a laceration on the center of his forehead and a large bruise on his chest. Pulses and motor and sensory function are present in all extremities. His pulse is rapid, and breathing is slightly labored.

1. What is your first concern in this situation?

   A. History taking
   B. Physical examination
   C. Scene size-up
   D. Reassessment

2. What type of chest injury is present?

   A. Blunt
   B. Penetrating
   C. Crushing
   D. Barotrauma

3. What is the Glasgow Coma Scale score for this patient?

   A. 15
   B. 14
   C. 13
   D. 12

4. You would use the Revised Trauma Score scoring system for this patient due to the potential for what type of trauma?

   A. Abdominal
   B. Head

C. Chest
D. Extremity

5. Given the patient's condition and the findings of your assessment, which of the following would be the most correct transport consideration?

   A. Transport the patient to a Level I Trauma Center 1 hour away.
   B. Transport the patient to a Level II Trauma Center that is the same distance as a Level I Trauma Center.
   C. Transport the patient to a Level III Trauma Center.
   D. Call for an ALS unit to respond to the scene or intercept the BLS transport.

6. What is index of suspicion?

   A. Life-threatening injuries are present with a significant mechanism of injury.
   B. The patient has an illness that is not caused by an outside force.
   C. Awareness that due to the mechanism of injury, unseen injuries may be present.
   D. Awareness that the mechanism of injury will rule out any life-threatening injuries.

7. What other injuries might you suspect in this patient?
8. Does this patient meet the criteria for rapid transport? Why or why not?
9. What is a coup-contrecoup injury?
10. What are the three collisions involved in a frontal motor vehicle crash?

CHAPTER
25

Bleeding

© microgen/iStock

National EMS Education Standard Competencies

Trauma

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

Bleeding

Recognition and management of

› Bleeding (pp 883–898)

Pathophysiology, assessment, and management of

› Bleeding (pp 881–898)

Pathophysiology

Applies fundamental knowledge of the pathophysiology of respiration and perfusion to patient assessment and management.

Knowledge Objectives

1. Describe the general structure of the circulatory system and the function of its parts, including the heart, arteries, veins, and capillaries. (pp 879–880)
2. Explain the significance of bleeding caused by blunt force trauma, including the importance of perfusion. (pp 881–882)
3. Discuss hypovolemic shock as a result of bleeding, including the signs of shock. (pp 882–886)
4. Explain the importance of following standard precautions when treating a patient with external bleeding. (p 883)
5. Describe the characteristics of external bleeding, including the identification of the following types of bleeding: arterial, venous, and capillary. (pp 883–884)
6. Explain how to determine the nature of the illness (NOI) for internal bleeding, including identifying possible traumatic and nontraumatic sources. (p 885)
7. Identify the signs and symptoms of internal bleeding. (pp 885–886)

8. Discuss internal bleeding in terms of the different mechanisms of injury (MOI) and their associated internal bleeding sources. (p 885)
9. Explain how to conduct a primary assessment, including identification of life threats beyond bleeding, ensuring a patent airway, and making a transport decision. (pp 886–887)
10. Explain how to assess a patient with external or internal bleeding, including the physical examination, vital signs, and the use of monitoring devices. (p 888)
11. Explain the emergency medical care of the patient with external bleeding. (pp 888–890)
12. Explain the emergency medical care of the patient with internal bleeding. (p 897)

Skills Objectives

1. Demonstrate the emergency medical care of the patient with external bleeding. (pp 890–891, Skill Drill 25-1)
2. Demonstrate the emergency medical care of the patient with external bleeding using a commercial tourniquet. (pp 891–893, Skill Drill 25-2)
3. Demonstrate emergency medical care of the patient with epistaxis, or nosebleed. (pp 895–896, Skill Drill 25-3)
4. Demonstrate the emergency medical care of the patient who shows signs and symptoms of internal bleeding. (pp 897–898, Skill Drill 25-4)

Introduction

After airway management, two of the most important skills you will learn as an EMT are to recognize bleeding and to understand how it affects the body. Bleeding can be external and obvious or internal and hidden. Either type of bleeding is potentially dangerous, first causing weakness and eventually, if left uncontrolled, shock and death. Uncontrolled bleeding is the most common cause of hypoperfusion (shock) following a traumatic injury.

This chapter will help you understand how the cardiovascular system reacts to blood loss. The chapter begins with a brief review of the anatomy and function of the cardiovascular system. It then describes the signs, symptoms, and emergency medical care of both external and internal bleeding. The chapter concludes with a discussion about the relationship between bleeding and hypovolemic shock.

Anatomy and Physiology of the Cardiovascular System

Recall from Chapter 6, *The Human Body*, that the cardiovascular system circulates blood to the body's cells and tissues, delivering oxygen and nutrients and carrying away metabolic waste products **Figure 25-1**.

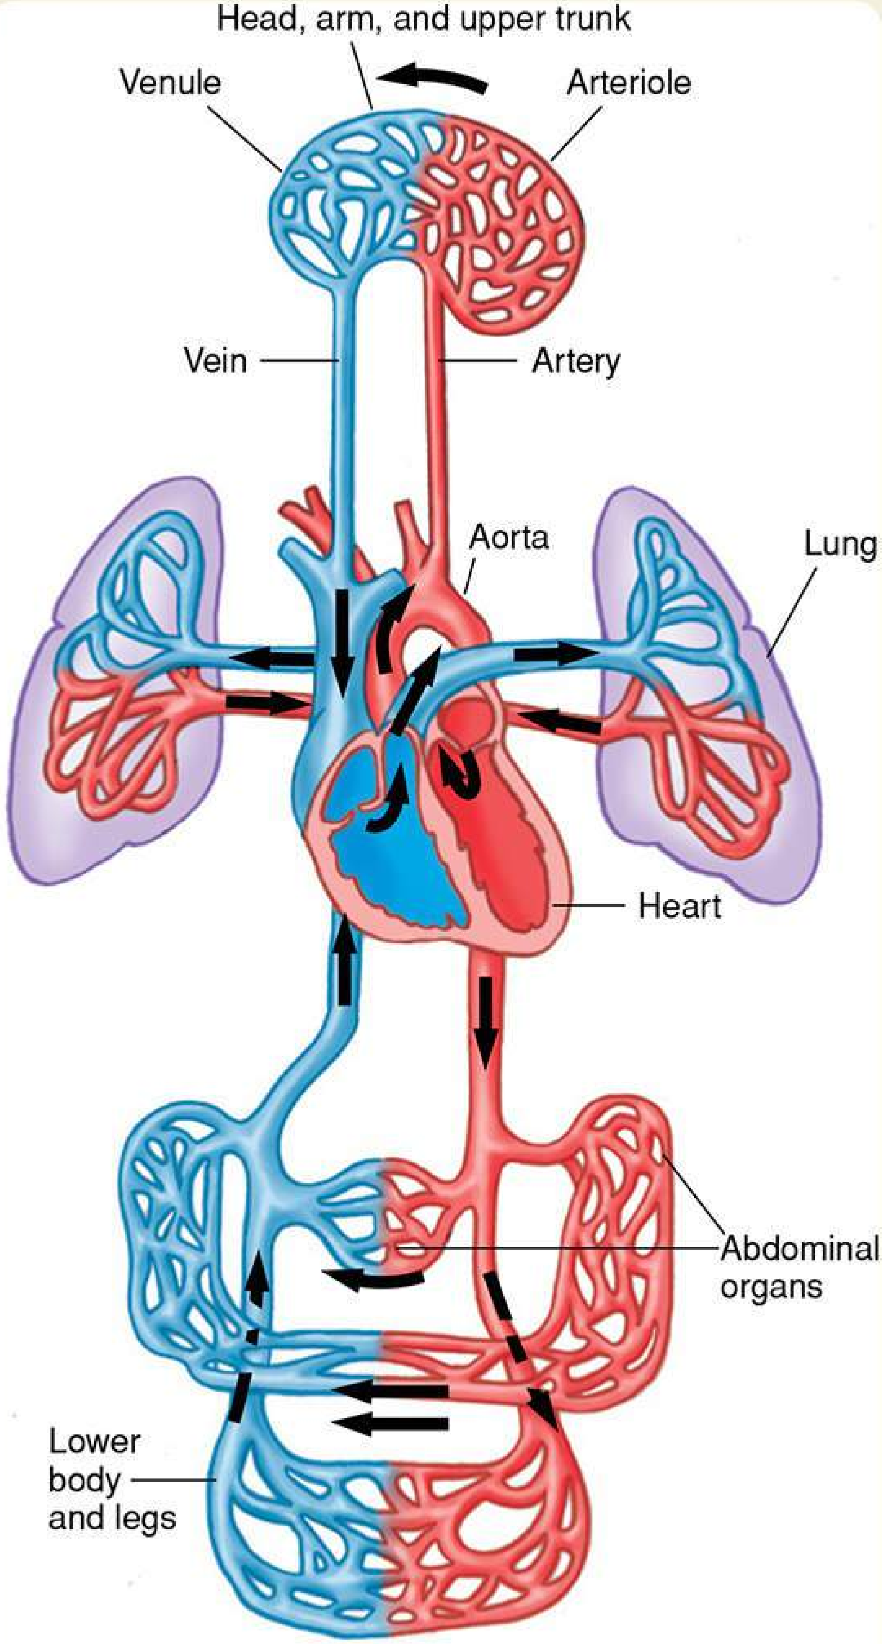

Figure 25-1 The cardiovascular system includes the heart, arteries, veins, and interconnecting capillaries.

The cardiovascular system is the main system responsible for supplying and maintaining adequate blood flow. It consists of three parts:

- The pump (the heart)
- A container (the blood vessels that reach the cells of the body)
- The fluid (blood and body fluids)

YOU are the Provider **PART 1**

At 1620 hours, you are dispatched to a woodworking shop at 517 East Graham Street for a 32-year-old man with severe bleeding from the arm. The exact mechanism of injury (MOI) is unknown. You and your partner proceed to the scene with a response time of approximately 6 minutes.

1. What are the functions of arteries? What major arteries are located in the upper extremity?
2. Why is arterial bleeding more severe than venous bleeding?

The Heart

All organs depend on the heart to provide a rich blood supply. For this reason, the heart muscle has several unique features. First, because the heart cannot tolerate a disruption of its blood flow for more than a few minutes, the heart muscle needs a rich and well-distributed blood supply. Second, the heart works as two paired pumps **Figure 25-2**. Each side of the heart has an upper chamber (atrium) and a lower chamber (ventricle), both of which pump blood. Blood leaves each chamber of a normal heart through a one-way valve, which keeps the blood moving in the proper direction by preventing backflow.

Blood Vessels and Blood

As blood flows out of the heart, it passes into the **aorta**, the largest **artery** in the body. The arteries become smaller the farther they are from the heart. The smaller blood vessels that connect the arteries and capillaries are **arterioles**. **Capillaries** are small tubes, with the diameter of a single red blood cell, that pass among all the cells in the body, linking the arterioles and the **venules**. Blood leaving the distal side of the capillaries flows into the venules. These small, thin-walled vessels empty into the **veins**, and the veins then empty into the inferior and superior venae cavae. This is the process that returns blood in the venous portion of the circulatory system to the heart. Oxygen and nutrients easily pass from the capillaries into the cells, and waste and carbon dioxide diffuse from the cells into the capillaries **Figure 25-3**. This transportation system allows the body to rid itself of waste products.

Blood contains red cells, white cells, platelets, and plasma **Figure 25-4**. Red blood cells transport oxygen to the cells and transport carbon dioxide (a waste product of cellular metabolism) away from the cells to the lungs, where it is removed from the body during exhalation. Platelets are the key to formation of blood clots. Blood clots are an important response from the body to control blood loss. In the body, blood clot formation depends on several factors: blood stasis, changes in the blood vessel wall (such as a wound), and the blood's ability to clot (affected by disease processes or medications). When tissues are injured, platelets begin to collect at the site of injury; this causes red blood cells to become sticky and clump together. As the red blood cells begin to clump, a protein in plasma reinforces the developing clot by converting to a threadlike mesh that forms a clot. Medical conditions that interfere with the normal clotting process will be discussed later in this chapter.

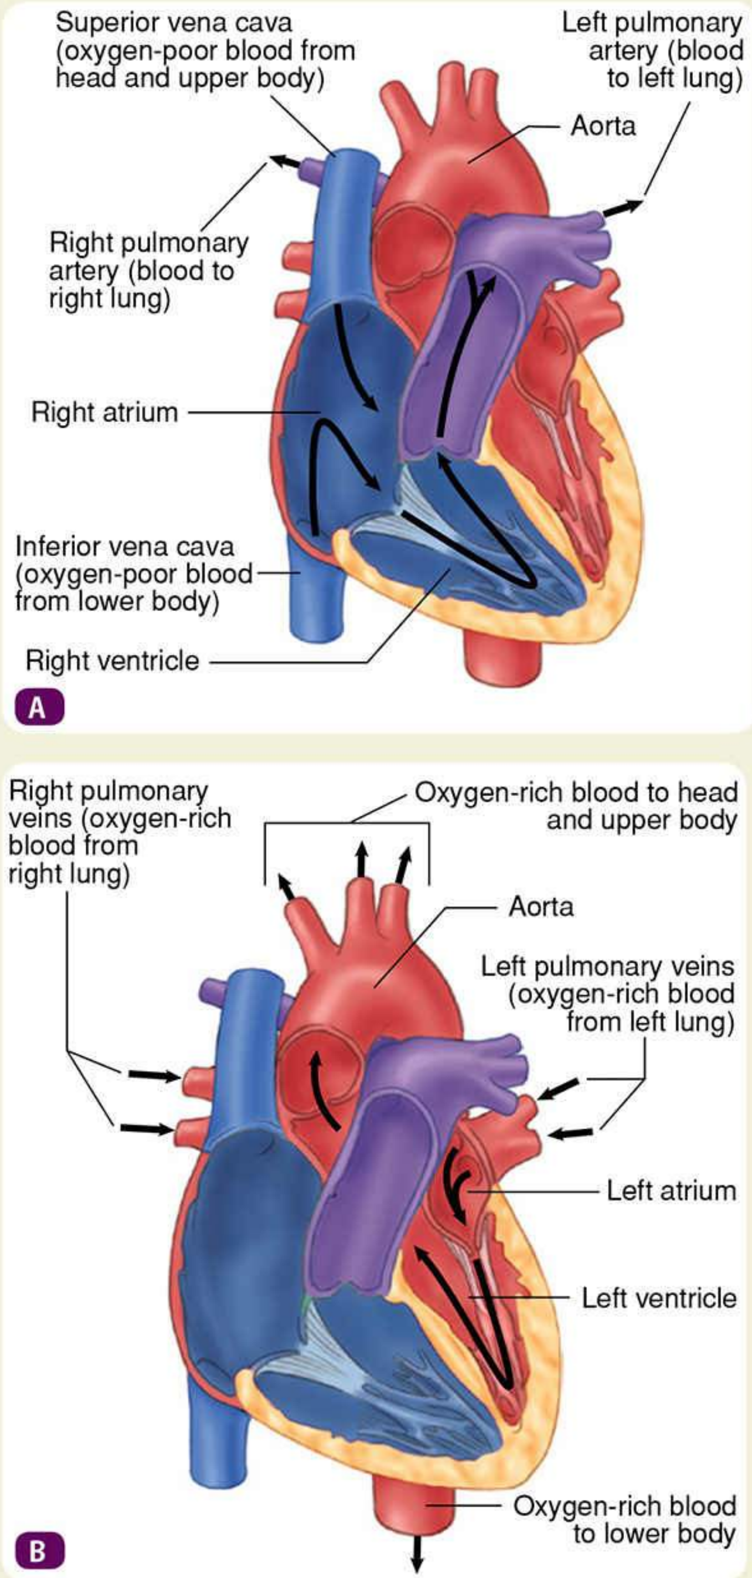

Figure 25-2 **A.** The right side of the heart circulates blood from the body to the lungs. **B.** The left side of the heart circulates oxygen-rich blood from the lungs to the rest of the body. It is the more muscular of the two pumps because it must pump blood into the aorta and arteries in order to reach all cells of the body.

The autonomic nervous system monitors the body's needs and adjusts the blood flow by constricting or dilating blood vessels as required. During an emergency, the autonomic nervous system automatically redirects blood away from other organs to the heart, brain, lungs, and kidneys. Thus, the cardiovascular system adapts to changing conditions in the body to maintain homeostasis and perfusion. As discussed in Chapter 12, *Shock*, if blood volume is significantly diminished and the system fails to provide sufficient circulation for every body part to perform its function, then **hypoperfusion**, or **shock**, results.

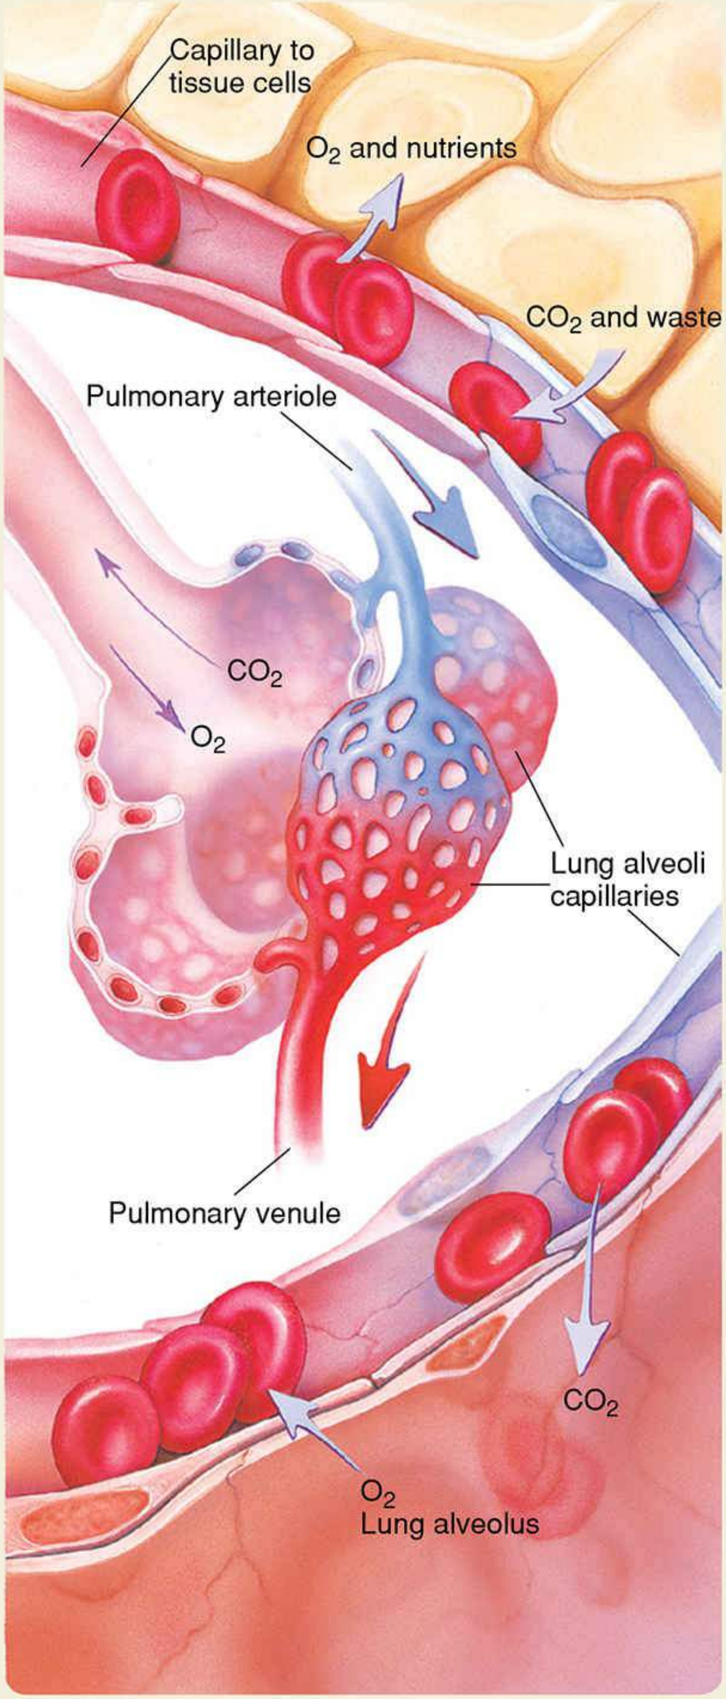

Figure 25-3 Oxygen and nutrients pass easily from the capillaries into the cells, and waste and carbon dioxide diffuse from the cells into the capillaries (top). Oxygen and carbon dioxide pass freely between the lungs and capillaries (bottom).

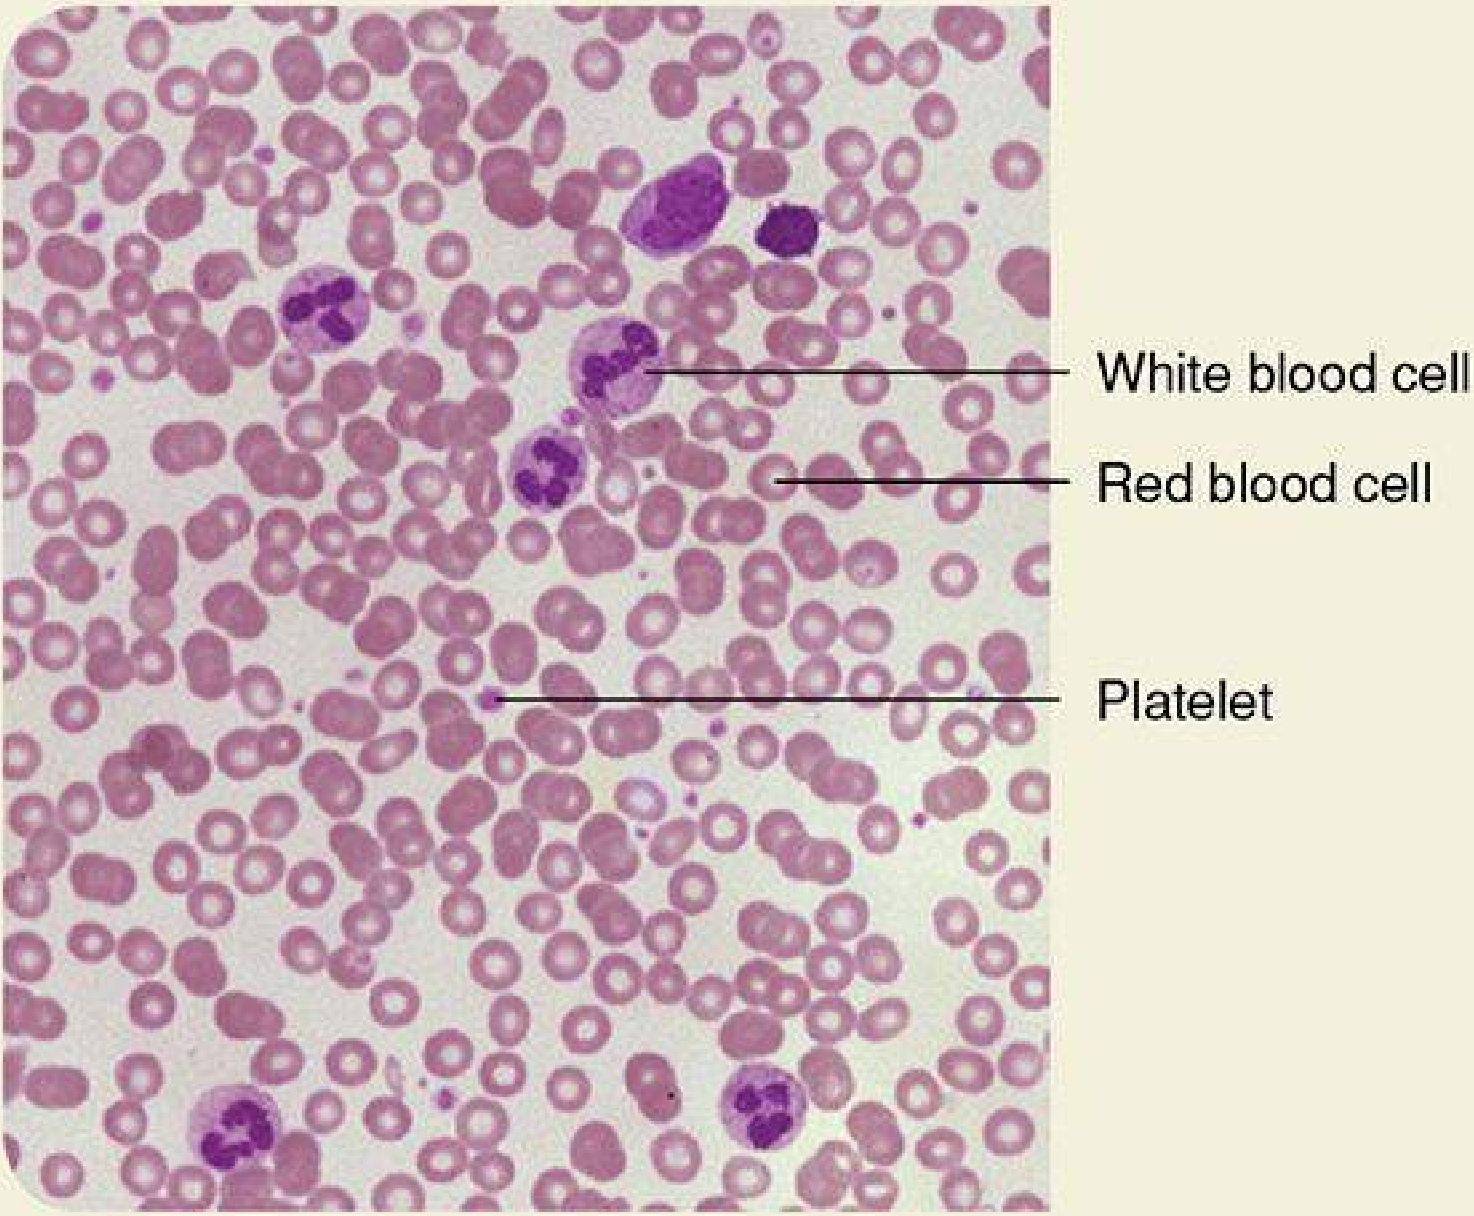

Figure 25-4 The microscopic appearance of the three major elements in blood: red blood cells, white blood cells, and platelets.

Pathophysiology and Perfusion

Perfusion is the circulation of blood within an organ or tissue in adequate amounts to meet the cells' current needs for oxygen, nutrients, and waste removal. Blood enters an organ or tissue first through the arteries, then the arterioles, and finally the capillary beds **Figure 25-5**. As it passes through the capillaries, the blood delivers nutrients and oxygen to the surrounding cells and picks up the wastes they have generated.

Blood must pass through the cardiovascular system fast enough to maintain adequate circulation throughout the body and to avoid clotting, yet slow enough to allow each cell time to exchange oxygen and nutrients for carbon dioxide and other waste products. Although some tissues never rest and require a constant blood supply, most require a large volume of circulating blood only intermittently, with less required when at rest. For example, skeletal muscles require a minimal blood supply during sleep, as opposed to a large blood supply during exercise. Another example is the gastrointestinal tract, which requires a high flow of blood after a meal. After digestion is completed, however, the gastrointestinal tract functions well with only a small fraction of that blood flow.

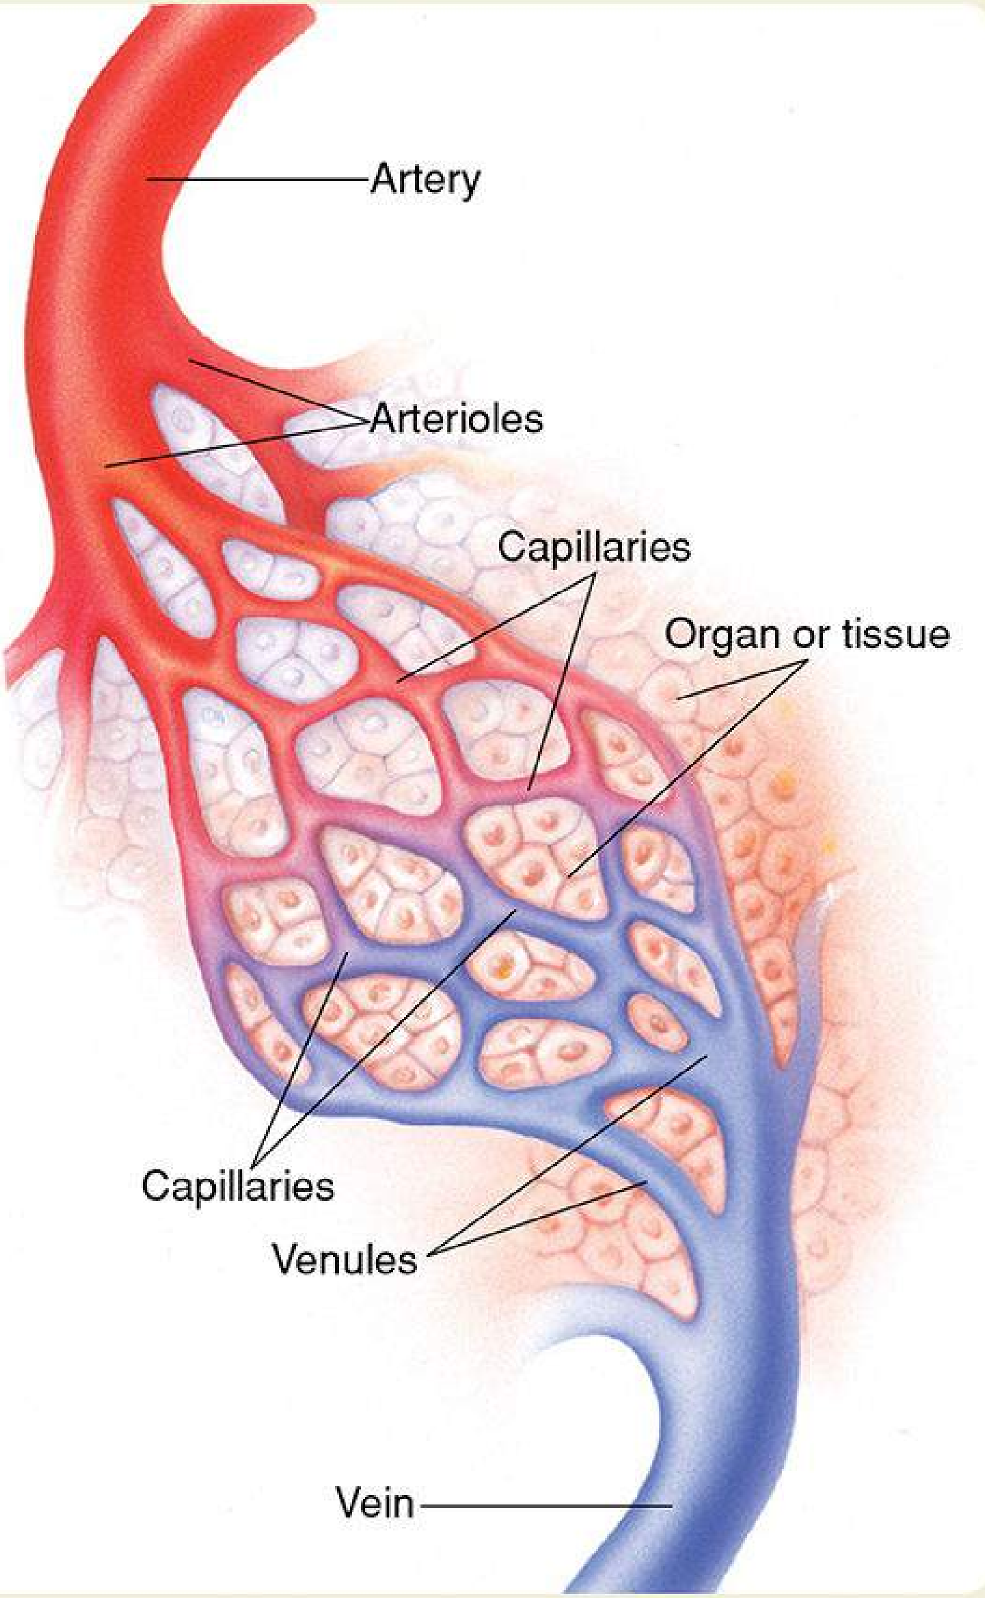

Figure 25-5 Perfusion occurs when blood circulates through tissues or an organ to provide the necessary oxygen and nutrients and remove waste products.

All organs and organ systems of the human body depend on adequate perfusion to function properly. Some organs require a rich supply of blood and do not tolerate interruption of blood supply for even a few minutes without sustaining damage. If perfusion to these organs is interrupted, then dysfunction and failure of that organ system will occur. The death of an organ system can quickly lead to the death of the patient. Emergency medical care is designed to support adequate perfusion of these critical organs and organ systems, listed in Table 25-1, until the patient arrives at the hospital.

The heart requires constant perfusion to function optimally; without it, cells in the brain and spinal cord start to die after 4 to 6 minutes. (Remember that cells of the central nervous system do not have the capacity to regenerate.) Without adequate perfusion, the lungs can survive only 15 to 20 minutes and kidneys can be damaged after 45 minutes. Skeletal muscle demonstrates evidence of injury after 2 to 3 hours of inadequate perfusion, while the gastrointestinal tract can tolerate slightly longer periods. These times are based on a normal core body temperature (98.6°F [37.0°C]). An organ or tissue that is kept at a considerably lower temperature may be better able to resist damage from hypoperfusion.

Table 25-1 Critical Organs and Corresponding Organ Systems

Organ	Organ System
Heart	Cardiovascular system
Brain	Central nervous system
Lungs	Respiratory system
Kidneys	Renal system

External Bleeding

Hemorrhage means bleeding. External bleeding is visible hemorrhage. Examples include nosebleeds and bleeding from open wounds. As an EMT, you must understand how to control external bleeding.

The Significance of External Bleeding

With serious external bleeding, it is often difficult to determine the amount of blood loss because blood will look different on different surfaces, such as when it is absorbed in clothing, when it has been diluted in water, or when the environment is dark. It is important to estimate the amount of external blood loss; however, treatment should be based on the patient's presentation and MOI.

The typical adult male body contains approximately 70 mL of blood per kilogram of body weight, whereas the adult female body contains approximately 65 mL of blood per kilogram of body weight. Therefore, a typical adult man weighing 175 pounds (79 kg) has a total blood volume of about 10 to 12 pints (6 L). The body cannot tolerate an acute blood loss of greater than 20% of this total blood volume, or more than 2 pints (about 1 liter) in the average adult. With significant blood loss, adverse changes in vital signs will occur, including increased heart and respiratory rates and decreased blood pressure. Because infants and children have less blood volume compared with adults, these effects are seen with smaller amounts of blood loss. For example, a 1-year-old has a typical total blood volume of about 27 oz (800 mL); the child will show significant symptoms of blood loss after only 3 to 6 oz (100 to 200 mL) of blood loss, or less than half the volume of liquid in a 12-oz (350-mL) can of soda.

How well a patient's body can compensate for blood loss is related to how rapidly the blood loss occurs. A healthy adult can comfortably donate 1 unit, or roughly 1 pint (500 mL) of blood within 15 to 20 minutes and adapt well to this decrease in blood volume. If this volume of blood loss occurs during a much shorter period, however, symptoms of **hypovolemic shock**, a condition in which low blood volume results in inadequate perfusion and even death, might develop. The age and preexisting health of the patient should also be considered.

In any situation, severe blood loss presents an immediate life threat. Your priority is to quickly control major external bleeding, even before you address airway and breathing concerns.

Safety Tips

Remember that a bleeding patient may expose you to potentially infectious body fluids; therefore, always follow standard precautions when treating patients with external bleeding. Wear gloves and eye protection in all situations, and wear a gown and mask if there is a risk of blood splatter **Figure 25-6**. Always keep spare gloves with you. Avoid direct contact with body fluids if possible. Take special care if you have an open sore, cut, scratch, or ulcer. Also remember that frequent, thorough handwashing between patients and after every call is a simple yet important protective measure. When you care for multiple patients, remember to wash your hands frequently and don clean gloves between patients to avoid cross-contamination of body fluids and blood. If soap and water are unavailable, use a waterless hand sanitizer, and wash with soap and water as soon as possible.

Figure 25-6 Your safety is paramount. Always wear proper protective equipment when caring for a patient who is bleeding.

Characteristics of External Bleeding

Injuries and some illnesses can disrupt blood vessels and cause external bleeding. You should consider bleeding to be severe if:

- The patient has a poor general appearance and has no response to external stimuli.
- Assessment reveals signs and symptoms of shock (hypoperfusion).
- You note a significant amount of blood loss.
- The blood loss is rapid and ongoing.
- You cannot control the bleeding.
- It is associated with a significant MOI.

Typically, arterial bleeding from an open artery is bright red (because it is oxygen rich) and spurts in time with the pulse. The pressure that causes the blood to spurt also makes this type of bleeding difficult to control. As the amount of blood circulating in the body drops, so does the patient's blood pressure and, eventually, the arterial spurting.

Venous bleeding from an open vein is darker than arterial blood (because it is oxygen poor) and can flow slowly or rapidly, depending on the size of the vein. Because it is under less pressure, most venous blood does not spurt and is easier to manage; however, it can be profuse and life threatening. Capillary bleeding from damaged capillary vessels is dark red and oozes from a wound steadily but slowly. Venous and capillary blood is more likely to clot spontaneously than arterial blood **Figure 25-7**.

On its own, bleeding tends to stop rather quickly, within about 10 minutes, in response to internal mechanisms and exposure to air. When a person's skin is broken, blood flows rapidly from the open blood vessel. Soon afterward, the cut ends of the blood vessel begin to narrow (**vasoconstriction**), reducing the amount of bleeding. Then a clot forms, plugging the hole and sealing the injured portions of the blood vessel. This process is called **coagulation**. With a severe injury, the damage to the blood vessel may be so great that a clot cannot completely block the hole. Bleeding will never stop if an effective clot does not form, unless the injured blood vessel is completely cut off from the main blood supply by direct pressure or a tourniquet.

Figure 25-7 **A.** Bleeding from capillary vessels is dark red and oozes from the wound slowly but steadily. **B.** Venous bleeding is darker than arterial bleeding and flows steadily. **C.** Arterial bleeding is characteristically bright red and spurts in time with the pulse.

Despite the efficiency of the circulatory system, it may fail in certain situations. Movement, disease process, certain medications (such as blood thinners), removal of bandages, the external environment, or body temperature commonly affect the blood's clotting factors. Occasionally, blood loss is very rapid. In these cases, the patient might die before clotting occurs.

A small portion of the population lacks one or more of the blood's clotting factors, a condition called **hemophilia**. There are several forms of hemophilia, most of which are hereditary and some of which are severe. Sometimes bleeding occurs spontaneously in patients with hemophilia. Because the patient's blood does not clot effectively, all injuries, no matter how trivial, are potentially serious. Transport a patient with hemophilia immediately.

Words of Wisdom

If a bandage has already been applied to control bleeding before your arrival on the scene, obtain a description of the wound and the amount of bleeding from the patient or bystanders. If blood has seeped through the dressing, do not remove it; most likely the clotting process has already begun and removing the dressing will disturb the clot. Instead, apply a clean dressing on top of the first one to reinforce it. You can also observe the old dressing to estimate the amount of blood loss.

Internal Bleeding

Internal bleeding is any bleeding that occurs in a cavity or space inside the body. Internal bleeding can be very serious, especially because it is not easy to detect immediately. Injury or damage to internal organs commonly results in extensive internal bleeding, which can cause hypovolemic shock before you realize the extent of blood loss. A person with a bleeding stomach ulcer may sustain a large amount of blood loss very quickly. Similarly, a person who has a lacerated liver or a ruptured spleen may sustain a considerable amount of blood loss within the abdomen, yet the patient may have no outward signs of bleeding.

Broken bones, especially broken ribs, also may cause serious internal blood loss. Sometimes this bleeding extends into the chest cavity and the soft tissues of the chest wall. A broken femur can easily result in the loss of 2 pints (about 1 liter) or more of blood into the soft tissues of the thigh. Often the only signs of such bleeding are local swelling and bruising (called a **contusion**, or **ecchymosis**) caused by the accumulation of blood around the ends of the broken bone. Severe pelvic fractures may result in life-threatening hemorrhage.

Always be alert to the possibility of internal bleeding. Assess the patient for related signs and symptoms, particularly if the MOI is significant. If you suspect that a patient is bleeding internally, treat for shock and promptly transport him or her to the hospital.

Mechanism of Injury for Internal Bleeding

A high-energy MOI should increase your index of suspicion for the possibility of serious, unseen injuries such as internal bleeding in the abdominal cavity. Internal bleeding is possible whenever the MOI suggests that severe forces affected the body. These forces include blunt and penetrating trauma. Internal bleeding commonly occurs as a result of falls, blast injuries, and motor vehicle crashes. Remember that internal bleeding can result from penetrating trauma as well.

As you assess a patient, look for signs of injury using the DCAP-BTLS mnemonic (Deformities, Contusions, Abrasions, Punctures, Burns, Tenderness, Lacerations, and Swelling) as well as any other signs of injury. Always suspect internal bleeding in a patient who has sustained a penetrating injury or blunt trauma.

Nature of Illness for Internal Bleeding

Internal bleeding is not always caused by trauma. Many illnesses can cause internal bleeding. Some of the more common causes of nontraumatic internal bleeding include bleeding ulcers, bleeding from the colon, ruptured ectopic pregnancy, and aneurysms.

Abdominal tenderness, guarding, rigidity, pain, and distention are frequent in these situations but are not always present. In older patients, dizziness, faintness, or weakness may be the first sign of non-traumatic internal bleeding. Ulcers or other gastrointestinal problems may cause vomiting of blood or bloody diarrhea.

It is not as important for you to know the specific organ involved as it is to recognize the patient is in shock. When combined with prompt transport decisions and limited time spent at the scene, the rapid recognition of a patient in shock should result in the rapid administration of potentially life-saving treatments.

Signs and Symptoms of Internal Bleeding

The most common symptom of internal bleeding is pain. Significant internal bleeding will generally cause swelling in the area of bleeding, but swelling is often undetected until massive blood loss has occurred. Internal bleeding is most common in head, extremity, and pelvic injuries and is often associated with significant abdominal trauma. Intra-abdominal bleeding will often cause pain and distention. Bleeding into the chest cavity or lung may cause dyspnea, tachycardia, **hemoptysis** (the coughing up of bright red blood), and hypotension. A **hematoma**, a mass of blood that has collected in the soft tissues beneath the skin, indicates bleeding into soft tissues and may be the result of a minor or a severe injury. Bruising or ecchymosis may not be present initially, and the only sign of severe pelvic or abdominal trauma may be redness, skin abrasions, or pain.

Bleeding from any body opening, however slight, is serious. It usually indicates internal bleeding that is not easy to see or control. Bright red bleeding from the mouth or rectum or blood in the urine (**hematuria**) may suggest serious internal injury or disease. Nonmenstrual vaginal bleeding is always significant.

Other signs and symptoms of internal bleeding in trauma and medical patients include the following:

- **Hematemesis**. The vomiting of blood. The vomitus may be bright red or dark red. If the blood has been partially digested, the vomitus may look like coffee grounds.
- **Melena**. Black, foul-smelling, tarry stool that contains digested blood.
- **Pain, tenderness, bruising, guarding, or swelling.** These signs and symptoms may mean that a closed fracture is bleeding.
- **Broken ribs, bruises over the lower part of the chest, or a rigid, distended abdomen.** These signs and symptoms may indicate a lacerated spleen or liver. Patients with an injury to one of these organs may have referred pain in the right shoulder (indicating the liver is injured) or left shoulder (indicating the spleen is injured). Suspect internal abdominal bleeding in a patient with referred pain.

The first sign of hypovolemic shock is a change in mental status, such as anxiety, restlessness, or combativeness. In nontrauma patients, weakness, faintness, or dizziness on standing is another early sign. Changes in skin color or pallor (pale skin) are often seen in both trauma and medical patients. Later signs of hypovolemic shock suggesting internal bleeding include the following:

- Tachycardia
- Weakness, fainting, or dizziness at rest
- Thirst
- Nausea and vomiting
- Cold, moist (clammy) skin
- Shallow, rapid breathing
- Dull eyes
- Slightly dilated pupils that are slow to respond to light
- Capillary refill time longer than 2 seconds in infants and children
- Weak, rapid (thready) pulse
- Decreasing blood pressure
- Altered level of consciousness

Patients with these signs and symptoms, particularly in the setting of significant MOI, require prompt transport, preferably to a trauma center. See Chapter 12, *Shock*, for a review of hypovolemic shock.

Patient Assessment for External and Internal Bleeding

Scene Size-up

As you approach the patient, be alert to potential hazards to yourself and the crew, bystanders, and the patient. At vehicle crashes, ensure there are no fluids leaking from the vehicle or energized power lines in the area where you will be working. In incidents involving violence, such as assaults or patients with gunshot wounds, make sure that police have advised the scene is safe. You may need to stage several blocks away until law enforcement personnel have secured the area.

Follow standard precautions. Place several spare pairs of gloves in your pocket for easy access in case your gloves tear or there are multiple patients with bleeding. If you enter a residence, be alert for anxious bystanders, family members, and even pets, as they may become hostile. Determine the number of patients needing care. Consider early on what you additional resources you may need, and verify as you begin your assessment.

Determine the nature of the illness (NOI) by observing signs (such as bloody emesis) or the MOI (such as an upturned step stool). Consider the need for spinal immobilization and/or additional resources, such as an advanced life support unit. Be sure to also consider environmental factors in your decision making. For example, caring for a sick or injured victim of a motor vehicle crash on a clear, sunny day is different from treating the same victim during a snowstorm. Extremely hot or cold weather can worsen a patient's overall condition.

Special Populations

In older patients, dizziness, syncope, or weakness may be the first sign of nontraumatic internal hemorrhage.

Primary Assessment

When you treat a patient with significant blood loss from a visible wound or with suspected internal bleeding, do not be distracted from identifying and managing life threats, which is the focus of your primary assessment. As you approach a trauma patient, note important indicators that may signal the seriousness of the patient's condition. For example, a patient with external bleeding may have bloodstains on his or her clothing. Be aware of obvious signs of injury and distress, such as facial grimace. Determine the patient's gender and age.

Perform a rapid exam of the patient, look for life threats, and treat them as you find them. If the patient has obvious, life-threatening external bleeding, remember to address it *first* (even before airway and breathing) by controlling it quickly; then assess the ABCs and provide treatment. If direct pressure is ineffective in controlling massive hemorrhage from an arm or leg, the patient may require a tourniquet before the airway is opened. Next, assess skin color: cool, moist skin that is pale or gray suggests a perfusion problem. Determine the patient's level of consciousness using the AVPU scale (Awake and Alert, Responsive to Verbal Stimuli, Responsive to Pain, Unresponsive). Does the patient have a patent (open) airway? If the patient is able to speak, then this indicates the airway is patent. What is the mental status of the patient? These indicators will help you assess how sick the patient is, which will help you develop an index of suspicion for serious illness or injuries related to internal bleeding.

Consider the need for spinal immobilization. At the same time, ensure a patent airway, look for adequate breathing, and check for breath sounds. If necessary, provide the patient with high-flow oxygen or assist ventilation with a bag-valve mask (BVM) or nonrebreathing mask, depending on the patient's level of consciousness and rate and quality of breathing. If the patient is unconscious, the airway may be obstructed. Insert an oropharyngeal (oral) airway to secure the airway.

Words of Wisdom

Non–life-threatening bleeding, such as from an abrasion, can be bandaged later in the assessment as necessary. However, significant and ongoing bleeding, whether internal or external, is an immediate life threat.

Quickly assess pulse rate and quality; determine the condition, color, and temperature of the skin; and check the capillary refill time to help establish the potential for internal bleeding and shock. Treat the patient for shock, if needed, by applying oxygen, improving circulation, and maintaining a normal body temperature.

The results of your initial general impression and your assessment of the ABCs will help you decide whether to manage the patient on scene or transport immediately and manage the patient en route to the hospital. If the patient has signs and symptoms of internal bleeding or airway or breathing problems, provide rapid transport to the most appropriate facility. The condition of patients with significant bleeding will quickly become unstable. Signs such as tachycardia, tachypnea, low blood pressure, weak pulse, and clammy skin are signs of impending circulatory collapse and indicate the need for rapid transport.

History Taking

After the primary assessment is complete, investigate the chief complaint and be alert for signs or symptoms of other injuries due to the MOI and/or NOI. Remember, internal bleeding can be found in both medical and trauma patients. For example, ectopic pregnancy, gastrointestinal bleeding, bleeding from a dialysis shunt, and severe nosebleed are medical causes of potential internal bleeding. If signs and symptoms of internal bleeding are not obvious, look more carefully during the patient assessment process. In a responsive trauma patient with an isolated injury and a limited MOI, consider a detailed physical examination of the specific area before you assess vital signs and obtain a history.

When you encounter a patient who is bleeding, avoid focusing solely on the bleeding. With significant trauma, assess the entire patient, looking for the source of the problem, any preexisting illnesses, and other issues.

If the patient is responsive, obtain a SAMPLE history (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury). It is important to ask the patient if he or she takes blood-thinning medications because bleeding is generally more profuse and difficult to control in patients who take blood thinners. Blood thinners are often prescribed for patients with a history of stroke, pulmonary embolism, or heart attack. Common blood thinners include aspirin, warfarin (Coumadin), rivaroxaban (Xarelto), dabigatran (Pradaxa), apixaban (Eliquis), and clopidogrel (Plavix).

YOU are the Provider — PART 2

You arrive at the scene and find the patient standing outside in front of the shop. He has a towel wrapped around his left wrist; it is soaked in blood and you can see a large amount of blood on the ground. He is conscious and alert but anxious. He tells you he cut his wrist on a table saw when his arm slipped and ran into the blade.

Recording Time: 0 Minutes	
Appearance	Anxious
Level of consciousness	Conscious and alert
Airway	Open; clear of secretions or foreign bodies
Breathing	Increased rate; adequate depth
Circulation	Bleeding from the left wrist; skin is cool, pale, and dry; pulse is rapid and strong

3. Is the patient effectively controlling the bleeding from his injury?
4. What should be your initial treatment priority?

If the patient is unresponsive, obtain medical history information from medical alert tags or ask family members or bystanders if they have any information. Look for signs and symptoms of hypoperfusion and determine how much blood loss has occurred.

Secondary Assessment

Unless you discover a life-threatening condition during the primary assessment, next conduct a secondary assessment, which is a detailed, comprehensive examination of the patient to uncover injuries or illness that may have been missed during the primary assessment. Record vital signs, complete an assessment of pain, and attach appropriate monitoring devices to quantify oxygenation and circulatory status. In some instances, such as a critically injured patient or a short transport time, there may not be time to conduct a secondary assessment.

Assess all areas for DCAP-BTLS to identify underlying or secondary injuries. For isolated injuries such as pain in the ankle, assess that area only (detailed physical examination). When examining the head, be alert for uncontrolled bleeding from large scalp lacerations. In the abdomen, feel all four quadrants for tenderness or rigidity. In the extremities, record pulse, motor, and sensory function.

Obtain baseline vital signs; this allows you to more easily identify any changes that may occur during treatment. In an adult patient, a systolic blood pressure of less than 100 mm Hg with a weak, rapid pulse and cool, moist skin that is pale or gray are signs of hypoperfusion that require immediate attention.

In geriatric patients and patients who take certain blood pressure medications, the pulse rate may not increase with early shock; therefore, try to determine the patient's baseline blood pressure and quickly obtain a medical history and list of medications to help you better assess the patient's condition.

Reassessment

Because the signs and symptoms of internal bleeding are often slow to develop, it is important to reassess the patient frequently. Children especially will compensate well for blood loss and then "crash" quickly. The reassessment is your best opportunity to determine whether your patient's condition is improving or getting worse and to determine the effectiveness of any interventions and treatments. Reassess an unstable patient every 5 minutes and a stable patient every 15 minutes.

Whenever you suspect significant bleeding, either external or internal, provide high-flow oxygen. If significant bleeding is visible, control external bleeding as shown in Skill Drill 25-1. Using multiple methods to control external bleeding usually works best. If the patient has signs of hypoperfusion, provide aggressive treatment for shock and rapid transport to the appropriate hospital. If internal bleeding is suspected, apply high-flow oxygen via a nonrebreathing mask and provide rapid transport to the hospital. See Skill Drill 25-4 for additional steps.

Do not delay transport of a patient to complete an assessment, particularly when significant bleeding is present, even if the bleeding is controlled. The assessment can be started during transport.

In patients with severe external bleeding, it is important to recognize, estimate, and report the amount of blood loss that has occurred and how rapidly or over what period of time it occurred. For example, you may report that approximately 2 pints (about 1 liter) of blood loss occurred or that the bleeding soaked through three trauma dressings. Report this information to hospital personnel during transport to allow the hospital to evaluate needed resources, such as the availability of surgical suites, surgeons, and other specialty providers. Your transfer report at the hospital should update hospital personnel on how your patient has responded to your care. Be sure your paperwork reflects all of the patient's injuries and the care you have provided.

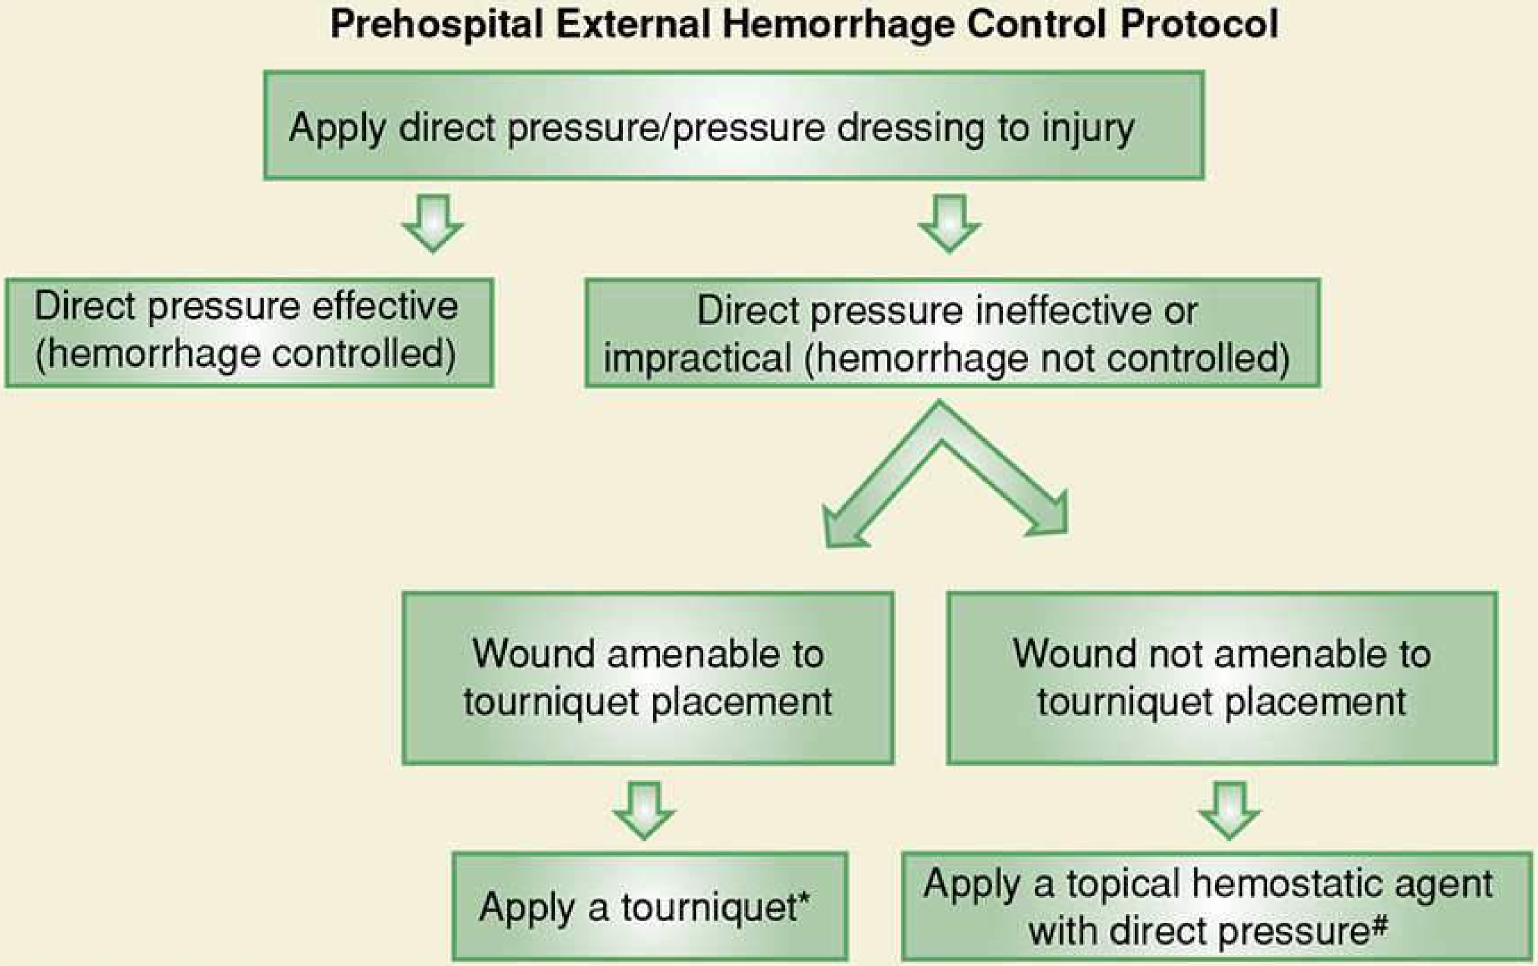
Emergency Medical Care for External Bleeding

Before you care for a patient with obvious external bleeding, remember to follow standard precautions. This includes gloves and eye protection at a minimum and may include a mask and gown. As with all patient care, make sure the patient has an open airway and is breathing adequately. Provide high-flow oxygen, then concentrate on controlling the bleeding. If obvious, life-threatening bleeding is present, control it as quickly as possible.

Several methods are available to control external bleeding. The most commonly used include:

- Direct, even pressure
- Pressure dressings and/or splints
- Tourniquets

To control bleeding, follow the steps shown in **Figure 25-8**. Begin with direct pressure, and move to the next steps if direct pressure does not control the bleeding.



*Use of tourniquet for extremity hemorrhage is strongly recommended if sustained direct pressure is ineffective or impractical; Use a commercially-produced, windlass, pneumatic, or ratcheting device, which has been demonstrated to occlude arterial flow and avoid narrow, elastic, or bungee-type devices; Utilize improvised tourniquets only if no commercial device is available; Do not release a properly-applied tourniquet until the patient reaches definitive care.

#Apply a topical hemostatic agent, in combination with direct pressure, for wounds in anatomic areas where tourniquets can not be applied and sustained direct pressure alone is ineffective or impractical; Only apply topical hemostatic agents in a gauze format that supports wound packing; Only utilize topical hemostatic agents which have been determined to be effective and safe in a standardized laboratory injury model.

Figure 25-8 Steps of bleeding control.

Most cases of external bleeding can be controlled simply by applying direct, local pressure to the bleeding site. This method is by far the most effective way to control external bleeding. (Previously, elevation of the extremity was also recommended, but there is no evidence it helps control bleeding and it may aggravate other injuries.) Pressure stops the flow of blood and permits normal coagulation to occur. You may apply pressure with your gloved fingertip or hand over the top of a sterile dressing if one is immediately available. If there is an object protruding from the wound, never remove it unless it is in the cheek and blocking the patient's airway. Apply bulky dressings to stabilize the impaled object in place, and apply pressure as best you can for at least 5 minutes without interruption.

In most cases, direct pressure will stop the bleeding. Once you have applied a dressing to control bleeding, create a pressure dressing to maintain the pressure by firmly wrapping a sterile, self-adhering roller bandage around the entire wound. Use 4-inch × 4-inch (101-mm × 101-mm) sterile gauze pads for small wounds and sterile universal dressings for larger wounds.

Cover the entire dressing with the bandage above and below the wound, and stretch the bandage tight enough to control bleeding. If you were able to palpate a distal pulse before applying the dressing, then you should still be able to palpate a distal pulse on the injured extremity after applying the pressure dressing. If bleeding continues, then the dressing is insufficient. If the bleeding oozes slowly through the dressing, then reinforce it by applying more dressings on top of it. Do not remove a dressing until a physician has evaluated the patient.

YOU are the Provider — PART 3

You immediately apply direct pressure to patient's wrist with a dry, sterile dressing and apply a splint. You then apply a pressure dressing. This effectively controls the patient's bleeding. While you further assess the patient, your partner applies high-flow oxygen, obtains the patient's vital signs, and inquires about his medical history. The patient denies having any medical problems and states he does not take any medications.

Recording Time: 5 Minutes	
Respirations	24 breaths/min; regular and adequate
Pulse	120 beats/min; strong and regular
Skin	Cool, pale, and dry
Blood pressure	104/60 mm Hg
Spo_2	94% (on oxygen)

5. What are the components of the cardiovascular system?
6. What factors determine the severity of external bleeding?

Bleeding will almost always stop when the pressure of the dressing exceeds arterial pressure. This will assist in controlling bleeding and helping blood to clot.

If direct pressure fails to immediately stop hemorrhage, then apply additional manual pressure through the dressing and apply a tourniquet above the level of the bleeding. If this is not possible because the bleeding is too proximal, then apply direct pressure and hold it until you arrive at the hospital.

Skill Drill 25-1 illustrates the basic techniques to control external bleeding:

1. Follow standard precautions.
2. Maintain the airway with cervical spine immobilization if the MOI suggests the possibility of spinal injury.
3. Apply direct pressure over the wound with a dry, sterile dressing Step 1.
4. Apply a pressure dressing Step 2.
5. If direct pressure and a pressure dressing are not immediately effective, apply a tourniquet to an extremity above the level of the bleeding Step 3.
6. Tighten the tourniquet until pulses are no longer palpable distal to the tourniquet Step 4. Position the patient supine unless there is a reason not to; for example, underlying respiratory issues.

Skill Drill 25-1 Controlling External Bleeding

Step 1

Take standard precautions. Apply direct pressure over the wound with a dry, sterile dressing.

Step 2

Apply a pressure dressing.

Step 3

If direct pressure with a pressure dressing does not control bleeding, apply a tourniquet above the level of the bleeding.

Step 4

Tighten the tourniquet until distal pulses are no longer palpable. Properly position the patient. Apply high-flow oxygen as necessary. Keep the patient warm. Transport promptly.

7. Apply high-flow oxygen, as necessary, once hemorrhage is controlled. Keep the patient warm. Transport promptly.

Words of Wisdom

Much of the bleeding associated with broken bones occurs because the sharp ends of the bones cut muscles and other tissues. As long as a fracture remains unstable, the bone ends will move and continue to injure partially clotted blood vessels. Therefore, immobilizing a fracture and decreasing movement will help control bleeding. Often, a simple splint will quickly control bleeding associated with a fracture **Figure 25-9**. If the patient is unstable, however, do not waste time splinting a fracture.

Figure 25-9 Use of a simple splint will often quickly control bleeding associated with a fracture. If a fracture is not immobilized, then the bone ends are free to move and may continue to injure partially clotted blood vessels.

▶ Hemostatic Agents

A **hemostatic agent** is any chemical compound that slows or stops bleeding by assisting with clot formation. Hemostatic agents are primarily utilized in military medicine to stop profuse bleeding. They come in two forms—a granular powder, which can be inserted into small wounds to create a tight seal (such as a gunshot wound), and gauze impregnated with a clay substance, which speeds blood clot formation. Gauze can also be packed into larger wounds to control hemorrhage.

Hemostatic agents can be used together with direct pressure when direct pressure alone is ineffective, such as with massive chest injuries, or when tourniquet placement is impossible **Figure 25-10**. These agents have the potential to improve prehospital bleeding control, especially when transport time to definitive care is prolonged. However, the use of hemostatic agents in EMS remains largely experimental. Because of the lack of scientific evidence demonstrating an effect on survival in civilian settings, most local protocols do not allow for their use. Be aware of and follow your local protocols.

Figure 25-10 When a wound is located on a part of the body where tourniquet placement is impossible, a hemostatic agent may be applied to increase clotting. Follow your local protocols.

Courtesy of Medtrade Products Ltd., UK.

Tourniquets

If direct pressure does not control extremity bleeding, then use a **tourniquet**. The tourniquet is especially useful if a patient has substantial bleeding from an extremity injury. Several different types of commercial tourniquets are on the market, including the mechanical advantage tourniquet (MAT), the combat application tourniquet (CAT), the ratcheting medical tourniquet (RMT), and the special weapons and tactics tourniquet (SWAT-T) **Figure 25-11**.

Follow the manufacturer's instructions for the specific type of tourniquet used by your service. Follow the steps in Skill Drill 25-2 to apply a commercial tourniquet.

1. Follow standard precautions.
2. Apply direct pressure over the bleeding site.
3. Place the tourniquet around the extremity high and tight, proximal to the bleeding site (in the axillary region for upper extremity injuries and at the groin for lower extremity injuries) Step 1.
4. Click the buckle into place and pull the strap tight.

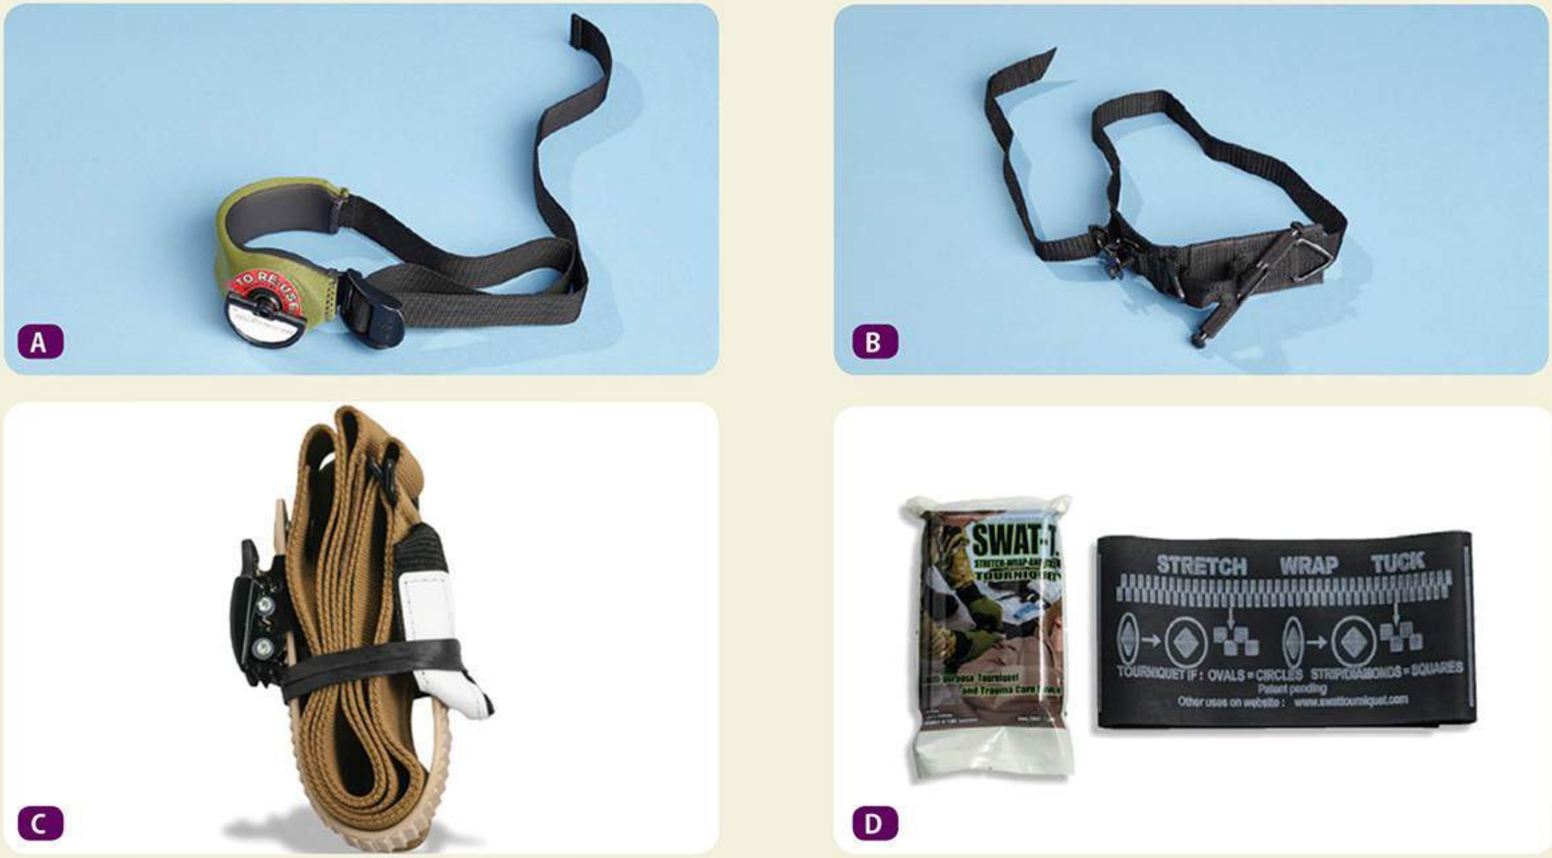


Figure 25-11 Different examples of commercial tourniquets. **A.** Mechanical advantage tourniquet (MAT). **B.** Combat application tourniquet (CAT). **C.** Ratcheting medical tourniquet (RMT). **D.** Special weapons and tactics tourniquet (SWAT-T).

Skill Drill 25-2 Applying a MAT Commercial Tourniquet

Step 1

Apply pressure over the bleeding site and place the tourniquet proximal to the injury (in the axillary region for upper extremity injuries and at the groin for lower extremity injuries).

Step 2

Click the buckle into place, pull the strap tight, and turn the tightening dial clockwise until pulses are no longer palpable distal to the tourniquet or until bleeding has been controlled.

Words of Wisdom

If the patient has an open fracture of an extremity, bleeding can be substantial. Consider a tourniquet early if bleeding is not easily controlled with direct pressure or if pressure results in excessive pain. The method used to control severe external bleeding may be governed by local protocol, but regardless of the method, it must be quick and effective. Remember, uncontrolled bleeding may result in shock and death. Patients can bleed to death from extremity injuries. It is imperative that you use effective techniques to stop bleeding when you encounter it. Twist the stick or rod to tighten the tourniquet until the bleeding stops.

5. Turn the tightening dial clockwise until pulses are no longer palpable distal to the tourniquet or until bleeding has been controlled Step 2.
6. Do not release a tourniquet once applied, unless instructed to do so by medical control.

If a commercial tourniquet is unavailable, then follow these steps to apply a tourniquet using a triangular bandage and a stick or rod:

1. Fold a triangular bandage until it is 4 inches (101 mm) wide and six to eight layers thick.
2. Wrap the bandage around the extremity twice. Place the bandage high and tight, proximal to the injury (in the axillary region for upper extremity injuries and at the groin for lower extremity injuries).
3. Tie one knot in the bandage. Then place a stick or rod on top of the knot, and tie the ends of the bandage over the stick in a square knot.
4. Use the stick or rod as a handle, and twist it to tighten the tourniquet until the bleeding has stopped; then stop twisting Figure 25-12.
5. Secure the stick in place, and make the wrapping neat and smooth.
6. Write “TK” (for “tourniquet”) and the exact time (hour and minute) that you applied the tourniquet on a piece of adhesive tape. Securely fasten the tape to the patient’s forehead or write the time directly on the forehead with a marker. Notify hospital personnel on your arrival that your patient has a tourniquet in place. Record this same information on the ambulance run report form.

7. As a last resort, you can use a blood pressure cuff as a tourniquet. Position the cuff proximal to the bleeding point and inflate it just enough to stop the bleeding. Leave the cuff inflated. Monitor the gauge continuously to make sure that the pressure is not gradually dropping, which could allow the bleeding to restart. You may have to clamp the tube leading from the cuff to the inflating bulb with a hemostat to prevent loss of pressure. Consider wrapping the cuff with tape to prevent the Velcro from loosening under continuous high pressure.

Figure 25-12 Twist the stick or rod to tighten the tourniquet until the bleeding stops.

Whenever you apply a tourniquet, make sure you observe the following precautions:

- Do not apply a tourniquet directly over any joint. Always place the tourniquet proximal to the injury (in the axillary region for upper extremity injuries and at the groin for lower extremity injuries).
- Make sure the tourniquet is tightened securely.
- Never use wire, rope, a belt, or any other narrow material that could cut into the skin.
- If it is possible to do so without causing a delay, consider placing padding under the tourniquet as you apply it. This step may protect the skin and help with arterial compression.

- Never cover a tourniquet with a bandage. Leave it in full view.
- Do not loosen the tourniquet after you have applied it, unless directed by medical control. Hospital personnel will loosen it once they are prepared to manage the bleeding.

Mark the exact time the tourniquet was applied and be sure to communicate the time of application, the site of application, and the rationale for application clearly and specifically to hospital personnel upon arrival.

Splints

Air splints (commonly known as soft splints or pressure splints) can control internal or external bleeding associated with severe extremity injuries, such as fractures **Figure 25-13**. They also immobilize the fracture itself. An air splint acts like a pressure dressing applied to an entire extremity rather than to a small, local area. Use only approved, clean, or disposable valve stems when orally inflating air splints.

Rigid splints will help immobilize fractures as well as reduce pain and further damage to soft tissues. Once you have applied a splint, be sure to monitor pulse and motor and sensory function in the distal extremity.

Figure 25-13 Air splints can also be used to control bleeding because they act as a pressure bandage for the entire extremity. They are not as effective as tourniquets, however, and should never be used when a tourniquet is otherwise indicated.

Words of Wisdom

Research indicates that a **pelvic binder** **Figure 25-14** is an effective method to reduce the width of pelvic ring injuries. This helps to control internal bleeding, specifically bleeding associated with a life-threatening **open-book pelvic fracture**. It is important to provide the correct amount of force when applying a compression device. A pelvic sling is designed to prevent over- and under-compression. Use of a pelvic compression device may or may not be allowed in your service, so always follow local protocols. A pelvic compression device or binder.

Figure 25-14 A pelvic compression device or binder.

SAM Medical Products®.

YOU are the Provider — PART 4

The patient is placed onto the stretcher and loaded into the ambulance. He remains conscious and alert but is still anxious. You place him in a supine position and cover him with a blanket. Shortly before departing the scene, you reassess him and obtain another set of vital signs.

Recording Time: 10 Minutes	
Level of consciousness	Conscious and alert; anxious
Respirations	24 breaths/min; regular and adequate
Pulse	116 beats/min; strong and regular
Skin	Cool, pale, and dry
Blood pressure	112/70 mm Hg
Spo_2	98% (on oxygen)

7. How might a patient's outcome be affected if bleeding is internal rather than external?
8. What are the signs and symptoms of internal bleeding?

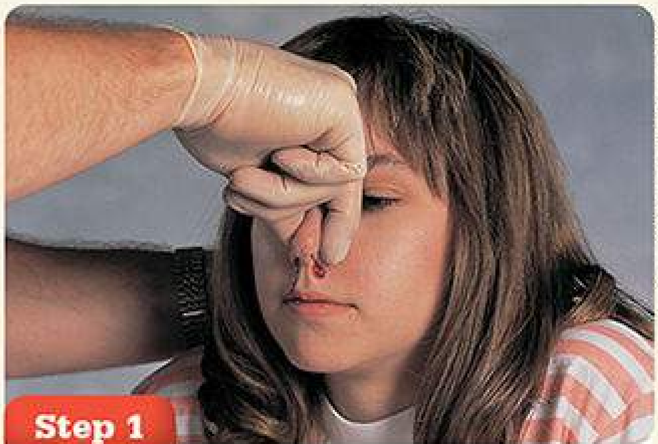
Bleeding From the Nose, Ears, and Mouth

Bleeding around the face always presents a risk for airway obstruction or aspiration. Maintain a clear airway by positioning the patient appropriately and using suction when indicated. Several conditions can result in bleeding from the nose, ears, and/or mouth, including the following:

- Skull fracture
- Facial injuries, including those caused by a direct blow to the nose
- Sinusitis, infections, nose drop use and abuse, dried or cracked nasal mucosa, intranasal use of street drugs (snorting), or other abnormalities
- High blood pressure
- Coagulation disorders
- Digital trauma (nose picking)

Epistaxis, or nosebleed, is a common emergency. Occasionally, it can cause blood loss great enough to send a patient into shock. Keep in mind that the blood that is visible may be only a small part of the total blood loss. Much of the blood may pass down the throat into the stomach as the patient swallows. A person who swallows a large amount of blood may become nauseated and start vomiting the blood, which is sometimes confused with internal bleeding. Most nontraumatic nosebleeds occur from sites in the septum (the tissue dividing the nostrils). You can usually handle this type of bleeding effectively by pinching the nostrils together. **Skill Drill 25-3** illustrates the basic techniques to control epistaxis.

Skill Drill 25-3 Controlling Epistaxis



Step 1

Position the patient sitting, leaning forward. Apply direct pressure, pinching the fleshy part of the nostrils together.

Step 2

Alternative method: Apply pressure with a rolled gauze bandage between the upper lip and gum. Calm the patient.

Step 3

Apply ice over the nose. Maintain pressure until bleeding is controlled. Initiate prompt transport while you or the patient applies pressure. Assess and treat for shock, including oxygen, as needed.

1. Follow standard precautions.
2. Help the patient to sit, leaning forward, with the head tilted forward. This position stops the blood from trickling down the throat or being aspirated into the lungs.
3. Apply direct pressure for at least 15 minutes by pinching the fleshy part of the nostrils together. This is the preferred method. This technique may also be performed by the patient Step 1.
4. Another option is to place a rolled 4-inch × 4-inch (101-mm × 101-mm) gauze bandage between the upper lip and the gum. Have the patient apply pressure by stretching the upper lip tightly against the rolled bandage and pushing it up into and against the nose. If the patient is unable to do this effectively, use your gloved fingers to press the gauze against the gum Step 2.
5. Keep the patient calm and quiet, especially if he or she has high blood pressure or is anxious. Anxiety tends to increase blood pressure, which could worsen the nosebleed.
6. Apply ice over the nose.

7. Maintain the pressure until the bleeding is completely controlled, usually no more than 15 minutes if this is the patient's only problem. Most often, failure to stop a nosebleed is the result of releasing the pressure too soon **Step 3**.
8. Provide prompt transport. You can initiate transport while having the patient maintain direct pressure or while maintaining pressure yourself.
9. Assess the patient for signs and symptoms of shock and treat appropriately.

Bleeding from the nose or ears following a head injury may indicate a skull fracture. In these cases, do not attempt to stop the blood flow. This bleeding may be difficult to control. Applying excessive pressure to the injury may force the blood leaking through the ear or nose to collect within the head. This could increase the pressure on the brain and possibly cause permanent damage. If you suspect a skull fracture, loosely cover the bleeding site with a sterile gauze pad to collect the blood and help keep contaminants away from the site. Apply light compression by wrapping the dressing loosely around the head **Figure 25-15**. If blood or drainage contains cerebrospinal fluid, you will see a characteristic staining of the dressing much like a target or halo shape **Figure 25-16**.

Figure 25-15 Bleeding from the ear after a head injury may indicate a skull fracture. Loosely cover the bleeding site with a sterile gauze pad and apply light compression by wrapping the dressing loosely around the head.

Figure 25-16 When cerebrospinal fluid is present in blood or drainage, a stain in the shape of a target or halo will appear.

Courtesy of Rhonda Hunt.

Emergency Medical Care for Internal Bleeding

Controlling internal bleeding or bleeding from major organs usually requires surgery or other procedures that must be done in the hospital. It is important for you to remain calm and reassure the patient. Keeping the patient as still and quiet as possible assists the body's clotting process. Provide high-flow oxygen and cover the patient with a blanket to maintain body temperature. You can usually control internal bleeding into the extremities in the field simply by splinting the extremity, usually most effectively with an air splint. Never use a tourniquet to control the bleeding from closed, internal, soft-tissue injuries. Follow the steps in **Skill Drill 25-4** to care for patients with possible internal bleeding.

1. Follow standard precautions.
2. Maintain the airway with cervical spine immobilization if the MOI suggests the possibility of spinal injury.
3. Administer high-flow oxygen and provide artificial ventilation as necessary Step 1.
4. Control all obvious external bleeding.
5. Treat suspected internal bleeding in an extremity by applying a splint Step 2.
6. Depending on local protocols, use a pelvic compression device or splint to control suspected internal bleeding from the pelvic area Step 3.
7. Monitor and record the vital signs at least every 5 minutes.
8. Keep the patient warm Step 4.
9. Give the patient nothing by mouth, not even small sips of water.
10. Provide prompt transport for all patients with signs and symptoms of hypoperfusion. Report any changes in the patient's condition to emergency department personnel.

YOU are the Provider PART 5

You continue to monitor the patient en route to the hospital and reassess his condition as appropriate. After reassessing the patient and his vital signs, you call your radio report into the receiving facility.

Recording Time: 17 Minutes	
Level of consciousness	Conscious and alert; restless
Respirations	20 breaths/min; regular and adequate
Pulse	110 beats/min; strong and regular
Skin	Cool, pale, and dry
Blood pressure	114/68 mm Hg
Spo_2	97% (on oxygen)

The patient is delivered to the hospital and you give your report to the attending physician. An intravenous line is started, and the patient is given normal saline to improve his perfusion status. He is taken to the operating room for repair of severed tendons, nerves, and an artery as a result of the injury.

9. How does the body typically respond to blood loss?

Skill Drill 25-4 Controlling Internal Bleeding

Step 1

Follow standard precautions. Maintain the airway and be alert for cervical spine injury. Administer oxygen and provide ventilation as necessary.

Step 2

Control obvious external bleeding and treat suspected internal bleeding using a splint. Apply a tourniquet for severe bleeding that cannot be controlled with direct pressure.

Step 3

Depending on local protocols, use a pelvic compression device or splint to control suspected internal bleeding in the pelvic region.

Step 4

Monitor vital signs and keep the patient warm.

YOU are the Provider — SUMMARY

1. What are the functions of arteries? What major arteries are located in the upper extremity?

Arteries are high-pressure blood vessels that distribute oxygenated blood throughout the body. The major arteries located in the upper extremity include the brachial artery, located on the inner (medial) aspect of the arm, just proximal to the elbow; the radial artery, located on the thumb-side (lateral) aspect of the wrist, proximal to the hand; and the ulnar artery, located on the opposite side of the forearm from the radial artery. The radial and ulnar arteries are the two terminal branches of the brachial artery.

2. Why is arterial bleeding more severe than venous bleeding?

Blood flow through the arteries is driven by contraction of the powerful left ventricle. Pressure in the arteries is much higher than pressure in the veins, so blood loss from an artery is generally more rapid and severe. Arterial bleeding is also more difficult to control than venous bleeding.

3. Is the patient effectively controlling the bleeding from his injury?

As evidenced by the blood-soaked towel and large amount of blood on the ground, it is clear that the patient is *not* effectively controlling the bleeding from his injury. Furthermore, you do not know how much blood loss he has sustained because he is standing outside—not in the area where the injury occurred. The fact that he is anxious and has cool, pale skin suggests significant external blood loss.

4. What should be your initial treatment priority?

You must take immediate action to control the patient's bleeding. His airway is patent, as evidenced by the fact that he is conscious, alert, and talking.

In most cases, direct pressure will control both venous and arterial bleeding. If direct pressure is ineffective in immediately controlling severe external bleeding, apply a tourniquet and transport. Only after the tourniquet is applied should you administer oxygen and consider splinting the arm.

5. What are the components of the cardiovascular system?

The cardiovascular system—the system responsible for supplying and maintaining adequate blood flow to the body's tissues and cells—consists of three components: the pump (the heart), the container (the blood vessels), and the fluid (blood and body fluids). These components of the cardiovascular system are interdependent—that is, they rely on each other to perform a common function.

6. What factors determine the severity of external bleeding?

The single most influential factor is the type and size of the blood vessel that is injured. A lacerated brachial artery, for example, will bleed more severely than a small vein in the leg. The patient's blood pressure and heart rate can also affect the severity of external bleeding. The greater the pressure on the arterial wall and the faster the heart rate, the more rapid the bleeding tends to be. The patient's medical history also should be considered. Bleeding in patients who take blood-thinning medications or in those with a bleeding disorder tends to be more difficult to control and may result in more blood loss because it takes longer for the blood to clot.

7. How might a patient's outcome be affected if bleeding is internal rather than external?

Internal bleeding is hidden and cannot be controlled in the prehospital setting. Many patients with internal bleeding do not have signs or symptoms of shock until a significant amount of blood loss has occurred. Overall, patients with internal bleeding have a higher mortality rate than those with external bleeding. Most of these deaths are the result of intrathoracic or intra-abdominal bleeding, in which surgical intervention is delayed. Internal bleeding can also be caused by multiple long bone fractures and pelvic fractures.

8. What are the signs and symptoms of internal bleeding?

Since internal bleeding is not visible, you must rely on your assessment skills and careful evaluation of the mechanism of injury. Signs and symptoms of internal bleeding are essentially those of shock: restlessness or anxiety; cool, pale, clammy skin; tachycardia; rapid, shallow breathing; and thirst. A late sign is hypotension. External indicators of internal bleeding in both medical and trauma patients include hematemesis (vomiting blood), melena (dark, tarry stools), and hemoptysis (coughing up blood). Other indicators of internal bleeding, which are more common in trauma patients, include redness or bruising, swelling, or tenderness over the injured area. Always be alert to the possibility of internal bleeding, particularly if the MOI is significant. Remember that if a trauma patient is in shock but does not have any obvious external signs of injury, suspect internal bleeding!

9. How does the body typically respond to blood loss?

If the typical adult sustains more than approximately 2 pints (about 1 L) of blood loss, significant changes in vital signs will occur, including increased heart and respiratory rates (compensatory phase) and, as a later sign, decreased blood pressure (indicating decompensation).

A loss of circulating blood volume is sensed by receptors in the body that send messages to the nervous system. In response, the sympathetic nervous system releases epinephrine and norepinephrine. Norepinephrine constricts the peripheral blood vessels (vasoconstriction), thus shunting blood from areas of lesser need (eg, skin and muscles) to areas of greater need (eg, heart, brain, kidneys, liver). If blood loss continues, however, the body's compensatory mechanisms will eventually fail, the patient's blood pressure will fall, and he or she will die.

Narrative

Dispatched for a patient with severe bleeding from the arm. Arrived on scene to find the patient, a 32-year-old male, standing in front of his place of employment, a woodworking shop. He was conscious and alert, but notably anxious. His airway was patent and his breathing, although increased, was producing adequate tidal volume. Patient had blood-soaked towel wrapped around his left wrist and a significant amount of blood was on the ground where he was standing. Patient stated that his hand slipped while he was working with a table saw and his left wrist ran across the blade. Immediately applied direct pressure to patient's wrist with sterile dressing and applied a splint. This intervention successfully controlled the bleeding; a pressure dressing was then applied to maintain bleeding control. Applied oxygen at 15 L/min via nonrebreathing mask and obtained vital signs, as noted above. Further assessment revealed that patient's skin was cool, pale, and dry. Patient denied significant past medical history and further denied taking any medications. Placed patient onto stretcher, covered him with a blanket, and placed him into the ambulance. Reassessed patient's vital signs and began transport to the hospital. Continued to monitor patient's condition en route; he remained conscious and alert, although anxious, and his vital signs remained stable. Reassessed bandaged wound and noted that the bleeding remained controlled. Called report to receiving facility and informed them of our arrival. Delivered patient to hospital without incident. Verbal report given to charge nurse. **End of report**

Prep Kit

Ready for Review

- Perfusion is the circulation of blood in adequate amounts to meet the cells' current needs for oxygen, nutrients, and waste removal.
- The cardiovascular systems contains three main parts: a working pump (heart), a container (blood vessels), and fluid (oxygen-carrying blood).
- Hypoperfusion, or shock, occurs when one or more of these three components is not working properly and the cardiovascular system fails to provide adequate perfusion.
- Always ask the patient if he or she takes blood-thinning medications (aspirin, warfarin) because bleeding is generally more profuse and difficult to control in these patients.
- Both internal and external bleeding can cause shock. You must know how to recognize and control both.
- The methods to control bleeding, in order, are:
  - Direct, local pressure
  - Pressure dressing
  - Tourniquet
  - Splinting device
- Bleeding from the nose, ears, and/or mouth may result from a skull fracture. Other causes include high blood pressure and sinus infection. Evaluate the MOI and consider the more serious problem of skull fracture.
- Bleeding around the face always presents a risk for airway obstruction or aspiration. Maintain a clear airway by positioning the patient appropriately and using suction when indicated.
- If bleeding is present at the nose and a skull fracture is suspected, place a gauze pad loosely under the nose.
- If bleeding from the nose is present and a skull fracture is not suspected, pinch both nostrils together for 15 minutes. If the patient is awake and has a patent airway, place a gauze pad inside the upper lip against the gum.
- Promptly transport any patient you suspect of having internal bleeding or significant external bleeding.
- If the MOI is significant, be alert to signs and symptoms of internal bleeding in the chest or abdomen, such as serious bruising or complaints of difficulty breathing or abdominal pain.
- Signs of serious internal bleeding include the following:
  - Vomiting blood (hematemesis)
  - Black, tarry stools (melena)
  - Coughing up blood (hemoptysis)
  - Distended abdomen
  - Broken ribs
- The signs and symptoms of internal bleeding are often slow to develop; therefore, reassess an unstable patient every 5 minutes and a stable patient every 15 minutes.

Vital Vocabulary

aorta The main artery that receives blood from the left ventricle and delivers it to all the other arteries that carry blood to the tissues of the body.

arterioles The smallest branches of arteries leading to the vast network of capillaries.

artery A blood vessel, consisting of three layers of tissue and smooth muscle, that carries blood away from the heart.

capillaries The small blood vessels that connect arterioles and venules; various substances pass through capillary walls, into and out of the interstitial fluid, and then on to the cells.

coagulation The formation of clots to plug openings in injured blood vessels and stop blood flow.

contusion A bruise from an injury that causes bleeding beneath the skin without breaking the skin; also see *ecchymosis*.

ecchymosis A buildup of blood beneath the skin that produces a characteristic blue or black discoloration as the result of an injury; also see *contusion*.

epistaxis A nosebleed.

hematemesis Vomited blood.

hematoma A mass of blood that has collected within damaged tissue beneath the skin or in a body cavity.

hematuria Blood in the urine.

hemophilia A hereditary condition in which the patient lacks one or more of the blood's normal clotting factors.

hemoptysis The coughing up of blood.

hemorrhage Bleeding.

hemostatic agent A chemical compound that slows or stops bleeding by assisting with clot formation.

hypoperfusion A condition in which the circulatory system fails to provide sufficient circulation to maintain normal cellular functions; also called shock.

hypovolemic shock A condition in which low blood volume, due to massive internal or external bleeding or extensive loss of body water, results in inadequate perfusion.

melena Black, foul-smelling, tarry stool containing digested blood.

open-book pelvic fracture A life-threatening fracture of the pelvis caused by a force that displaces one or both sides of the pelvis laterally and posteriorly.

pelvic binder A device to splint the bony pelvis to reduce hemorrhage from bone ends, venous disruption, and pain.

perfusion The circulation of blood within an organ or tissue in adequate amounts to meet the current needs of the cells.

shock A condition in which the circulatory system fails to provide sufficient circulation to maintain normal cellular functions; also called hypoperfusion.

tourniquet The bleeding control method used when a wound continues to bleed despite the use of direct pressure; useful if a patient is bleeding severely from a partial or complete amputation.

vasoconstriction The narrowing of a blood vessel, such as with hypoperfusion or cold extremities.

veins The blood vessels that carry blood from the tissues to the heart.

venules Very small, thin-walled blood vessels.

Assessment *in Action*

Your unit is dispatched to a roadside construction site for a blast-related injury. Fire department personnel arrive before you and radio to tell you that the scene is safe. On your arrival, you are informed that your patient is a 46-year-old man who had been blasting rock and had set the fuse too short. As he was leaving the area to seek cover from the explosion, he was blown forward onto a gravel area. He tells you that he remembers everything and he did not have a loss of consciousness. He also indicates that the entire front of his body hurts and he can't hear well. He denies having any past medical history or allergies and does not take any medications.

On examination, you find minor bleeding from his ears and some cuts and bruises to his arms. As you remove his clothing, you find that his chest and abdomen are bruised. He reports increasing pain and experiences severe trouble breathing. As you begin your transport, you notice that he is now has hematemesis, cool and clammy skin, tachycardia, and hypotension.

1. Which is the first important factor to consider in this scenario?

   A. Scene safety
   B. Mechanism of injury
   C. Level of consciousness
   D. Apparent injuries

2. After considering this, which factor should you consider next?

   A. Scene safety
   B. Mechanism of injury
   C. Level of consciousness
   D. Apparent injuries

3. The minor bleeding from his ears is most likely an indication of:

   A. a skull fracture.
   B. internal hemorrhaging.

C. cardiac distress.
D. an ocular cavity.

4. You determine that your patient is experiencing internal bleeding. What should you do first?

   A. Apply pressure dressings.
   B. Immobilize the injury.
   C. Administer oxygen.
   D. Apply cold packs.

5. Which condition is likely when signs of hypotension, tachycardia, and cool, clammy skin are found?

   A. Internal bleeding
   B. Shock
   C. Central nervous system depression
   D. Intracranial bleeding

6. Effective primary treatment of this patient should consist of:

   A. tourniquet use.
   B. direct pressure.
   C. rapid transport.
   D. placing the patient in the recovery position.

7. Which is the best position to immobilize and transport this patient?

   A. Supine
   B. Left lateral recumbent
   C. Fowler
   D. Prone

8. Is your patient's pain likely to be a result of internal or external injuries? Explain your answer.
9. What aspect of the MOI should make you suspect this patient has a serious injury?
10. What is the significance of hypotension in this patient?

CHAPTER

Knowledge Objectives

1. Describe the anatomy of the skin; include the layers of the skin. (pp 905–906)
2. Know the major functions of the skin. (p 906)
3. Name the three types of soft-tissue injuries. (p 907)
4. Describe the types of closed soft-tissue injuries. (pp 907–909)
5. Describe the types of open soft-tissue injuries. (pp 909–912)
6. Explain patient assessment of closed and open injuries. (pp 912–918)
7. Explain patient assessment of closed and open injuries in relation to airway management. (pp 914–915)
8. Explain the emergency medical care for closed and open injuries. (pp 918–919)
9. Explain the emergency medical care for an open wound to the abdomen. (pp 919–920)
10. Explain the emergency medical care for an impaled object. (pp 920–921)
11. Explain the emergency medical care for neck injuries. (pp 921–922)
12. Describe the steps of the emergency treatment of small animal bites, human bites, and rabies. (pp 922–923)
13. Explain how the seriousness of a burn is related to its depth and extent. (pp 924–925)
14. Define superficial, partial-thickness, and full-thickness burns; include the characteristics of each burn. (pp 925–926)
15. Explain the primary assessment of a burn patient. (pp 928–929)
16. Explain the emergency medical care for burn injuries. (p 931)
17. Describe the emergency management of chemical, electrical, thermal, inhalation, and radiation burns. (pp 931–938)
18. Know the functions of sterile dressings and bandages. (pp 938–939)

Skills Objectives

1. Demonstrate the emergency medical care of an open chest wound. (pp 911, 914–915, 918)
2. Demonstrate the emergency medical care of closed soft-tissue injuries. (p 918)
3. Demonstrate how to control bleeding from an open soft-tissue injury. (pp 918–919)
4. Demonstrate the emergency medical care of an open abdominal wound. (pp 919–920)
5. Demonstrate how to stabilize an impaled object. (pp 920–921, Skill Drill 26-1)
6. Demonstrate how to care for a burn. (pp 931–932, Skill Drill 26-2)
7. Demonstrate the emergency medical care of a chemical, electrical, thermal, inhalation, or radiation burn. (pp 931–938)

Introduction

As an EMT, you will be regularly called to care for victims with soft-tissue injuries. These injuries can be as simple as a cut or scrape or as serious as a life-threatening internal injury. It is important to not allow yourself to become distracted by dramatic wounds and make the critical mistake of neglecting more life-threatening conditions such as airway obstructions. It is your responsibility as an EMT to assess and treat each of these injuries within the current standard of care guidelines.

The soft tissues of the body can be injured through a variety of mechanisms. A blunt injury occurs when the energy exchange between the patient and an object is more than the tissues can tolerate, as discussed in Chapter 24, *Trauma Overview*. While a blunt injury does not penetrate the skin, a penetrating injury occurs when an object, such as a bullet or knife, breaks through the skin and enters the body. Barotrauma, commonly seen in blast injury victims, refers to injuries that result from sudden or extreme changes in air pressure. Burns may also result in soft-tissue injuries.

Soft-tissue trauma is a common form of injury. Open wounds accounted for approximately 4.1 million emergency department (ED) visits in 2011. In fact, wound care is one of the most frequently performed procedures in EDs across the United States. Most of these injuries require basic interventions such as wound irrigation, dressing, bandaging, and limited suturing.

Death resulting from soft-tissue injury is often related to hemorrhage or infection. Uncontrolled hemorrhage can quickly lead to shock and death. When the skin barrier is breached, invading pathogens—bacteria, fungi, and viruses—can cause local or systemic infection. Infection can be life or limb threatening, especially in children, older adults, and people with diabetes or other conditions that may compromise the immune system.

Soft-tissue injuries and their associated complications can often be prevented by using simple protective actions. For example, wearing gloves when working with abrasive materials helps prevent skin injuries. To reduce injuries in the workplace, safety measures have been implemented that include the use of safety devices to prevent interaction between machine parts and body parts. Using plastic scissors, plastic knives, and plastic drinking cups at home will reduce the risk of cuts and other skin injuries among children. Effective strategies that have reduced injury and death from burns include using smoke alarms, controlling the temperature of hot water heaters, and enforcing building codes that regulate electrical and construction practices.

This chapter discusses the various types of soft-tissue injuries and the appropriate assessment and treatment of this classification of injuries.

Anatomy and Physiology of the Skin

The skin is our first line of defense against external forces and infection. It is also the largest organ in the body. Although it is relatively tough, skin is still quite susceptible to injury. Injuries to soft tissues range from simple bruises and abrasions to serious lacerations and amputations. Soft-tissue injury may result in exposure of deep structures such as blood vessels, nerves, and bones. In all instances, you must control bleeding, prevent further contamination to decrease the risk of infection, and protect the wound from further damage. Therefore, you must know how to apply dressings and bandages to various parts of the body.

YOU are the Provider — PART 1

You and your partner are standing by at the scene of a house fire when firefighters bring over a 45-year-old man who was rescued from the burning structure. The patient is wrapped in a blanket. He is conscious and alert, he is in severe pain, and his face is covered with soot.

1. What should be your most immediate priority?

2. What is a thermal burn? What are the causes of thermal burns?

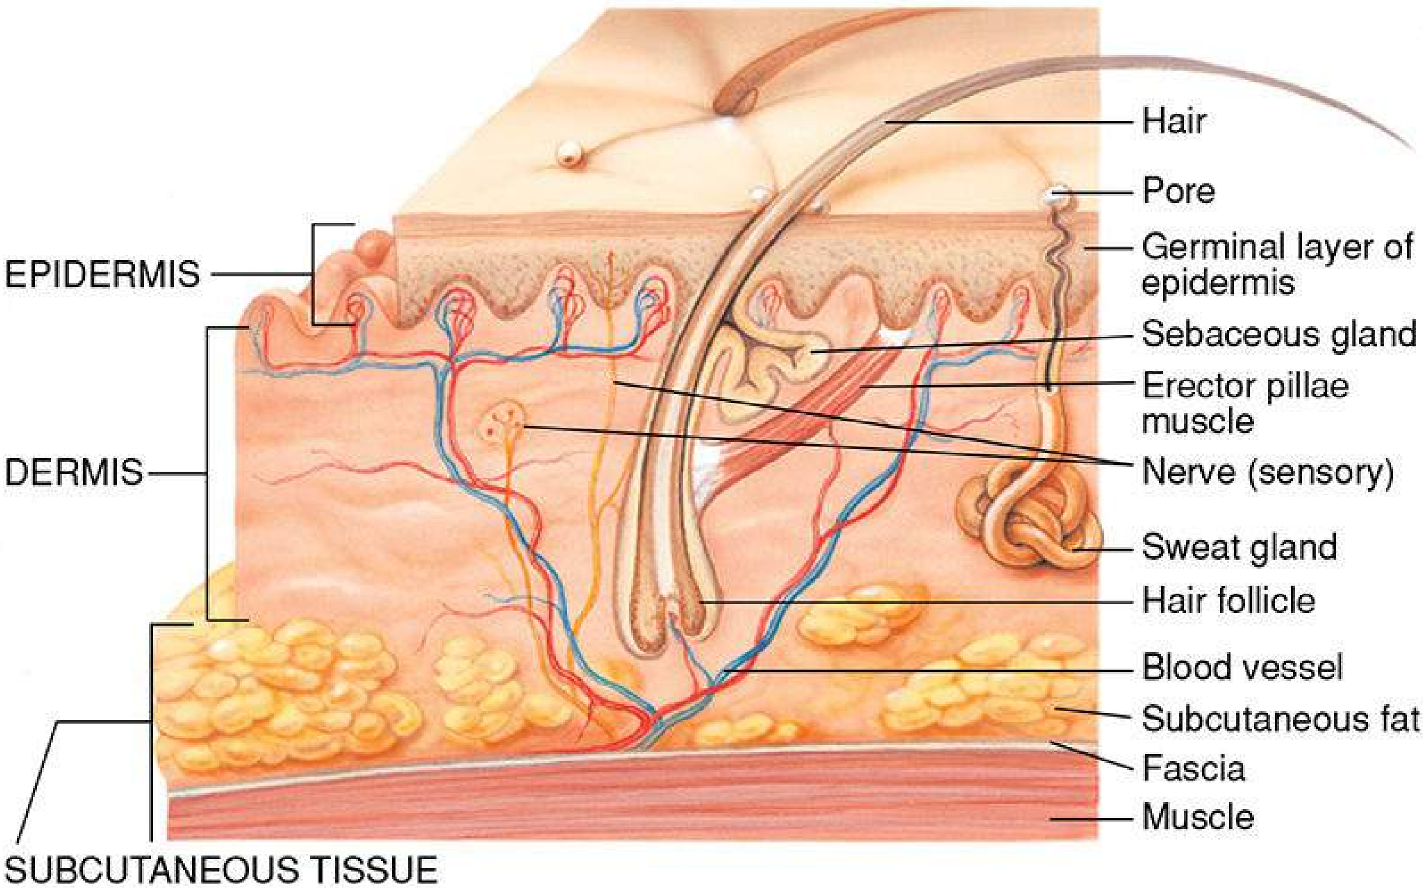

Figure 26-1 The skin comprises a tough external layer called the epidermis and a vascular inner layer called the dermis.

Skin varies in thickness, depending on a person's age and the area the skin covers. The skin of the very young and the very old is thinner than the skin of a young adult. The skin covering the scalp, the back, and the soles of the feet is quite thick, while the skin of the eyelids, lips, and ears is very thin. Thin skin is more easily damaged than thick skin.

Anatomy

The skin has two principal layers: the epidermis and the dermis **Figure 26-1**. The **epidermis** is the tough, external layer that forms a watertight covering for the body. The epidermis contains several layers. The cells on the surface layer of the epidermis are constantly worn away. They are replaced by cells that are pushed to the surface when new cells form in the germinal layer at the base of the epidermis. Deeper cells in the germinal layer contain pigment granules. Along with blood vessels in the dermis, these granules produce skin color.

The **dermis** is the inner layer of the skin. It lies below the germinal cells of the epidermis. The dermis contains the structures that give the skin its characteristic appearance: hair follicles, sweat glands, and sebaceous glands. The sweat glands' primary function is to cool the body. They discharge sweat onto the surface of the skin through small pores, or ducts, that pass through the epidermis. Sebaceous glands produce sebum, the oily material that waterproofs the skin and keeps it supple. Sebum travels to the skin's surface along the shaft of adjacent hair follicles. *Hair follicles* are small organs that produce hair. There is one follicle for each hair, each connected with a sebaceous gland and a tiny muscle. This muscle pulls the hair erect whenever a person is cold or frightened.

Blood vessels in the dermis provide the skin with nutrients and oxygen. Small branches reach up to the germinal cells, but blood vessels do not penetrate farther into the epidermis. There are also specialized nerve endings within the dermis.

The skin covers all external surfaces of the body. The various openings in the body, including the mouth, nose, anus, and vagina, are not covered by skin. Instead, these openings are lined with **mucous membranes**. Similar to skin, these membranes provide a protective barrier against bacterial invasion, but mucous membranes differ from skin in that they secrete a watery substance that lubricates the openings. Therefore, mucous membranes are moist, whereas skin is generally dry.

Physiology

The skin serves many functions. It protects the body by keeping pathogens out and fluids in, and it helps regulate body temperature. The nerves in the skin report to the brain on the environment and on many sensations. It is this nerve pathway connection that allows the body to adapt to environments through responses in the skin and surrounding tissues.

The skin is the body's major organ for regulating temperature. In a cold environment, the blood vessels in the skin constrict, diverting blood away from the skin and decreasing the amount of heat that radiates from the body's surface. In hot environments, the vessels in the skin dilate. The skin becomes flushed or red, and heat radiates from the body's surface. In addition, sweat glands secrete sweat to help cool the body. As the sweat evaporates from the skin's surface, the body temperature drops, and the person begins to cool down.

Any break in the skin allows bacteria to enter and increases the possibilities of infection, fluid loss, and loss of temperature control. Any one of these conditions can cause serious illness and even death. Soft tissues are often injured because they are exposed to the environment. There are three types of soft-tissue injuries:

- **Closed injuries**, in which soft-tissue damage occurs beneath the skin or mucous membrane but the surface of the skin or mucous membrane remains intact.
- **Open injuries**, in which there is a break in the surface of the skin or the mucous membrane, exposing deeper tissues to potential contamination.
- **Burns**, in which the soft-tissue damage occurs as a result of thermal heat, frictional heat, toxic chemicals, electricity, or nuclear radiation.

Pathophysiology of Closed and Open Injuries

Wounds heal in a natural process that involves several overlapping stages, all directed toward the larger goal of maintaining homeostasis or balance. Ultimately, the goal is for the body to return to a functional state, although the injured area may not always be restored to its preinjury state.

Among the primary concerns in wound healing is the cessation of bleeding. Loss of blood, internal or external, hinders the provision of vital nutrients and oxygen to the affected area. It also impairs the tissue's ability to eliminate wastes. The end result is abnormal or absent function, which interferes with homeostasis. To stop the flow of blood, the vessels, platelets, and clotting cascade must work in unison.

During inflammation (the next stage of wound healing), additional cells move into the damaged area to begin repair. White blood cells migrate to the area to combat pathogens that have invaded exposed tissue. Foreign products and bacteria are also removed from the body. Similarly, lymphocytes (a type of white blood cell) destroy bacteria and other pathogens. Mast cells release histamine as part of the body's response in the early stages of inflammation. Histamine dilates blood vessels, increasing blood flow to the injured area and resulting in a reddened, warm area immediately around the site. Histamine makes capillaries more permeable, and swelling may occur as fluid seeps out of these "leaky" capillaries. Inflammation ultimately leads to the removal of foreign material, damaged cellular parts, and invading microorganisms from the wound site.

In the outer layer of skin, cells are stacked in layers. To replace the area damaged in a soft-tissue injury, a new layer of cells must be moved into this region. This is the next stage of wound healing. Cells quickly multiply and redevelop across the edges of the wound. Except in cases of clean incisions, the appearance of the restructured area seldom returns to the preinjury state. For example, large wounds or injuries that result in significant disruption of the skin will often not complete this process. People with lightly pigmented skin may see a pink line of scar tissue signaling the presence of collagen, a structural protein that has reinforced the damaged tissue. Despite the changed appearance, the function of the area may be restored to near normal.

During the next stage of wound healing, new blood vessels form as the body attempts to bring oxygen and nutrients to the injured tissue. New capillaries bud from intact capillaries that lie adjacent to the damaged skin. These vessels provide a channel for oxygen and nutrients and serve as a pathway for waste removal. Because they are new and delicate, bleeding might result from a very minor injury. It may take weeks to months for the new capillaries to be as stable as preexisting vessels.

Collagen is a tough, fibrous protein found in scar tissue, hair, bones, and connective tissue. In the last stage of wound healing, collagen provides stability to the damaged tissue and joins wound borders, thereby closing the open tissue. Unfortunately, collagen cannot restore damaged tissue to its original strength.

Words of Wisdom

Wound healing does not always follow the pattern described. Infection or an abnormal scar may develop, excessive bleeding may occur, or healing may be slow.

Closed Injuries

Closed soft-tissue injuries are characterized by a history of blunt trauma, pain at the site of injury, swelling beneath the skin, and discoloration. Such injuries can vary from mild to quite severe.

A **contusion**, or bruise, is an injury that causes bleeding beneath the skin but does not break the skin. Contusions result from blunt forces striking the body. The epidermis remains intact, but cells within the dermis are damaged, and small blood vessels are usually torn. The depth of the injury varies, depending on the amount of energy absorbed. As fluid and blood leak into the damaged area, the patient may have swelling and pain. The buildup of blood produces a characteristic blue or black discoloration called **ecchymosis** **Figure 26-2**.

A **hematoma** is blood that has collected within damaged tissue or in a body cavity **Figure 26-3**. A hematoma occurs whenever a large blood vessel is damaged and bleeds rapidly. It is usually associated with extensive tissue damage. A hematoma can result from a soft-tissue injury, a fracture, or any injury to a large blood vessel. In severe cases, the hematoma may contain more than a liter of blood.

A **crushing injury** occurs when significant force is applied to the body **Figure 26-4**. The extent of the damage depends on how much force is applied and how long it is applied. In addition to causing direct soft-tissue damage, continued compression of the soft tissues cuts off circulation, producing further tissue destruction. For example, if a patient's legs are trapped under a collapsed pile of rocks, damage to the leg tissues will continue until the rocks are removed.

When an area of the body is trapped for longer than 4 hours and arterial blood flow is compromised, **crush syndrome** can develop. When a patient's tissues are crushed beyond repair, muscle cells die and release harmful substances into the surrounding tissues. The oppressing force prevents blood from returning to the injured body part, so these harmful substances are released into the body's circulation *after* the limb is freed and blood flow is returned. For this reason, when possible, advance life support (ALS) providers should administer IV fluid *before* the crushing object is lifted off the body. Freeing the limb or other body part from entrapment not only results in the release of the by-products of metabolism and harmful products of tissue destruction, but it also creates the potential for cardiac arrest and renal failure. Consider requesting ALS assistance for situations of prolonged entrapment prior to extrication.

Figure 26-2 Contusions, more commonly known as bruises, occur as a result of a blunt force striking the body. The characteristic blue or black discoloration (ecchymosis) signifies bleeding underneath the skin.

Compartment syndrome develops when edema and swelling result in increased pressure within a closed soft-tissue compartment. Because tissues are limited in the amount they can stretch or expand, pressure increases within the compartment, which in turn interferes with circulation. Compartment syndrome commonly develops in the extremities and may occur in conjunction with open or closed injuries or when swelling occurs under restrictive immobilization devices such as a cast. As pressure develops, delivery of nutrients and oxygen is impaired and by-products of normal metabolism accumulate. This causes pain, especially on passive movement. Signs of impaired circulation may also be present. The longer this situation persists, the greater the chance for tissue death. Continually reassess skin color, temperature, and pulses distal to the injury site during transport if crush injury is suspected.

Figure 26-3

A hematoma develops whenever a large blood vessel is damaged and bleeds rapidly.

Courtesy of Rhonda Hunt.

Figure 26-4 The damage associated with a crush or compression injury varies depending on the direct damage to the soft tissues and how long the tissue was cut off from circulation.

Severe closed injuries can also damage internal organs. The greater the amount of energy absorbed from the blunt force, the greater the risk of injury to deeper structures. Therefore, you must assess all patients with closed injuries for more serious hidden injuries. Remain alert for signs of shock or internal bleeding, and begin treatment of these conditions if necessary.

Open Injuries

Open injuries differ from closed injuries in that the protective layer of skin is damaged. This can produce extensive bleeding.

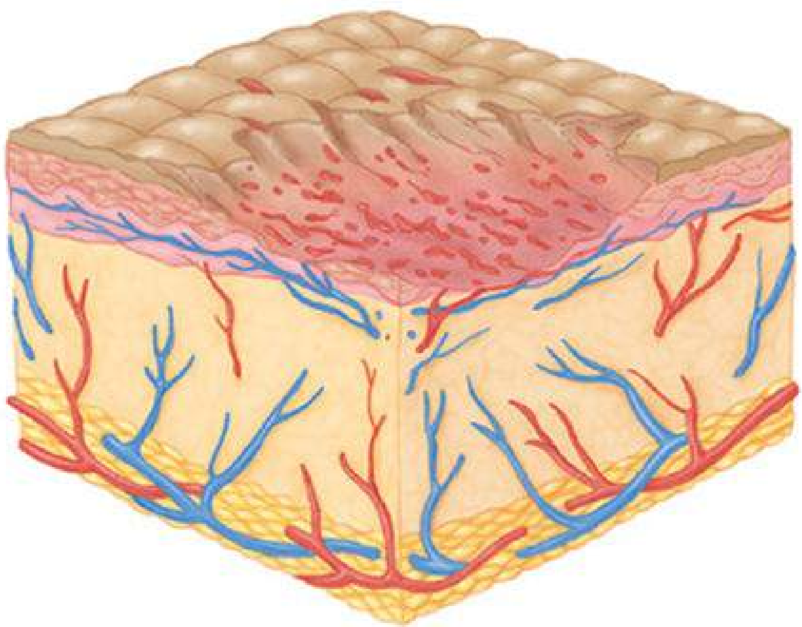
More important, a break in the protective skin layer or mucous membrane means the wound is contaminated and may become infected. **Contamination** is the presence of infectious organisms (pathogens) or foreign bodies, such as dirt, gravel, or metal, in the wound. You must address excessive bleeding and contamination in your treatment of open soft-tissue wounds. There are four types of open soft-tissue wounds that you must be prepared to manage:

- Abrasions
- Lacerations
- Avulsions
- Penetrating wounds

An **abrasion** is a wound of the superficial layer of the skin, caused by friction when a body part rubs or scrapes across a rough or hard surface. An abrasion usually does not penetrate completely through the dermis, but blood may ooze from the injured capillaries in the dermis. Also known as road rash, road burn, strawberry, and rug burn, abrasions can be extremely painful because the nerve endings are located in this area **Figure 26-5**.

A **laceration** is a jagged cut in the skin caused by a sharp object or a blunt force that tears the tissue, whereas an **incision** is a sharp, smooth cut. The depth of the injury can vary, extending through the skin and subcutaneous tissue, even into the underlying muscles and adjacent nerves and blood vessels **Figure 26-6**. Lacerations and incisions may appear linear (regular) or stellate (irregular) and may occur along with other types of soft-tissue injury. Lacerations or incisions that involve arteries or large veins may result in severe bleeding.

A



B

Figure 26-5 Abrasions usually do not penetrate completely through the dermis, but blood may ooze from the capillaries. These wounds are typically superficial and result from rubbing or scraping across a hard, rough surface.

An **avulsion** is an injury that separates various layers of soft tissue (usually between the subcutaneous layer and **fascia**) so they become either completely detached or hang as a flap **Figure 26-7**. Often there is significant bleeding. If the avulsed tissue is hanging from a small piece of skin, the circulation through the flap may be at risk. If you can, replace the flat avulsed flap in its original position as long as it is not visibly contaminated with dirt and/or other foreign materials. If an avulsion is complete, you should wrap the separated tissue in sterile gauze and take it with you to the ED. This type of avulsion often poses serious infection concerns. Never remove an avulsion skin flap, regardless of its size.

Figure 26-6 Lacerations vary in depth and can extend through the skin and subcutaneous tissue to the underlying muscles, nerves, and blood vessels. These wounds can be smooth or jagged depending on the object that caused the injury.

An **amputation** is an injury in which part of the body is completely severed. Chapter 31, *Orthopaedic Injuries*, covers this topic in detail. We usually think of amputations as involving the upper and lower extremities. But other body parts, such as the scalp, ear, nose, penis, or lips, may also be totally avulsed, or amputated. You can easily control the bleeding from some amputations, such as the fingers, with direct pressure and pressure dressings. If an amputation involves a large area of muscle mass, such as a thigh, there may be massive bleeding. In this situation, you should stop the bleeding, which often requires a tourniquet, and treat the patient for hypovolemic shock. See Chapter 25, *Bleeding*.

A **penetrating wound** (or puncture wound) is an injury resulting from a piercing object, such as a knife, ice pick, splinter, or bullet. Such objects leave relatively small entrance wounds, so there may be little external bleeding **Figure 26-8**. However, these objects can damage structures deep within the body and cause unseen bleeding. If the wound is to the chest or abdomen, the injury can cause rapid, fatal bleeding. Assessing the amount of damage a puncture wound has created is very difficult and is reserved for the physician at the hospital.

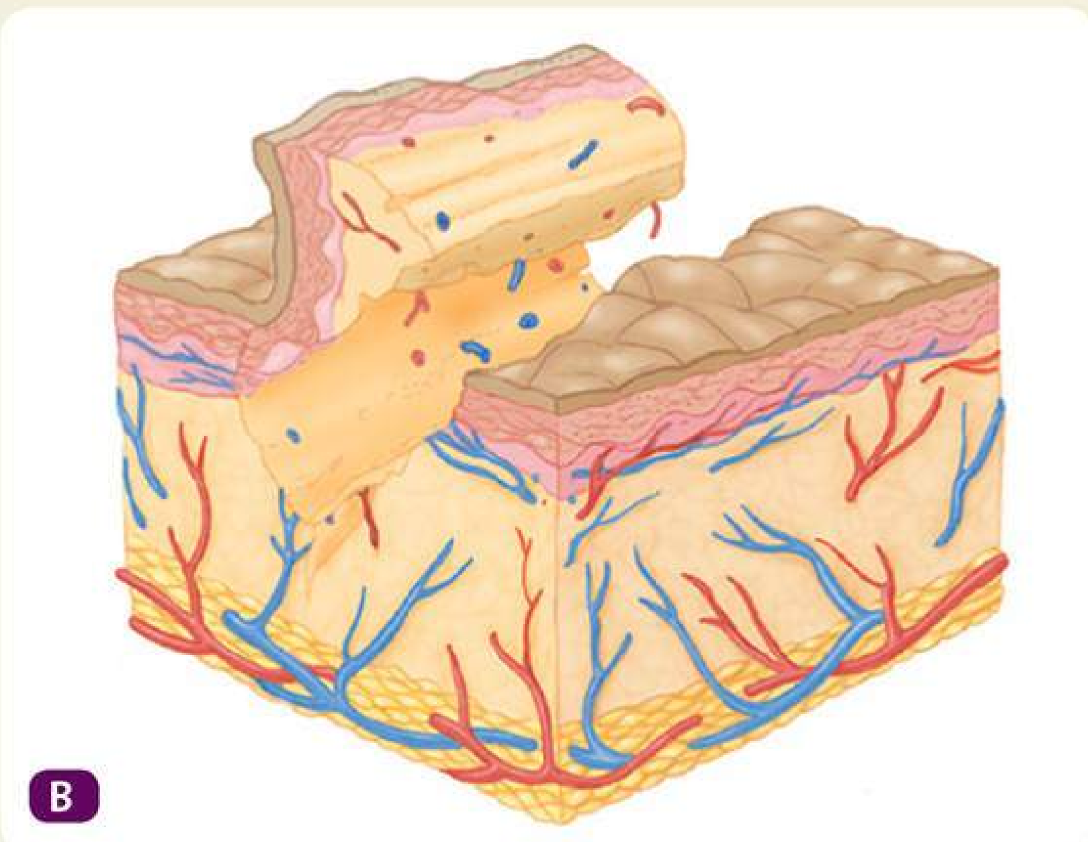


Figure 26-7 Avulsions are injuries characterized by complete separation of tissue or tissue hanging as a flap. Significant bleeding is common.

Objects that penetrate the skin but remain in place are referred to as **impaled objects**. The concerns with this type of injury include the amount of damage to structures deep inside the body and the presence of foreign materials deep inside the tissue. The damage to underlying structures is difficult to determine and manage, and the presence of foreign materials inside the tissue results in a significantly higher risk of infection. An impaled object also requires specific treatments and care, described later in this chapter.

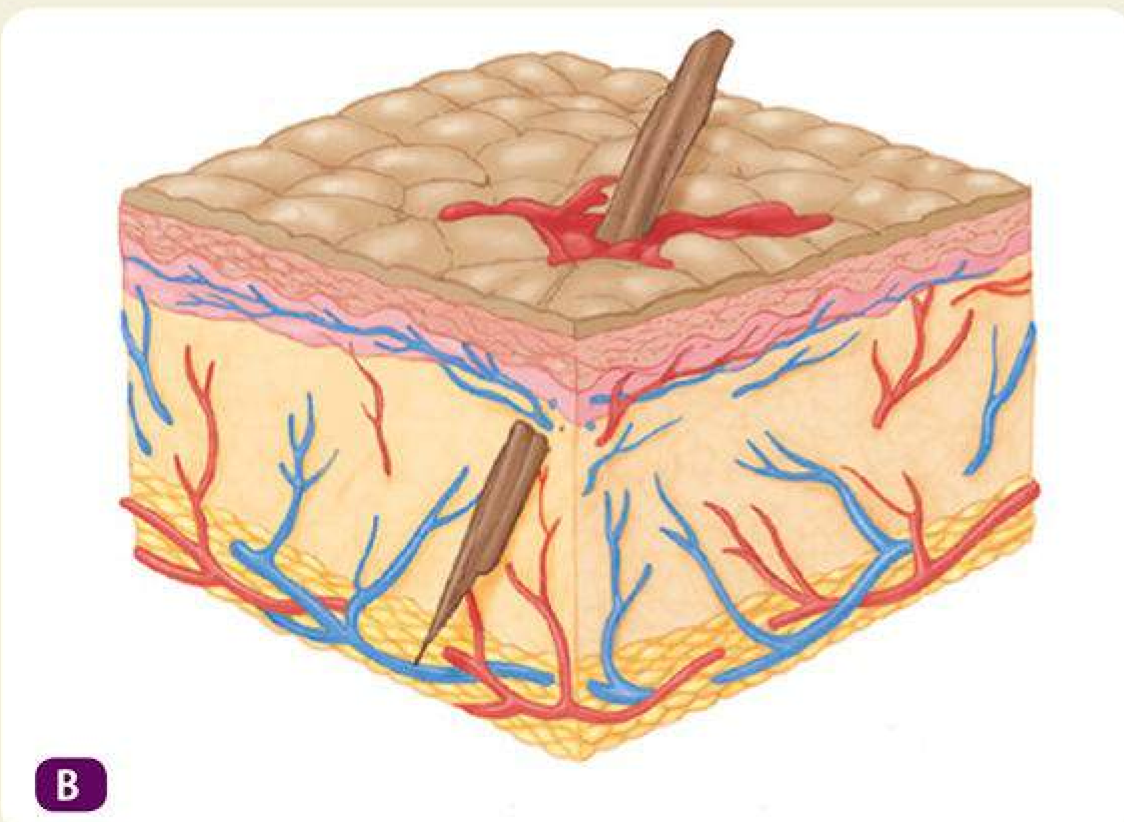

Figure 26-8 Penetrating wounds and impaled objects may cause very little external bleeding but can damage structures deep within the body.

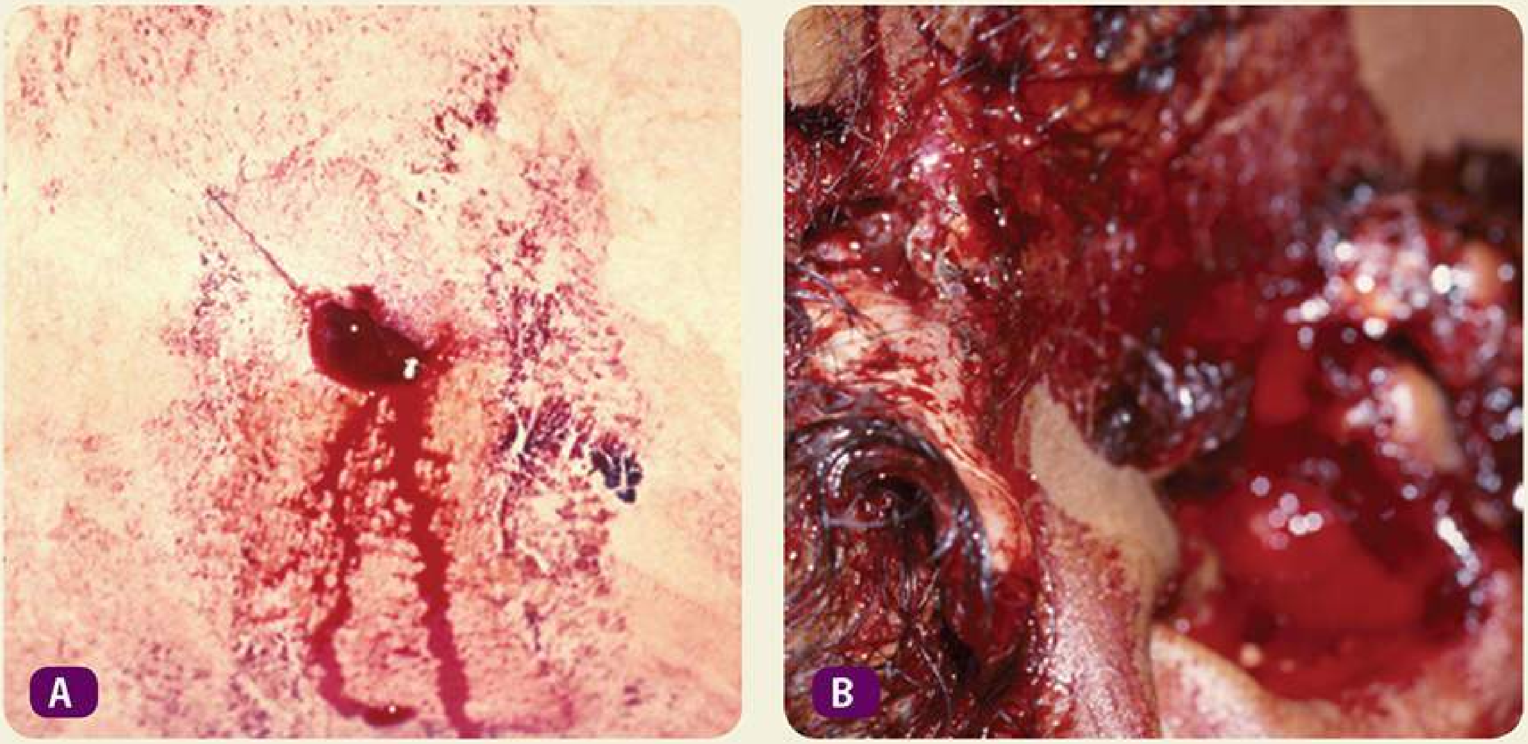

Figure 26-9 **A.** An entrance wound from a gunshot may have burns around the edges. **B.** An exit wound is often larger than an entrance wound and is associated with greater damage to soft tissues locally.

Words of Wisdom

Treat all penetrating wounds of the neck, chest, back, and upper abdomen with an occlusive dressing to prevent the possible movement of air into the vascular space, thoracic cavity, and/or abdominal cavity.

Words of Wisdom

Do not spend time trying to distinguish between an entrance and an exit wound. Find the wounds and treat them, but be aware of the number of wounds overall and the relative location of each.

Stabbings and shootings often result in multiple penetrating injuries. You must assess these patients carefully to identify all wounds. Since a penetrating object can pass completely through the body, always count the number of penetrating injuries (or holes), especially with gunshot wounds. Knowing the difference between entrance wounds and exit wounds may be difficult in a prehospital setting, especially with the different types of ammunition available. While entrance wounds are often smaller than exit wounds **Figure 26-9**, it is better to simply count the number of penetrating injuries, and leave the distinction between entrance and exit to the physician who is working in a more controlled environment. Gunshot wounds have some unique characteristics that require special care. The amount of energy transmitted by a gunshot injury is directly related to the speed of the bullet. When possible, determine the type of gun used in the shooting, but do not let this delay patient transport. Sometimes, the patient or bystanders can tell you how many rounds were fired, but given the stress of the environment their information may be unreliable; however, it may help hospital personnel to better care for the patient.

Shotgun wounds create multiple paths of missiles (shot) and create a larger surface area and volume of tissue damage.

Many cases involving shootings go to court at some point, and you may be called to testify. Therefore, you must carefully document the circumstances surrounding any gunshot injury, the patient's condition, and the treatment you give.

As with closed wounds caused by crushing, open wounds caused by crushing may involve damaged internal organs or broken bones, as well as extensive soft-tissue damage **Figure 26-10**. Whereas external bleeding may be minimal, internal bleeding may be severe, or even life threatening. The crushing force damages soft tissues as well as vessels and nerves. This frequently results in a painful, swollen, deformed area.

Blast injuries, as discussed in Chapter 24, *Trauma Overview*, may also result in multiple penetrating injuries. The mechanism of injury (MOI) from a blast is generally due to three factors:

- **Primary blast injury:** Injuries to the body caused by the blast wave itself; damage to the body is caused by the sudden pressure changes generated by the explosion.
- **Secondary blast injury:** Injuries caused to the body from being struck by flying debris, propelled by the force of the blast. These small objects may cause multiple penetrating wounds.
- **Tertiary blast injury:** Injuries to the body from being thrown or hurled by the force of the explosion into an object or onto the ground.

It is very important to conduct a complete primary and secondary assessment to determine what types of injuries are sustained from a blast injury and treat appropriately.

Figure 26-10 A crushing open wound is characterized by extensive tissue damage and deformity that is often accompanied by swelling and extreme pain.

Courtesy of Andrew N. Pollak, MD, FAAOS.

Patient Assessment of Closed and Open Injuries

Assessing closed injuries is much more difficult than assessing open injuries. Therefore, anytime you observe bruising, swelling, or deformity, or the patient reports pain, the possibility of a closed injury should be considered.

Assessing an open injury is generally easier than assessing a closed injury because you can see the injury. Open wounds are defined as injuries in which there is a break in the surface of the skin or the mucous membrane, exposing deeper tissues to potential contamination. You must use caution to avoid letting a patient's non–life-threatening gruesome injury distract you from recognizing another injury that is considered life threatening.

Words of Wisdom

Extremities that are painful, swollen, or deformed should be splinted. When you splint these types of injuries, remember to assess the patient's pulses and motor, and sensory functions before and after applying the splint. You should also evaluate the mechanism of injury (MOI). Because diffuse or generalized soft-tissue injuries can be life threatening, all patients with a significant MOI should be considered to have internal bleeding and shock until proven otherwise by the ED staff.

Scene Size-up

As you arrive on scene, observe the scene for hazards and threats to the safety of the crew, bystanders, and the patient. Assess the impact of hazards on patient care and address the hazards. As always, ensure the scene is safe and consider the need for additional resources.

Ensure that you and your crew have taken the necessary standard precautions before you approach the scene—a minimum of gloves and eye protection. Eye exposures may occur from splashes and droplets at a busy scene. Eye protection is required when managing open injuries to avoid potential splashing. Place several pairs of gloves in your pocket for easy access in case your gloves tear or there are multiple patients with bleeding.

Open soft-tissue injuries can be very messy but should not take priority over more serious life-threatening injuries. Controlling bleeding and bloody contaminants can be difficult because of the nature of the wounds. Be very careful where you put your hands or place your equipment and how you package the patient for transport. Because of the color of blood and how well it soaks through clothing, you can often identify patients with an open injury as you approach the scene. However, blood can be hidden under thick, dark clothing, such as denim and leather, or in the environment, such as sand, grass, or carpeting. Do not spend time trying to estimate blood loss; focus on controlling the bleeding.

Words of Wisdom

With blunt and penetrating injuries, the MOI may provide insight into the potential damage underneath the skin that may not be immediately evident during your physical assessment.

As you observe the scene, look for indicators of the MOI. This helps you develop an early index of suspicion for underlying injuries in a patient who has sustained a significant MOI. Remember, the MOI alone does not necessarily describe the true extent of injuries but it helps you understand the potential for injury. When you put together information from dispatch and your observations of the scene, consider how the MOI produced the injuries expected. Remember, medical emergencies may result in trauma, so there may be conditions to consider beyond the traumatic injuries. Your interactions with the patient and your assessment will ultimately provide you with additional information about the extent of the actual injuries. For example, in a vehicle crash, a patient who has sustained abrasions and lacerations to the face from an impact with the steering wheel or windshield may have experienced enough force to injure the cervical spine as well. In this case and in many trauma situations, spinal immobilization should be maintained throughout your care of the patient. The MOI may also provide information about potential safety threats. For example, gunshot wounds may indicate the presence of an angry and violent offender in the area or a dangerous scene. Make sure you use all available information to evaluate scene safety and consider whether additional resources may be necessary.

Primary Assessment

The primary assessment for a patient with a closed or open injury should focus on identifying and managing life-threatening concerns and identifying transport priority.

Your general impression will help you develop an index of suspicion for serious injuries and determine how urgently your patient needs care. As you approach the patient, important indicators will alert you to the seriousness of the patient's condition, such as:

YOU are the Provider — PART 2

The patient is ambulatory, so you immediately move him to the ambulance that is parked a short distance away and complete your primary assessment. Your partner obtains additional information from the firefighters who rescued him.

Recording Time: 2 Minutes	
Appearance	Shivering; in obvious pain
Level of consciousness	Conscious and alert

Airway	Open; clear of secretions or foreign bodies
Breathing	14 breaths/min; adequate depth; unlabored
Circulation	Increased pulse rate; strong at the radial site; no obvious bleeding

You apply high-flow oxygen via a nonrebreathing mask and then carefully remove clothing that is not adhered to his skin so you can assess the severity of his burns.

3. What additional information should you obtain from the firefighters who rescued the patient?
4. How are thermal burns classified? What are the characteristics of each type of burn?

- Is the patient awake and interacting with his or her surroundings, or lying still and not making sounds?
- Is he or she appropriately or inappropriately responding to you?
- Is the patient's breathing pattern rapid or slow, deep or shallow?
- What is the color and condition of the patient's skin?
- Does the patient have any apparent life threats?

The answers to these questions contribute to your general impression and help to determine your treatment priorities and the urgency of care needed. A good question to ask yourself is, "How sick is my patient based on what I know right now?"

Closed soft-tissue injuries may appear to be minor; however, they may indicate serious internal injuries. For example, a patient with a hematoma on the head and a decreased level of consciousness may have a serious brain injury. Open injuries may be obvious and significant, likely indicating a serious condition. However, other injuries may not be as obvious but may still indicate a serious condition.

Words of Wisdom

It is easy to become distracted when a patient has significant soft-tissue injuries, there is a large amount of blood, or the patient is frightened or screaming. However, this is when you need to focus on the problems at hand and follow the protocols you have learned.

Check for responsiveness. If the patient is alert, ask about the chief complaint to help direct you to any apparent life threats. If the patient is not alert, determine if he or she responds to verbal or painful stimuli or if he or she is unresponsive. An unresponsive patient may indicate a life-threatening condition. Administer high-flow oxygen via a nonrebreathing mask to patients whose level of consciousness is less than alert and oriented, treat for potential shock, and provide immediate transport to the ED.

If significant trauma has likely affected multiple body systems, start with a rapid exam of the patient to be sure you have found all of the problems and injuries. A rapid 60- to 90-second exam may identify factors that assist you in determining whether a patient requires rapid transport. Begin with the head and neck while manually holding the head in place. When you are done, apply a cervical collar if it is indicated.

When performing the rapid exam, look for life threats and treat them as you find them. Significant bleeding is an immediate life threat and must be controlled quickly using appropriate methods. A patient with massive hemorrhage may require a tourniquet (or direct pressure dressings if tourniquets are not available) *before* the airway is opened. If the patient has obvious life-threatening external bleeding, control the bleeding first (even *before* airway and breathing), then assess and treat the ABCs, and provide treatment for shock.

Words of Wisdom

As you consider the MOI and form suspicions about where bleeding is occurring, expose that part of the body. Blood flowing freely from veins in a large gash can be as much of a threat as blood spurting from an artery.

Providing high-flow oxygen may help reduce the effects of shock and assist in perfusion of damaged tissues, particularly in crush injuries. If the patient has signs of hypoperfusion, treat aggressively for shock: place the patient supine, prevent heat loss with a blanket, and provide rapid transport to the hospital. Request ALS as necessary to assist with more aggressive shock management.

Ensure the patient has a clear and patent airway. If the airway is not patent, take the necessary steps to make it clear and patent. Protect the patient from further spinal injury as you manage the airway by preventing the head and torso from moving. If the patient is unresponsive or has a significantly altered level of consciousness, consider inserting an oropharyngeal airway or nasopharyngeal airway and suction the airway as needed.

You must quickly assess the patient for adequate breathing. Inspect and palpate the chest wall for DCAP-BTLS. If a soft-tissue injury is discovered on the chest or abdomen, auscultate for clear and symmetric breath sounds, and look at the structure of the chest wall to ensure equal expansion and rise and fall of the chest. Then provide high-flow oxygen, or provide assisted ventilations using a bag-valve mask (BVM) as needed, depending on the level of consciousness and if your patient is breathing inadequately.

Open soft-tissue injuries of the face and neck have a potential to interfere with the effectiveness of the airway and breathing. Evaluate the patient's voice and ability to speak to identify throat injuries. If an open injury is found on the chest, evaluate for air movement through the wound in the form of bubbling or sucking sounds, which indicate a deep penetrating injury. Assess the patient's back for injuries that might need treatment as well. Quickly place an occlusive dressing over the wound. Provide high-flow oxygen or assisted ventilations with a BVM as needed, depending on the patient's level of consciousness and on the adequacy of the patient's breathing. Monitor the patient for signs of increasing respiratory distress that may require you to relieve pressure built up under the dressing (caused by a pneumothorax).

Quickly assess the patient's pulse rate, rhythm, and quality; determine the skin condition, color, and temperature; and check the capillary refill time. These assessments will help you determine the presence of circulatory problems or shock. Closed soft-tissue injuries may not always have visible signs of bleeding because most of the bleeding is occurring inside the body. Your assessment of the pulse and skin will indicate how aggressively you need to treat your patient for shock.

Determine whether your patient needs immediate transport or stabilization on scene. If the patient you are treating has an airway or breathing problem or signs and symptoms of shock or internal bleeding, you must consider rapid transport to the hospital for treatment or request ALS support. Also, if you identify conditions that have the potential to become unstable, such as a distended abdomen or femur fractures, the patient requires rapid and immediate transport.

You should also consider whether transport to the closest hospital is appropriate or whether the patient would be better served by transport to a trauma center that might be farther away. In some situations it may be appropriate to request aeromedical transport to expedite transfer to a trauma or specialty center. Each consideration requires that you clearly and completely understand your local resources and protocols.

Most patients do not require immediate load-and-go transportation, but there are certain conditions for which treatment is limited in the field, and, therefore, immediate transport is the better choice. The following list will help guide you in determining the types of patients that need immediate transportation:

- Poor initial general impression
- Altered level of consciousness
- Dyspnea
- Abnormal vital signs
- Shock
- Severe pain

Do not delay transport of a seriously injured trauma patient to complete nonlifesaving treatments in the field, such as splinting extremity fractures or treating minor bleeding such as abrasions; instead, complete these types of treatments en route to the hospital during the secondary assessment.

YOU are the Provider — PART 3

The patient tells you he sustained the burns when he was trying to escape from the burning house. Both of the exits were blocked by fire and debris, so he ran into the bedroom. However, he was unable to exit through the window because of burglar bars he had installed; this was when the firefighters found him. He denies losing consciousness. Your partner assesses his vital signs as you perform a secondary assessment.

Recording Time: 6 Minutes	
Respirations	14 breaths/min; adequate depth; unlabored
Pulse	108 beats/min; strong and regular
Skin	Red, warm, and dry; burns to the torso and arms
Blood pressure	166/86 mm Hg
Oxygen saturation (Spo_2)	98% (on oxygen)

Your secondary assessment reveals partial-thickness burns to his anterior chest and abdomen, and partial- and full-thickness burns to both of his arms, including his hands. His face is covered with soot, and his facial hair and the hair just above his hairline are singed. You do not see any obvious skin burns to his facial area, and the remainder of your assessment does not reveal any other injuries. The patient denies having difficulty breathing or any other symptoms other than pain.

5. What percentage of the patient's body surface area has been burned?
6. What factors should you consider to determine the severity of a burn?

Patients who have visible significant bleeding or signs of significant internal bleeding may quickly become unstable. Stay alert for signs of hypoperfusion (tachycardia; tachypnea; weak pulse; cool, moist skin) and reassess your priority and transport decision if they develop.

History Taking

After you manage life threats during the primary assessment, investigate the chief complaint or history of present illness. Obtain a medical history and be alert for injury-specific signs and symptoms as well as any pertinent negatives such as no pain or loss of sensation.

Make every attempt to obtain a SAMPLE history from your patient. Using OPQRST may provide some background on isolated extremity injuries. When you use SAMPLE, OPQRST, and DCAP-BTLS together, your assessment will be well-rounded and provide significant insight into the patient's condition. You have the opportunity to interview the patient well before the ED physician's examination. Any information you receive will be very valuable if the patient loses consciousness.

If the patient is not responsive, attempt to obtain the history from other sources, such as friends, family members, or even bystanders who might have witnessed the event. Medical identification jewelry and cards in wallets may also provide information about the patient's medical history or alert you to the presence of implanted medical devices. While these items may not seem significant, they can provide information about the patient's underlying medical conditions. This information, in conjunction with the physical assessment, may help provide an overview of the patient's overall status.

Typical signs of an open injury include bleeding, a break in the skin, shock, hemorrhage, and disfigurement or loss of a body part. Typically, symptoms include pain and/or burning at the injury site. Chronic medical conditions such as anemia (low quantity of hemoglobin in the blood) and hemophilia (a disorder in which blood has a diminished ability to clot) as well as a host of other medical conditions can complicate open soft-tissue injuries. Medications, such as aspirin or others that impair the blood's ability to clot and are frequently taken by older patients, may make it more difficult to control bleeding.

Secondary Assessment

After you evaluate ABCs and identify and treat immediate life threats, a more detailed assessment should follow. The secondary assessment is a more systematic full-body scan or focused examination of the patient that is used to reveal injuries or medical conditions that may have been missed during the primary assessment. In some instances, such as with a critically injured patient or a short transport time, you may not have time to conduct a full secondary assessment. Typically, the secondary assessment, which includes assessing interventions and repeating vital signs, occurs en route to the ED.

Listen to breath sounds with a stethoscope. Breath sounds should be clear and equal bilaterally, anteriorly, and posteriorly. Determine the patient's respiratory rate and note the pattern and quality of the respiratory effort. Assess for asymmetric chest wall movement.

Assess the neurologic system to gather baseline data on your patient. This examination should include the level of consciousness, pupil size and reactivity, and motor and sensory response.

Assess the musculoskeletal system by performing a detailed exam of the entire body. Look for DCAPBTLS. Assess the chest, abdomen, and extremities for hidden bleeding and injuries. Log roll the patient, and assess the posterior torso for injuries. Once the back has been assessed, the patient can be log rolled back down onto a backboard, followed by complete spinal immobilization if indicated. Log rolling and securing the patient to a backboard or other full-body immobilization device should take into consideration injuries found during the primary assessment as well as local protocols.

Assess all anatomic regions, looking for the following signs/symptoms:

- Check the neck for jugular vein distention and tracheal deviation. Be alert for patients with a stoma or tracheostomy.
- Check the pelvis for stability.
- Check the abdomen; feel all four quadrants for tenderness rigidity, and inspect for bruising. If the abdomen is tender, expect internal bleeding.
- Check the extremities, and record pulse, motor, and sensory function.

Patients who have hidden internal injuries under a closed soft-tissue injury may have internal bleeding and may rapidly become unstable. It is important to reassess the vital signs to identify how quickly the patient's condition is changing; a single vital sign will not always provide the necessary information to evaluate the patient's condition. Make sure you obtain a series of vital signs to ensure subtle changes are evident as soon as possible. Signs such as tachycardia, tachypnea, low blood pressure, weak pulse, and cool, moist, and pale skin indicate hypoperfusion and imply the need for rapid transport and treatment at the hospital. Remember that soft-tissue injuries, even without a significant MOI, can cause shock. The reassessment of your patient's vital signs will give you a good understanding of how well or how poorly your patient is tolerating the injury and whether your interventions have been effective.

Reassessment

Reassessment of a patient is just as important as your original assessment and should be regularly conducted during transport to ensure your patient's condition is not declining. Repeat the primary assessment completely, but pay extra attention to areas of concern that you identified during your initial assessment and assess the effectiveness of prior treatments. Reassess vital signs and the chief complaint. Are the airway, breathing, and circulation still adequate? Recheck patient interventions. Are the treatments you provided for problems with the ABCs still effective? Reassessing a patient with an open soft-tissue injury is extremely important, especially if you did not put the bandage on the patient's injury. Frequently, other emergency care personnel may have dressed and bandaged the wound before your arrival. You may need to place additional dressings over the original dressing or bandages. If so, frequently reassess the effectiveness of the bandaging. If blood continues to soak through bandages, use additional methods to control bleeding as discussed later in the chapter. How is the patient's condition improving with the interventions? Identify and treat changes in the patient's condition.

Closed soft-tissues injuries can be life threatening if not appropriately treated. Assess and manage all threats to the patient's airway, breathing, and circulation. Supplemental oxygen is commonly given to all patients with traumatic injuries impacting airway or ventilation or those with a potential for shock via a nonrebreathing mask.

Although most open soft-tissues injuries are not serious, they tend to be graphic and can be distracting to the patient. If not appropriately treated, they can lead to substantial blood loss and even shock. By appropriately treating open soft-tissue injuries, you can decrease the risk of common complications such as bleeding, shock, pain, and infection. Expose all wounds, control bleeding, and be prepared to treat the patient for shock. Consider flushing small wound surfaces *without* significant bleeding with sterile saline prior to applying a dressing. If any material is "stuck" in the wound, do not remove it as this may worsen bleeding and shock.

Extremities that are painful, swollen, or deformed should be splinted. Take great care when splinting these types of injuries. If done correctly, splinting can actually assist with pain management and bleeding control, but if done poorly may cause greater harm. When splinting these types of injuries, remember to assess the patient's pulse, motor, and sensory functions distal to the injury zone both before and after applying the splint.

YOU are the Provider — PART 4

After caring for the patient's burns, you cover him with a blanket and begin transport to the hospital. You contact medical control as soon as you leave the scene, and you are advised to provide transport to the emergency department because the closest burn center is 75 miles away. You reassess the patient, including his vital signs.

Recording Time: 12 Minutes	
Level of consciousness	Conscious and alert, but anxious
Respirations	22 breaths/min; becoming labored; voice is becoming hoarse
Pulse	120 beats/min; strong and regular
Skin	Red, warm, and dry
Blood pressure	158/84 mm Hg
Spo_2	95% (on oxygen)

7. What is the proper treatment for the patient's burns?
8. How has the patient's condition changed? What should you do now?

Words of Wisdom

Estimating blood loss is very difficult and even the most skilled providers are often not able to accurately estimate blood loss, especially when blood has been absorbed into fabrics or porous surfaces. Note that blood has soaked through a towel, an article of clothing, or the number of bandages used to control the patient's bleeding as these are valuable descriptors for the ED staff.

Your communication and documentation must include a description of the MOI and the position in which you found the patient when you arrived on scene. This will provide key information to the hospital staff that may impact the patient care plan provided at the hospital. You should attempt to report blood loss using terms that you are comfortable with and that will be easily understood by other personnel. For example, you may say "the bleeding soaked through the patient's jeans prior to our arrival" or "the bleeding has soaked through three trauma dressings during our time with the patient." Include the location and description of any soft-tissue injuries or other wounds you have located and treated. Describe the size and depth of the injury. Provide an accurate account of how you treated these injuries. Your ability to clearly and accurately communicate and document enables the physicians and nurses at the hospital to continue to deliver quality care.

Emergency Medical Care for Closed Injuries

Small contusions generally do not require special emergency medical care, but you should note their presence when trying to determine the true extent of the patient's injuries. More extensive closed injuries may involve significant swelling and bleeding beneath the skin, which could lead to hypovolemic shock. Depending on the time the injury occurred and the response time, the injuries might not have had time to cause swelling or bruising. Closely watch any area of injury throughout the time you are caring for the patient, no matter how minor it may look upon initial assessment.

Treat a closed soft-tissue injury by applying the mnemonic RICES:

- **Rest.** Keep the patient as quiet and comfortable as possible.
- **Ice.** Use ice or cold packs to slow bleeding by causing blood vessels to constrict and also to reduce pain.
- **Compression.** Apply pressure over the injury site to slow bleeding by compressing the blood vessels.
- **Elevation.** Raise the injured part just above the level of the patient's heart to decrease swelling.
- **Splinting.** Immobilize a soft-tissue injury or an injured extremity to decrease bleeding and reduce pain.

In addition to using these measures to control bleeding and swelling, you should also be alert for signs of developing shock. Look for anxiety or agitation and changes in mental status as these can be early signs of developing shock. An increased heart rate, increased respiratory rate, diaphoresis, cool or clammy skin, and eventual decreases in blood pressure may not develop until late in your care of the patient. Any or all of these signs may indicate internal bleeding resulting from injuries to internal organs. If the patient exhibits signs and symptoms of shock, treat accordingly and aggressively.

Emergency Medical Care for Open Injuries

Before you begin caring for a patient with an open wound, be sure to protect yourself by following standard precautions. If life-threatening bleeding is observed, assign a team member to apply direct pressure over the wound to control the bleeding. Then assess the severity of the wound. If the wound is in the chest, upper abdomen, or upper back, cover it with an occlusive dressing.

Words of Wisdom

While most wounds are simple and can be managed with direct pressure, do not spend time trying to use pressure, elevation, and pressure dressings on a wound that is hemorrhaging profusely. Apply a tourniquet early when there is massive hemorrhage to rapidly stop bleeding, avoid further blood loss, and allow you to quickly focus on providing other treatments for shock.

Your treatment priorities are the primary assessment and to begin lifesaving interventions. This includes controlling the bleeding, which can be extensive and severe. Several methods are available to control open injuries or external bleeding. Start with the most commonly used; these include the following:

- Direct, even pressure and elevation
- Pressure dressings and/or splints
- Tourniquets

It will often be useful to combine these methods. Different types of tourniquets are shown in **Figure 26-11**.

All open wounds are assumed to be contaminated and present a risk of infection. By applying a sterile dressing, you are reducing the risk of further contamination. This keeps foreign material, such as hair, clothing, and dirt, out of the wound and decreases the risk of infection. In general, you should not remove material from an open wound, no matter how dirty the wound is. Rubbing, brushing, or washing an open wound can cause additional bleeding, but small wound surfaces without significant bleeding can be flushed with sterile saline prior to applying a dressing. Chemical burns and contamination should be flushed to remove remaining chemicals. In most circumstances, hospital personnel, rather than EMTs, will clean open wounds. To prevent a wound from drying, you may apply sterile dressings moistened with sterile saline solution and then cover the moist dressing with a dry, sterile dressing.

In some cases, you can better control bleeding from open soft-tissue wounds by splinting the extremity, even if there is no fracture. Splinting can help you keep the patient calm and quiet, as it typically reduces pain. Splinting also keeps sterile dressings in place, minimizes damage to an already injured extremity, and makes it easier to move the patient.

Words of Wisdom

Hypovolemic shock is a risk for any patient who has had significant bleeding or bleeding that cannot be controlled. Be alert for this potential and treat aggressively to reduce the risk.

Figure 26-11 If bleeding continues or recurs, apply a tourniquet above the site of bleeding in an extremity–preferably the groin for leg wounds and the axilla for arm wounds. **A.** A CAT tourniquet. **B.** An EMT tourniquet. **C.** A SOF-T tourniquet.

Abdominal Wounds

An open wound in the abdominal cavity may expose internal organs. In some cases, the organs may even protrude through the wound, an injury called an **evisceration** **Figure 26-12**. Do not touch or move the exposed organs. Instead, cover the wound with sterile gauze moistened with sterile saline solution and secure with an occlusive dressing **Figure 26-13**. Because the open abdomen radiates body heat very effectively and quickly, and because exposed organs lose fluid rapidly, you must keep the organs moist and warm. If you do not have gauze compresses, you may use moist sterile dressings, covered and secured in place with a bandage and tape. Do not use any material that is adherent or loses its substance when wet, such as toilet paper, facial tissue, paper towels, or absorbent cotton. If the patient's legs and knees are uninjured, and spinal injury is *not suspected*, flex them to relieve pressure on the abdomen. Most patients with abdominal wounds require immediate transport to a trauma center, depending on the local protocol.

Figure 26-12 An abdominal evisceration is an open wound to the abdomen in which organs protrude through the wound.

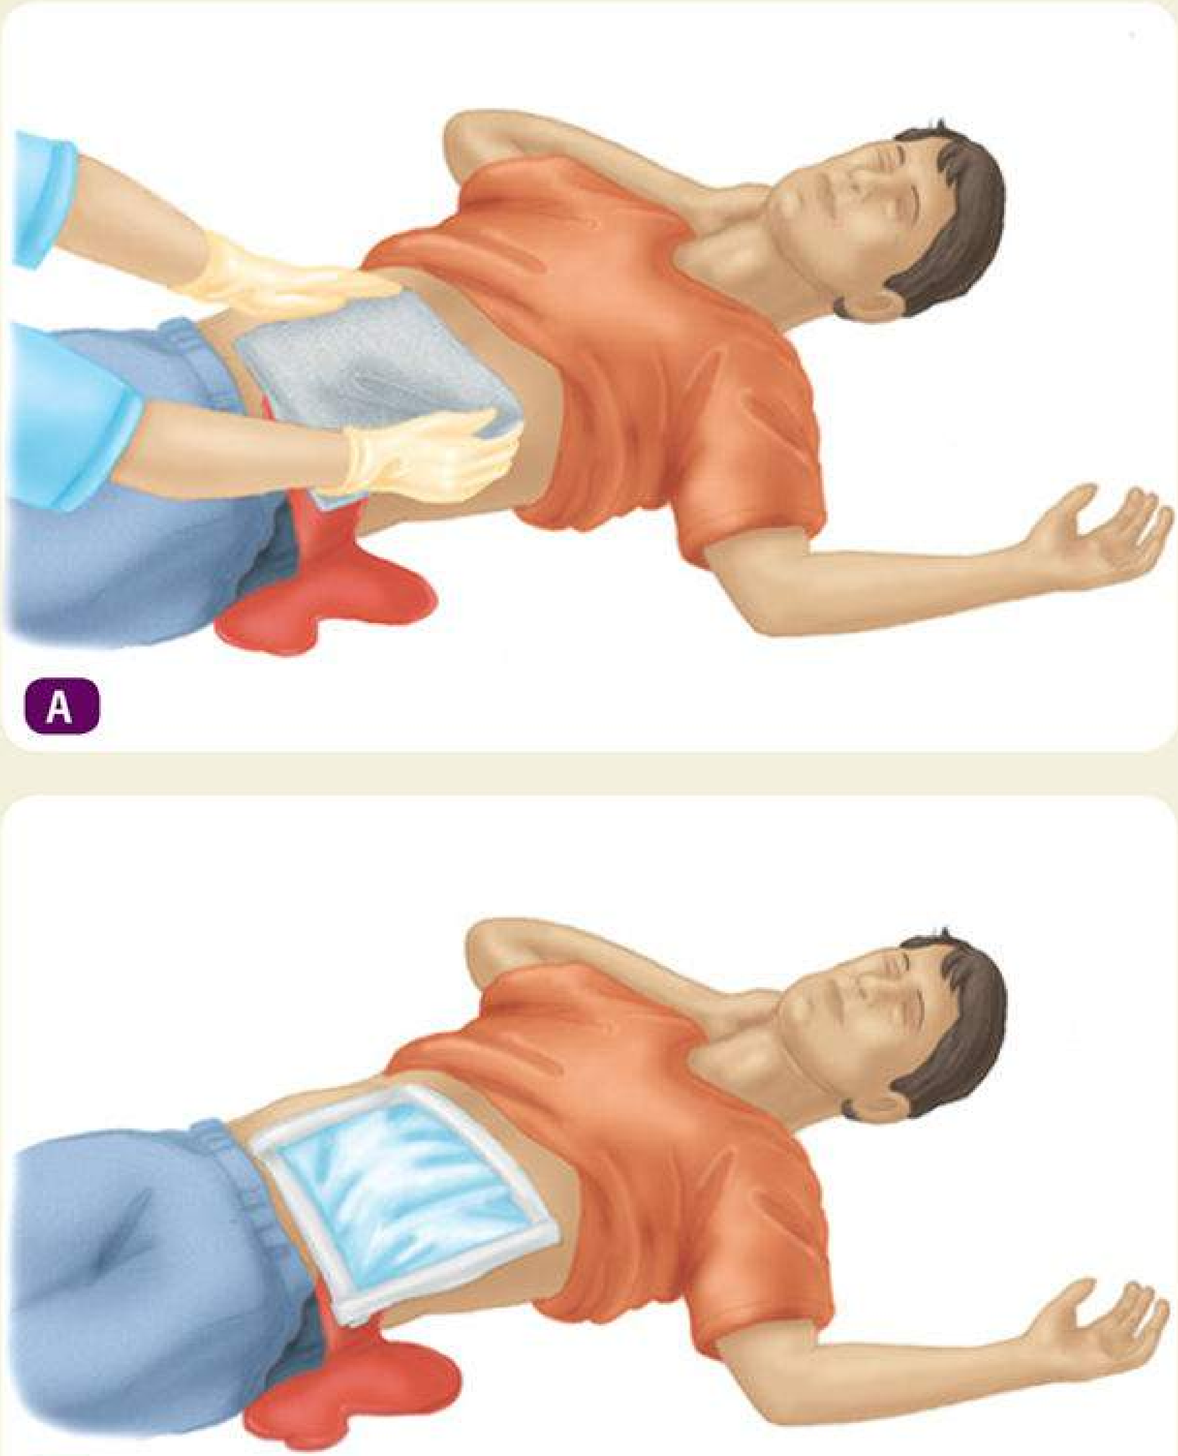

Figure 26-13

A. Cover exposed organs with sterile gauze compresses moistened with sterile saline solution. **B.** Place an occlusive dressing over the compresses, and secure it in place by taping all four sides.

Impaled Objects

Occasionally, a patient will have an object, such as a knife, fishhook, wood splinter, or piece of glass, impaled in his or her body. To treat this, follow the steps in **Skill Drill 26-1**:

1. Do not attempt to move or remove the object unless it is impaled through the cheek or mouth causing airway obstruction, or if the object is in the chest, or if the patient is pulseless and you must remove it to perform cardiopulmonary resuscitation (CPR). In most cases, a surgeon will have to remove the object; removing it in the field may cause more bleeding or damage nerves, blood vessels, or muscles within the wound. Stabilize the impaled body part Step 1.
2. Remove any clothing covering the injury. Control bleeding with direct pressure, and apply a bulky dressing to stabilize the object. If the object is in the chest, neck, or back, consider applying a base layer of occlusive dressing around the object to prevent air from entering the wound. Some combination of soft dressings, gauze, and tape may be effective, depending on the location and size of the object. To prevent further injury, manually secure the object by incorporating it into the dressing Step 2.
3. Protect the impaled object from being bumped or moved during transport by taping a rigid item such as a plastic cup, a section of a plastic water bottle, or a supply container over the stabilized object and its bandaging Step 3.

The only exceptions to the rule of not removing an impaled object are objects in the cheek or mouth that obstruct breathing and objects in the chest that directly interfere with performing CPR on a patient who is already in cardiac arrest. If the object is very long, cut off (shorten) the exposed portion, first securing it to minimize motion and, thus, internal damage and pain. Once the object has been properly secured and the bleeding is under control, provide prompt transport.

Skill Drill 26-1 Stabilizing an Impaled Object

Step 1

Do not attempt to move or remove the object. Stabilize the impaled body part.

Step 2

Control bleeding, and stabilize the object in place using soft dressings, gauze, and/or tape.

Step 3

Tape a rigid item over the stabilized object to prevent it from moving during transport.

Neck Injuries

An open neck injury can be life threatening. If the veins of the neck are open to the environment, they may suck in air **Figure 26-14**. If enough air is sucked into a blood vessel, it can actually block the flow of blood into the lungs and cause cardiac arrest. This condition is called *air embolism.* To control bleeding and prevent the possibility of air embolism, cover the wound with an occlusive dressing. Apply manual pressure, but do not compress both carotid vessels at the same time; if you do, this may impair circulation to the brain and cause a stroke. Secure a pressure dressing over the wound by wrapping roller gauze loosely around the neck and then firmly through the opposite axilla **Figure 26-15**.

Use caution with patients suffering from a neck injury depending on the MOI involved. Immobilize the C-spine if indicated, including placing a cervical collar. The cervical collar may assist with holding a dressing in place over a neck wound.

Figure 26-14 Open injuries to the neck can be very dangerous. If veins are open to the environment, they can suck in air, resulting in a potentially fatal condition called air embolism.

Figure 26-15 Cover neck wounds with an airtight dressing, and apply manual pressure. Do not compress both carotid arteries at the same time, as this may impair circulation to the brain.

Bites

Small Animal Bites and Rabies

At times you may be called to care for a person who has been bitten by a small animal such as a dog, cat, raccoon, squirrel, or other small nonlivestock animal. Be sure to consider scene and crew safety prior to entering the environment.

Most people who are bitten by small animals do not report the incident to a physician, believing that these bites are not serious; however, they can be very serious. A small animal's mouth is heavily contaminated with bacteria. You should consider all small animal bites as contaminated and potentially infected wounds that may require debridement (the removal of damaged tissue), antibiotics, and tetanus prophylaxis **Figure 26-16**. Occasionally, small animal bites result in mangled, complex wounds that require surgical repair. For these reasons, all small animal bites should be evaluated by a physician. Place a dry, sterile dressing over the wound, and promptly transport the patient to the ED. If an arm or leg was injured, splint that extremity. Often, the patient will be extremely upset and frightened, a situation that calls for reassurance on your part.

Figure 26-16 Small animal bite wounds should be examined at the hospital, as these wounds are heavily contaminated with bacteria. **A.** Dog bite. **B.** Cat bite.

A: Courtesy of Moose Jaw Police Service; B: © Chuck Stewart, MD.

A major concern with small animal bites is the spread of rabies, an acute, potentially fatal viral infection of the central nervous system that can affect all warm-blooded animals. Although rabies is extremely rare today, particularly with widespread vaccination of pets, it still exists. Stray dogs that have not been vaccinated can be carriers of the disease, as can squirrels, bats, foxes, skunks, and raccoons. The virus is in the saliva of a rabid, or infected, animal and is transmitted through biting or licking an open wound. Infection can be prevented in a person who has been bitten by such an animal only by a series of special vaccine injections, a painful procedure that must be started soon after the bite. Since animals that have rabies do not always demonstrate symptoms immediately, a person's only chance to avoid the vaccine is to find the animal and turn it over to the health department for observation and/or testing. Refer to your local animal control procedures.

Children, particularly young ones, may be seriously injured or even killed by dogs. These dogs are not always vicious or **rabid**; sometimes a child unknowingly provokes the animal. However, you must assume the animal may turn and attack you as well. Therefore, you generally should not enter the scene until the animal has been secured by the police or an animal control officer. Then you may carry out the necessary emergency care and transport the child to the ED.

Words of Wisdom

In many locations, reporting animal bites to public health officials is mandatory. Based on your protocols you may need to have law enforcement respond to the scene or to the hospital.

Human Bites

The human mouth, more so than even the small animal's mouth, contains an exceptionally wide range of bacteria and viruses. For this reason, you should regard any human bite that has penetrated the skin as a very serious injury. Similarly, any laceration caused by a human tooth can result in a serious, spreading infection **Figure 26-17**. Remember this if you treat someone who has been punched in the mouth; the person who delivered the punch may also need treatment.

Figure 26-17 Human bites can result in a serious, spreading infection. Thus, patients must be evaluated at the hospital.

The emergency treatment of bites consists of the following steps:

1. Apply a dry, sterile dressing.
2. Promptly immobilize the area with a splint or bandage.
3. Provide transport to the ED for surgical cleansing of the wound and antibiotic therapy.

Burns

As an EMT, you will often provide care to patients who have been burned. According to the American Burn Association, burns account for approximately 3,400 deaths per year. Burns are also among the most serious and painful of all injuries. A burn occurs when the body, or a body part, receives more radiant energy than it can absorb, resulting in an injury. Potential sources of this energy include heat, toxic chemicals, and electricity. The proper emergency care of a burn may increase a patient's chances of survival and decrease the risk or duration of a long-term disability. Although a burn may be the patient's most obvious injury, you should always perform a complete assessment to determine whether there are other serious injuries. Finally, keep in mind that children, older patients, and patients with chronic illnesses are more likely to experience shock from burn injuries. Be prepared to treat accordingly.

Safety Tips

Many fires generate toxic compounds such as cyanides, which are produced as a result of the combustion of synthetic materials. This environment is dangerous to all responders. You should enter only if you have been trained and are equipped to function in those areas.

Pathophysiology of Burns

Burns are soft-tissue injuries spread out over a large area created by the transfer of radiation, thermal, or electrical energy. Thermal burns can occur when skin is exposed to temperatures higher than 111°F (44°C). In general, the severity of a thermal injury directly correlates with temperature, concentration, or amount of heat energy possessed by the object or substance and the duration of exposure. For example, solids generally have higher heat content than gases, so exposure to a hot solid (such as the rack inside an oven) typically causes a more significant burn than exposure to hot gases (such as those coming out of an oven). Burn injuries are progressive—the greater the heat energy, the deeper the wound.

Exposure time is another important factor. Thermal injury can occur to unresponsive or paralyzed patients from seemingly innocent heat sources such as heating pads or heat lamps if the patient is left unattended and exposed for long periods of time. It may be difficult to evaluate the amount of heat energy or the amount of exposure time in many cases. There can be a vast difference in the temperature of a fire from the floor to the ceiling. Although most people naturally limit the amount of time they are exposed to such heat, if clothing is on fire or the person is trapped or unconscious, exposure time can be extended.

Complications of Burns

There are several complications that can result secondary to a burn injury, all of which can be life threatening. The skin serves as a barrier between the environment and the body. When a person is burned, this barrier is destroyed; the victim is now at a high risk for infection, hypothermia, hypovolemia, and shock. Burns to the airway are of significant importance because the loose mucosa in the hypopharynx can swell and lead to complete airway obstruction. Circumferential burns of the chest can compromise breathing. Circumferential burns of an extremity can lead to compartment syndrome, resulting in neurovascular compromise and irreversible damage if not appropriately treated. If you suspect any complications, call for ALS backup.

Words of Wisdom

Burns can cause hypothermia and acidosis and can prevent the blood from clotting effectively. These conditions increase the likelihood of death. Therefore, in the field and during transport, keep the patient warm and provide supplemental oxygen.

Words of Wisdom

Burn centers have different protocols and criteria for burn classification. If you have a burn center, pediatric hospital, or trauma center in your area, consult with them on how burns should be treated in the field and where these patients should be transported.

Burn Severity

The seriousness of a burn may influence the choice of a treatment facility. Five factors will help you to determine the severity of a burn.

1. What is the depth of the burn?
2. What is the extent of the burn?

These first two factors are the most important. After gauging these, ask yourself the following questions.

3. Are any critical areas (face, upper airway, hands, feet, genitalia) involved? Also included in critical areas are any

circumferential burns, which are burns that go completely around a body part such as an arm, foot, or chest.

4. Does the patient have any preexisting medical conditions or other injuries?
5. Is the patient younger than 5 years or older than 55 years?

If the answer to any of these three questions is yes, you should upgrade the classification Table 26-1.

Remember, burns to the face are of particular importance owing to the potential of airway involvement. Burns to the hands or feet or over joints are also considered serious because of a potential for loss of function as a result of scarring.

Special Populations

Abuse

When you are treating older adults, pediatric, or special needs patients with burns, it is important to be alert for the possibility of abuse. Older adult patients who are institutionalized, disoriented, or incapable of clear communication are particularly susceptible to abuse. Pediatric and special needs patients are similarly susceptible to abuse.

Signs of abuse include evidence of multiple injuries in various stages of healing (eg, multiple bruises of different colors, new and old fractures involving more than one extremity), injuries that do not seem to correspond to the history provided by caregivers, and burns associated with a suspicious history.

Burns that appear in a “pattern” are suspicious for intentional injuries. Multiple, small circular burns may be indicative of cigarette or cigar injuries. Other patterns may indicate irons, stovetops, or other hot surfaces not easily encountered accidentally. Scalding injuries to the buttocks, hands, or feet may also be indicative of abuse. Remember, these injuries are often inflicted in areas not readily seen. If you are suspicious that an older adult has been abused, fully examine the patient under his or her clothing for signs of abuse. As always, your priority is to provide appropriate support and transport the patient in a timely manner.

Table 26-1 Classification of Burns in Adults

Severe Burns

- Full-thickness burns involving the hands, feet, face, upper airway, or genitalia or circumferential burns of other areas
- Full-thickness burns covering more than 10% of the body's total surface area
- Partial-thickness burns covering more than 30% of the body's total surface area
- Burns associated with respiratory injury (smoke inhalation or inhalation injury)
- Burns complicated by fractures
- Burns on patients younger than 5 years or older than 55 years that would be classified as "moderate" on young adults

Moderate Burns

- Full-thickness burns involving 2% to 10% of the body's total surface area (excluding hands, feet, face, genitalia, and upper airway)
- Partial-thickness burns covering 15% to 30% of the body's total surface area
- Superficial burns covering more than 50% of the body's total surface area

Minor Burns

- Full-thickness burns covering less than 2% of the body's total surface area
- Partial-thickness burns covering less than 15% of the body's total surface area
- Superficial burns covering less than 50% of the body's total surface area

Depth

Burns are first classified according to their depth **Figure 26-18**. You must be able to identify the following three types of burns:

- **Superficial (first-degree) burns** involve only the top layer of skin, the epidermis. The skin turns red but does not blister or burn through this top layer. The burn site is often painful. Sunburn is a good example of a superficial burn.
- **Partial-thickness (second-degree) burns** involve the epidermis and some portion of the dermis. These burns do not destroy the entire thickness of the skin nor is the subcutaneous tissue injured. Typically, the skin is moist, mottled, and white to red. Blisters are present. Partial-thickness burns cause intense pain.
- **Full-thickness (third-degree) burns** extend through all skin layers and may involve subcutaneous layers, muscle, bone, or internal organs. The burned area is dry and leathery and may appear white, dark brown, or even charred. Some full-thickness burns feel hard to the touch. Clotted blood vessels or subcutaneous tissue may be visible under the burned skin. If the nerve endings have been destroyed, a severely burned area may not have feeling and the surrounding less severely burned areas may be extremely painful.

Words of Wisdom

The depth of burns can vary. A full-thickness burn may be surrounded by areas of partial-thickness and superficial burns. So, while the area of the full-thickness burn is painless, the patient can still experience pain due to the extent of damage to the surrounding tissues. Request ALS for assistance with pain management if appropriate.

A pure full-thickness burn is unusual. Severe burns are typically a combination of superficial, partial-thickness, and full-thickness burns. Superficial burns heal well without scarring. Small partial-thickness burns also heal without scarring. However, deep partial-thickness burns and all full-thickness burns are prone to scarring and may be best managed surgically.

Significant airway burns are also serious. They may be associated with singed hair within the nostrils, soot around the nose and mouth, hoarseness, and hypoxia. These patients should be rapidly transported to an ED or facility capable of advanced airway management. It becomes increasingly more difficult to achieve airway control once swelling begins.

It may be impossible to accurately estimate the depth of a particular burn shortly after injury. Even experienced burn surgeons sometimes underestimate or overestimate the extent of a particular burn.

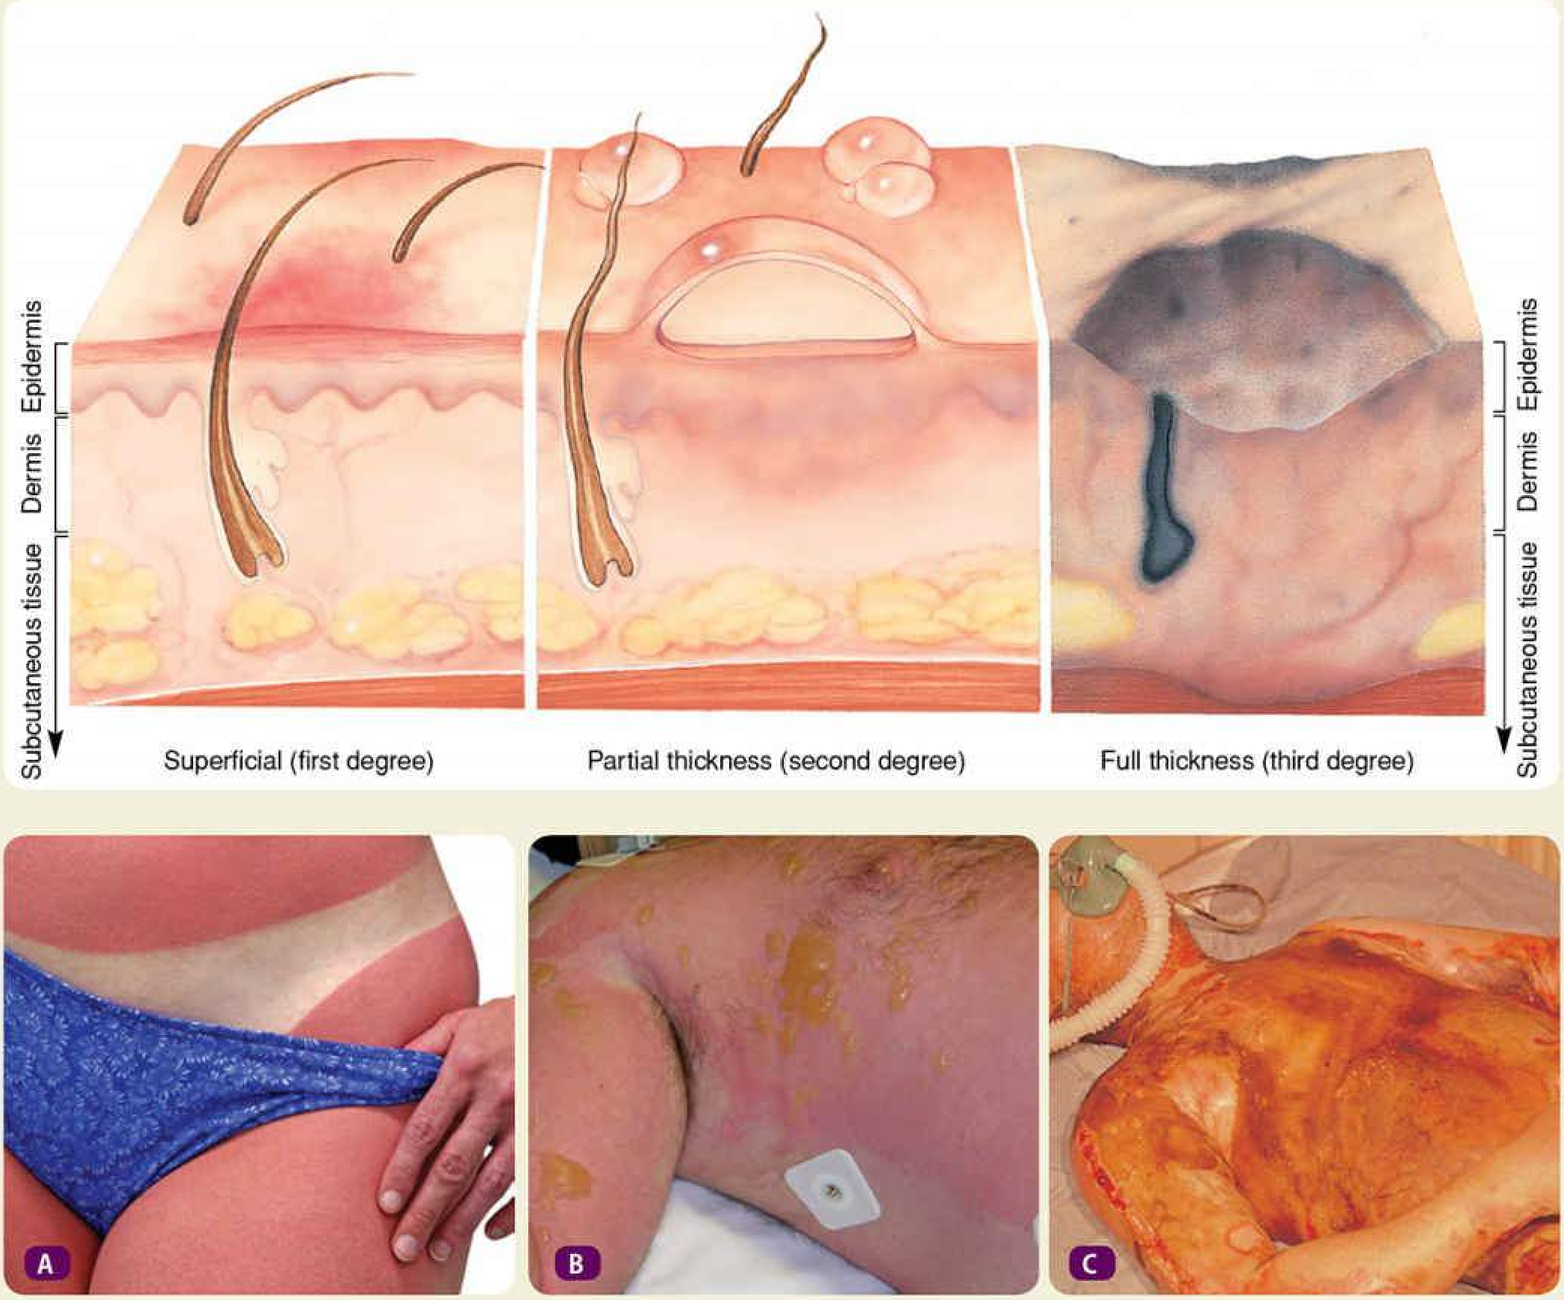

Figure 26-18 Classification of burns. **A.** Superficial or first-degree burns involve only the epidermis. The skin turns red but does not blister or actually burn through. **B.** Partial-thickness or second-degree burns involve some of the dermis, but they do not destroy the entire thickness of the skin. The skin is mottled, white to red, and is often blistered. **C.** Full-thickness or third-degree burns extend through all layers of the skin and may involve subcutaneous tissue and muscle. The skin is dry, leathery, and often either white or charred.

Extent

One quick way to estimate the surface area that has been burned is to compare it to the size of the patient's palm, which is roughly equal to 1% of the patient's total body surface area. This technique is called the rule of palm. Another useful measurement system is the rule of nines, which divides the body into sections, each of which is approximately 9% of the total surface area **Figure 26-19**. Remember that the head of an infant or child is relatively larger than the head of an adult, and the legs are relatively smaller. When you calculate the extent of burn injury, include only partial-thickness (second-degree) and full-thickness (third-degree) burns. Document superficial (first-degree) burns, but do not include them in the body surface area estimation of extent of burn injury.

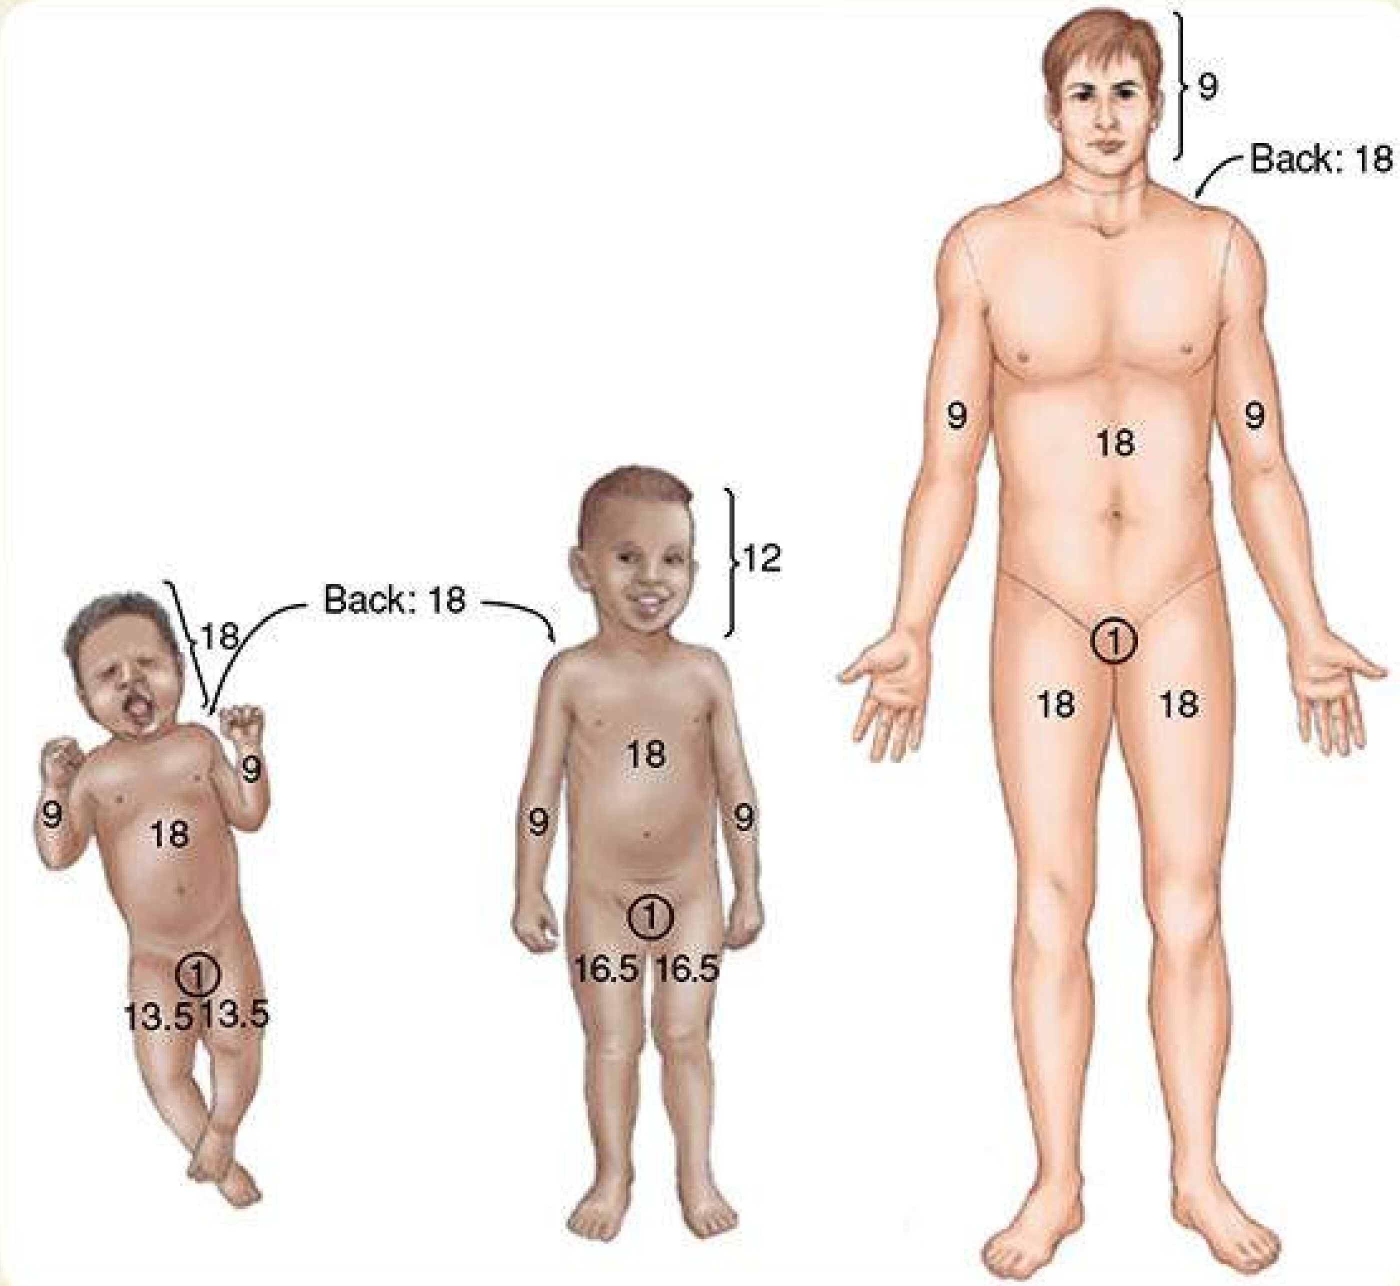

Figure 26-19 The rule of nines is a quick way to estimate the amount of surface area that has been burned; it divides the body into sections, each representing approximately 9% of the total body surface area. The proportions differ for infants, children, and adults.

Special Populations

Pediatric Needs

Burns to children are generally considered more serious than burns to adults Table 26-2. The reason is infants and children have more surface area relative to total body mass, which means greater fluid and heat loss. In addition, children do not tolerate burns as well as adults do. Children are also more likely to go into shock, have hypothermia develop, and experience airway difficulties because of the unique differences associated with their ages and anatomy.

Many burns in infants and children result from child abuse. The classic burn resulting from deliberate immersion involves the hands and wrists, as well as the feet, lower legs, and buttocks. Similarly, burns around the genitals and multiple cigarette burns should be viewed as possible abuse. Report all suspected cases of abuse to the proper authorities, especially those where a significant delay in evaluation and treatment is evident (see Chapter 34, *Pediatric Emergencies*).

Table 26-2 Classification of Burns in Infants and Children

Classification
Severe Burns
▪ Any full-thickness burn ▪ Partial-thickness burns covering more than 20% of the body's total surface area
Moderate Burns
▪ Partial-thickness burns covering 10% to 20% of the body's total surface area
Minor Burns
▪ Partial-thickness burns covering less than 10% of the body's total surface area

Patient Assessment of Burns

When you assess a burn, it is important to classify the patient's burns. Classifying burns involves determining the source of the burn, the depth of the burn, and its severity. Assessing a burn patient is essentially the same as assessing any other trauma patient. Again, be careful to focus not on the dramatic appearance of the injury, but, rather, on potential life threats that require treatment.

Scene Size-up

As you arrive on scene, observe the scene for hazards and threats to the safety of you and your crew, bystanders, and the patient. Ensure that the factors that led to the patient's burn injury do not pose a hazard to you and your crew. Is the electricity turned off? Is the chemical leak secure? Has the fire been extinguished? Is there any potential for violence? Has the patient been decontaminated, if needed?

When possible, determine the type of burn that has been sustained and the MOI. What the patient reports will often provide some important information about the extent of the injury. Burn patients can be a challenge to manage both physically and emotionally. It is easy to become overwhelmed by the sights, sounds, and smells of burn victims.

Assess the scene for any environmental hazards. If the patient is the victim of a lightning strike, is the weather still a threat to your safety? Wear gloves and eye protection when treating any burn patient and gowns when serious injuries are expected. Determine the number of patients; the possibility for multiple patients grows if you are responding to a lightning strike or a vehicle crash. At vehicle crashes, ensure the scene is safe from energized electrical lines or leaking fuel in the area where you will be working. If you determine the power company, the fire department, or ALS units are needed, call for additional resources early. Remember, the burn patient is a trauma patient. Consider the potential for spinal injuries, broken bones, inhalation injuries, and other injuries.

Primary Assessment

The primary assessment includes a rapid exam of the patient to identify and manage life-threatening concerns and to assist with transport decisions. The primary assessment begins when you approach the patient and form a general impression.

As you approach the burn trauma patient, simple clues can help identify how serious the injuries are and how quickly you need to assess and treat them. If your patient greets you with a hoarse voice or reports being in an enclosed space with a fire or intense heat source, these should be indications of a significant MOI. The presence of stridor means your patient's airway is significantly swollen and can signal impending complete airway obstruction. Similarly, if the patient has singed facial hair, eyebrows, or nasal hair, your initial general impression might be the patient has a potential airway and/or breathing problem.

Child abuse and elder abuse are unpleasant situations to handle. Unfortunately, they are often situations that involve burns. As you enter a scene where burns are involved, be suspicious of clues that may indicate abuse.

The burned patient you encounter may have graphic injuries; however, stay focused on the primary assessment. As you begin, always consider the need for manual spinal stabilization.

Check for responsiveness using the AVPU scale. Assess a patient's mental status by asking the patient about his or her chief complaint. If the patient is alert, this should help direct you to any apparent life threats. If the patient is not alert, determine if he or she responds to verbal or painful stimuli or if he or she is unresponsive. An unresponsive patient may indicate a life-threatening condition. In all patients whose level of consciousness is less than alert and oriented, you should administer high-flow oxygen via a nonrebreathing mask and provide immediate transport to the ED.

Ensure the patient has a clear and patent airway. If the patient is unresponsive or has a significantly altered level of consciousness, consider inserting a properly sized oropharyngeal or nasopharyngeal airway. Be alert to signs that the patient has inhaled hot gases or vapors, such as singed facial hair or soot present in or around the airway. Heavy amounts of secretions and frequent coughing may also indicate a respiratory burn.

Quickly assess for adequate breathing. Inspect and palpate the chest wall for DCAP-BTLS. Check for clear and symmetrical breath sounds and provide high-flow oxygen or provide assisted ventilations using a BVM as needed, depending on the level of consciousness and breathing rate/quality of your patient. Burn patients are trauma patients. Evaluate and treat them for spinal injuries and airway problems concurrently. How you open the airway depends on whether a neck injury is suspected. Could the patient have fallen? Do the circumstances surrounding the MOI suggest a possible spinal injury?

YOU are the Provider — PART 5

You reassess the patient and then call your radio report to the receiving facility. The patient is still experiencing respiratory distress, but he is moving air adequately. Your estimated time of arrival at the hospital is 6 minutes.

Recording Time: 17 Minutes	
Level of consciousness	Conscious and alert, but anxious
Respirations	22 breaths/min; labored; hoarse voice
Pulse	116 beats/min; strong and regular
Skin	Red, warm, and dry
Blood pressure	160/80 mm Hg
Spo_2	96% (on oxygen)

9. What, if any, additional treatment is indicated for this patient?

Quickly assess the pulse rate and quality and determine perfusion based on the patient's skin condition, color, temperature, and capillary refill time. If you see significant bleeding, take the necessary steps to control it. Significant bleeding is an immediate life threat. If the patient has obvious life-threatening external hemorrhage, control the bleeding first (before airway and breathing); then treat the patient for shock as quickly as possible. Shock frequently develops in burn patients. Treat the shock by preventing heat loss. This is very important because the damaged skin has only a limited ability to regulate body temperature. Cover the patient with a blanket to prevent heat loss.

If the patient you are treating has an airway or breathing problem, significant burn injuries, significant external bleeding, or signs and symptoms of internal bleeding, consider rapid transport to the nearest hospital, trauma center, or burn center for treatment. Consulting with ALS providers may be appropriate for burn patients with moderate or severe burns and burns of the airway or inhalation injury. ALS providers can treat these patients with endotracheal intubation and intravenous fluids to support airway, breathing, and circulation (shock) difficulties. These can progress so rapidly that immediate ALS assistance can make the difference between life and death.

History Taking

Investigate the chief complaint or history of present illness. Next, be alert for signs or symptoms of other injuries due to the MOI. If the patient was burned in a confined space, suspect an inhalation injury. When burns result from explosive forces, be alert for other internal injuries and fractures.

Obtain a medical history and be alert for injury-specific signs and symptoms as well as any pertinent negatives such as no pain. Typical signs of a burn are pain, redness, swelling, blisters, or charring. Typically, symptoms include pain and/or burning at the injury site. Regardless of the type of burn injury, it is important to stop the burning process, apply dressings to prevent contamination, and treat the patient for shock.

Obtain a SAMPLE history from your patient. In addition, ask the following questions of a burn patient:

- Are you having any difficulty breathing?
- Are you having any difficulty swallowing?
- Are you having any pain?

When you assess a burn patient, check to see whether he or she has an emergency medical identification device—a wallet card, necklace, or bracelet—or ask the patient or a family member about preexisting conditions, which may increase the chances of a poor outcome. Remember that the environment, bystanders, and medical identification devices may provide important clues about your patient's condition.

Secondary Assessment

The secondary assessment is a more detailed, comprehensive, or focused examination of the patient that is conducted to reveal injuries that may have been missed during the primary assessment. In some instances where the patient is critically injured or the transport time is short, you may not have time to conduct a secondary assessment. In other instances, the secondary assessment may occur en route to the ED.

After you complete the primary assessment, perform an exam of the entire body. Quickly assess the patient from head to toe looking for DCAP-BTLS to ensure you have found all of the problems and injuries. Make a rough estimate, using the rule of nines, of the extent of the burned area to report to medical control. Determine what classification of burns the victim has sustained. The patient may report pain depending on the amount of nerve damage. Before you package your patient, determine the severity of the burns the victim has sustained. Severity is calculated by considering what caused the burn, the body region that is burned, the depth and extent of the burn, the patient's age, and preexisting illness or injuries. Follow your local protocols for criteria for transport to a burn center. Package the patient for transport based on your findings. Remember to immobilize your patient for spinal injuries as appropriate.

Assessing the respiratory system involves looking, listening, and feeling. A patient who is conscious, alert, and talking does not have immediate airway or breathing difficulties. When you assess the respiratory system of a burn patient, look specifically for the following findings:

1. Soot around the mouth
2. Soot around the nose
3. Singed nasal hairs

If any of these findings are present, open the patient's mouth and examine for burns or swelling of the tongue. Ask the patient to cough, and assess for black sputum, which indicates smoke inhalation.

Next, listen to breath sounds with a stethoscope. Breath sounds should be clear and equal bilaterally, anteriorly, and posteriorly. Determine the patient's rate and quality of respiration. Finally, assess the chest for DCAP-BTLS and asymmetrical chest wall movement. Burn patients who present with any type of airway problem should be considered critical.

Quickly assess pulse rate and quality; determine the skin condition, color, and temperature; and check the capillary refill time. If you see visible significant bleeding, you must begin the steps necessary to control bleeding. Significant bleeding, internal or external, is an immediate life threat. If the patient has obvious life-threatening bleeding, quickly control it and treat for shock as quickly as possible. Non-life-threatening bleeding, such as in abrasions, can be bandaged later in your assessment as necessary.

Assess the patient's neurologic system to formulate baseline data for further decisions on patient management. This examination should include assessing for the following:

- Level of consciousness—use AVPU
- Pupil size and reactivity
- Motor response
- Sensory response

Assess the musculoskeletal system by performing a detailed full-body scan. Assess all anatomic regions looking for DCAP-BTLS. Specifically look for the following features:

- In the head, check for singed nasal or facial hair, burns or swelling of the face or ears, or burns or swelling in the mouth. If the patient sustained electrical injury, examine the scalp for signs of entrance or exit wounds.
- In the neck, check for burns, especially if they encircle the entire neck, which can impair circulation.
- In the chest, check for burns that encircle the entire chest, which can impair normal chest rise.
- In the abdomen and pelvis, feel all four quadrants for tenderness or rigidity. If the abdomen is tender, expect internal bleeding. Look for burns of the genitalia, as burns to this area are considered high risk.
- Look for burns that encircle an extremity, as they can impair circulation. If the patient sustained an electrical injury, assess thoroughly for entry or exit burn wounds. This should include the axilla and the area between digits. Record pulse and motor and sensory function.
- Examine the posterior surface of the body, as large burns or electrical exit burns may be located in this body area.

A systematic examination helps you understand what has happened to the outside of your patient. Vital signs are a good indication of how your patient is doing on the inside. If you determine an early set of vital signs, you will know how your patient is tolerating his or her injuries while en route to the hospital. Because shock is often pronounced in a burn patient, blood pressure, pulse, and skin assessment for perfusion are important vital signs to obtain.

In addition to hands-on assessment, use monitoring devices, including oxygen saturation monitors and carbon monoxide monitors, to quantify oxygenation and circulatory status.

Reassessment

Repeat the primary assessment, and reassess the patient's vital signs. Reassess the patient's chief complaint. Reevaluate interventions and treatment you have provided to the patient, particularly those used to treat shock. Identify and treat any changes in the patient's condition.

The goals in treating patients with burns are to stop the burning process, assess and treat breathing, support circulation, and provide rapid transport. Because burn patients are also trauma patients, provide spinal immobilization consistent with your local protocol if you suspect spinal injuries. Oxygen is mandatory for inhalation burns and large body surface area burns. If the patient has signs of hypoperfusion, treat aggressively for shock and provide rapid transport to the appropriate hospital. Cover all burns according to your local protocols. The risk of infection is very high and can be reduced if you cover large burn areas with sterile burn sheets or clean linen. Do not delay transport of a seriously injured patient to complete nonlifesaving treatments in the field such as splinting extremity fractures. Instead, complete these types of treatment en route to the hospital.

Provide hospital personnel with a description of how the burn occurred. Many times the ED staff can determine the appropriate dilutant for chemical burns or calculate appropriate treatments for other types of burns with enough advanced notice. Report and document the extent of the burns. This should include the amount of body surface area involved, the depth of the burn, and the location. For example, you may say 10% full-thickness burns, 15% partial-thickness burns, and 25% superficial burns to the chest, abdomen, and left lower extremity. If special areas are involved (genitalia, feet, hands, face, or circumferential), they should be specifically mentioned and documented.

Emergency Medical Care for Burns

Your first responsibility in caring for a patient with a burn is to stop the burning process and prevent additional injury. When caring for a burn patient, follow the steps in **Skill Drill 26-2**:

1. Follow standard precautions. Because a burn destroys the patient's protective skin layer, always wear gloves and eye protection when treating a burn patient.
2. Move the patient away from the burning area. If any clothing is on fire, wrap the patient in a blanket or follow the specific guidelines outlined by your local fire department protocol to put out the flames, and then remove any smoldering clothing and/or jewelry.
3. If allowed by local protocol, immerse the area in cool, sterile water or saline solution, or cover with a clean, wet, cool dressing if the skin or clothing is hot. This not only stops the burning, it also relieves pain. Prolonged immersion, however, may increase the risk of infection and hypothermia. For this reason, you should not keep the affected part submersed in water for more than 10 minutes. If the burning has stopped before you arrive, do not immerse the affected part at all. As an alternative to immersion, irrigate the burned area until the burning stops; next apply a sterile dressing Step 1.

   Cover large (greater than 10%) BSA burns with a dry, sterile, nonadherent dressing (eg, a sterile burn sheet). Other than for the purpose of stopping the burning process, do not apply water or saline to large surface burn areas.
4. Provide high-flow oxygen. Also remember that more fire victims die of smoke inhalation than of skin burns. A patient who has facial burns or has inhaled smoke or fumes may experience respiratory distress. Therefore, provide high-flow oxygen to the patient. Keep in mind that a patient who appears to be breathing well at first may suddenly experience severe respiratory distress. Therefore, continually assess the airway for possible problems Step 2.
5. Rapidly estimate the burn's severity. Cover the burned area with a dry, sterile dressing to prevent further contamination. Sterile gauze is best if the area is not too large. You may cover larger areas with a clean, white sheet. Do not put anything else on the burned area. Never use ointments, lotions, or antiseptics of any kind and do not intentionally break any blisters.
6. Check for traumatic injuries or other medical conditions that may be immediately life threatening. Most patients who have been burned have normal vital signs and can communicate at first, which will make your assessment easier Step 3.
7. Treat the patient for shock.
8. An extensive burn can produce hypothermia (loss of body heat). Prevent further heat loss by covering the patient with warm blankets.
9. Provide prompt transport by local protocol. Do not delay transport to perform a prolonged assessment or to apply coverings to burns in a critical patient Step 4.

Words of Wisdom

The key to initial burn treatment is to stop the burning process and not to “cool” the skin. Using cool water and not cold water is crucial. Using cold water or ice water can cause further injury to the tissue.

Management of Specific Burns

Thermal Burns

Thermal burns are caused by heat (as opposed to electricity, chemicals, or radiation). Many different situations can cause thermal burns, and all pose a safety hazard to responding emergency care providers. Most commonly, thermal burns are caused by scalds or an open flame. A **flame burn** is very often a deep burn, especially if a person’s clothing catches fire. Hot liquids produce scald injuries. A **scald burn** is most commonly seen in children and handicapped adults but can happen to anyone, particularly while cooking. Scald burns often cover large surface areas of the body because liquids can spread quickly. Coming in contact with hot objects produces a **contact burn**. Ordinarily, reflexes protect a person from prolonged exposure to a very hot object, so contact burns are rarely deep unless the patient was prevented from drawing away from the hot object (for example, unconscious, intoxicated, restrained, or impaired).

Skill Drill 26-2 Caring for Burns

Step 1

Follow standard precautions to help prevent infection. If safe to do so, remove the patient from the burning area; extinguish or remove hot clothing and jewelry as necessary. If the wound is still burning or hot, immerse the hot area in cool, sterile water, or cover with a wet, cool dressing.

Step 2

Provide high-flow oxygen, and continue to assess the airway.

Step 3

Estimate the severity of the burn, and then cover the area with a dry, sterile dressing or clean sheet. Assess and treat the patient for any other injuries.

Step 4

Prepare for transport. Treat for shock. Cover the patient with blankets to prevent loss of body heat. Transport promptly.

A **steam burn** can produce a topical (scald) burn. Minor steam burns are common when uncovering the plastic wrap from microwaved food. When the plastic is peeled away, hot steam escapes directly onto the person's hand. Steam (that is, gaseous water) is also responsible for causing airway burns.

Another important source of thermal burns is the **flash burn** produced by an explosion, which may briefly expose a person to very intense heat. Lightning strikes can also cause a flash burn. These injuries are usually minor compared with the potential for trauma from whatever caused the flash.

Manage thermal burns largely the same as you would manage any other burn. Stop the burning source, cool the burned area if appropriate, and remove all jewelry. Maintain a high index of suspicion for inhalation injuries. Increased exposure time will increase damage to the patient. The larger the burn, the more likely the patient will be susceptible to hypothermia and/or hypovolemia. All patients with large surface burns should have a dry sterile dressing applied to help maintain body temperature, prevent infection, and provide comfort.

Inhalation Burns

Inhalation injuries can occur when burning takes place in enclosed spaces without ventilation. When the upper airway is exposed to excessive heat, the patient can experience rapid and serious airway compromise. The heat can be an irritant to the lungs and the airway, causing coughing, wheezing, and rapid swelling or edema of the mucosa of the upper airway tissues, often evidenced by stridor. Upper airway damage is often associated with the inhalation of superheated gases. Lower airway damage is more often associated with the inhalation of chemicals (eg, acids, aldehydes) and particulate matter. When treating a patient for inhalation injuries, you may encounter severe upper airway swelling which requires immediate intervention. Sometimes airway swelling and compromise will develop more slowly and not manifest until transport. You should consider requesting ALS backup if the patient has signs or symptoms of edema, such as stridor, a hoarse voice, singed nasal hairs, singed facial hairs, burns of the face, or carbon particles in the sputum. Apply cool mist, aerosol therapy, or humidified oxygen to help reduce some minor edema. Because most ambulances do not carry misters, apply an ice pack to the throat to help reduce the swelling, provided the tissue in that area does not have burns.

Inhalation of Toxic Gases

The combustion process produces a variety of toxic gases. The less efficient the combustion process, the more toxic the gases—such as carbon monoxide (CO) and carbon dioxide (CO_2)—that may be created. When furnaces, kerosene heaters, and other heating devices are in poor repair, they may emit unsafe levels of these toxic gases. Internal combustion engines may emit many of the same gases and, consequently, should always have their exhaust vented to the outdoors. A common cause of CO exposure is running a small engine in an enclosed space like a garage or basement. For this reason, many ambulance services and fire departments have added CO detectors to their garages or ambulance bays. Firefighters who are performing an overhaul after a fire may be exposed to high levels of CO, as may people who are exposed to large amounts of car exhaust (such as toll takers and auto mechanics).

CO intoxication should be considered whenever a group of people in the same place all report a headache or nausea (a malfunctioning furnace or car exhaust being sucked into the air-handling system can cause CO intoxication in groups of people). Similarly, you should be suspicious when people complain of feeling sick at home but not when they go to work or school.

CO can displace oxygen from the alveolar air and from its attachment sites on hemoglobin molecules contained in circulating red blood cells. Because CO binds to receptor sites on hemoglobin at least 250 times more easily than oxygen (O_2), the patient's hemoglobin may become saturated with the wrong chemical. Being exposed to relatively small concentrations of CO (such as in cigarette smoke) will result in progressively higher blood levels of CO. Most people have approximately 2% CO attached to their hemoglobin, but these levels may be as high as 4% to 8% in heavy smokers. Levels of 50% or higher may be fatal.

Traditional wisdom tells us that patients with CO intoxication will appear "cherry red." Most practitioners agree that cherry red skin, lips, and nail beds are more commonly observed in patients who have died and less often observed in patients who are alive after exposure to CO. So, never rule out CO intoxication because the patient's skin is not cherry red.

Patients with severe CO intoxication usually have an O_2 saturation (Spo_2) level that is normal. For this reason, you should be suspicious of pulse oximeter readings when you are dealing with a patient who is suspected of having CO poisoning. New devices that can measure a patient's CO level are becoming more widespread in EMS systems, allowing providers to recognize and treat low-level CO intoxication rapidly.

The gaseous form of cyanide is hydrogen cyanide (HCN). It is generated by the combustion of commonly encountered substances such as paper, cotton, and wool. HCN is colorless and has the smell of bitter almonds; however, it can be difficult to detect at the scene of a fire. Prehospital diagnosis of HCN poisoning is difficult because laboratory studies are necessary. Signs and symptoms involve the central nervous, respiratory, and cardiovascular systems of the body and include faintness, anxiety, abnormal vital signs, headache, seizures, paralysis, and coma.

In situations where you have patients who have sustained inhalation injuries, you must first ensure your own safety and the safety of your coworkers. Once you have taken precautions, prehospital treatment of a patient with suspected HCN poisoning may include decontamination and supportive care according to signs and symptoms displayed by the patient until an antidote can be administered by ALS providers.

Exposure to other toxic gases can also cause damage to organs and systems and may cause death. Care for any toxic gas exposure includes recognition, identification, and supportive treatment as necessary according to the patient's signs and symptoms.

Chemical Burns

A chemical burn can occur whenever a toxic substance contacts the body. Most chemical burns are caused by strong acids or strong alkalis. The eyes are particularly vulnerable to chemical burns **Figure 26-20**. Sometimes the fumes alone from strong chemicals can cause burns, especially to the respiratory tract. The severity of the burn is directly related to the type of chemical, the concentration of the chemical, and the duration of the exposure.

In cases of severe chemical burns or exposure, consider mobilizing a hazardous materials (HazMat) team, if appropriate. To prevent exposure to hazardous materials, determine if you can safely approach the patient. In some cases you will need to wait to provide care until hazardous materials technicians have decontaminated the patient. You must wear the appropriate chemical-resistant gloves and eye protection whenever you are caring for a patient with a chemical burn. Be particularly careful not to get any chemical, dry or liquid, on yourself or on your uniform; consider wearing a protective gown when this is a possibility. Remember that exposure risk is also present when you are cleaning up after a call.

Figure 26-20 The eyes are particularly vulnerable to chemical burns.

Treatment of chemical burns can be specific to the chemical agent. If available, read all of the labels of the chemical agent. Do not risk exposure while attempting to gather information on the chemical. If the exposure occurs at an industrial site, such as a chemical manufacturing plant, an expert should be on-site and should be able to provide you with valuable information on the chemical.

The emergency care of a chemical burn is basically the same as that for a thermal burn, discussed later in the chapter. The severity of the burn will depend on the type of chemical, its strength, the duration of exposure, and the area of the body exposed. To stop the burning process, remove any chemical from the patient. A dry chemical that is activated by contact with water may damage the skin more when it is wet than when it is dry. Therefore, always brush off dry chemicals from the skin and clothing before flushing the patient with water **Figure 26-21**. Remove the patient's clothing, including shoes, stockings, gloves, and any jewelry or eyeglasses, because there may be small amounts of chemicals in the creases. Take great care to ensure you do not come in contact with the chemical. The patient should be properly decontaminated by properly trained personnel.

For liquid chemicals, immediately flush the burned area with large amounts of water **Figure 26-22**. Take care not to contaminate uninjured areas or make the patient hypothermic. Never direct a forceful stream of water from a hose at the patient; the extreme water pressure may mechanically injure the burned skin. Continue flooding the area with gallons of water for 15 to 20 minutes after the patient says the burning pain has stopped. If the patient's eye has been burned, hold the eyelid open (without applying pressure over the globe of the eye) while flooding the eye with a gentle stream of water **Figure 26-23**. Flush the eyes from the inside corners to the outside to prevent cross contamination. If only one eye has been affected, turn the patient's head to that side and flush. If both eyes are affected, consider hooking up a nasal cannula to a bag of saline to flush both eyes simultaneously. The prongs can be placed on the bridge of the nose to flush from the inside corners of the eyes to the outside corners. Be careful not to touch the prongs to the eye or surrounding tissue. Continue flushing the contaminated area en route to the hospital.

Figure 26-21 Brush off dry chemicals before you flush the burned area with water.

Figure 26-22 Flush the burned area with large amounts of water for 15 to 20 minutes after the patient says that the burning pain has stopped. Avoid contaminating uninjured areas.

As with any substance, once the fluid has been contaminated with the chemical, collect it and properly dispose of it. Conduct a proper decontamination prior to loading any patient into the ambulance and again prior to entering a hospital.

Electrical Burns

Electrical burns may be the result of contact with high- or low-voltage electricity. High-voltage burns may occur when utility workers make direct contact with power lines. Ordinary household current is still powerful enough to cause severe burns as well as cardiac dysrhythmias.

Figure 26-23 Flood the affected eye with a gentle stream of water. Hold the eyelids open, a challenging task because the patient's reflex is to keep the eye shut. Take care to prevent any of the chemical from getting into the other eye during flushing.

There must be a complete circuit between the electrical source and the ground for electricity to flow. Any substance that prevents this circuit from being completed, such as rubber, is called an insulator. Any substance that allows a current to flow through it is called a conductor. The human body, which is primarily water, is a good conductor. Thus, electrical burns occur when the body, or a part of it, completes a circuit connecting a power source to the ground **Figure 26-24**.

The type of electric current, magnitude of current (amperage), and voltage have effects on the seriousness of burns. When an electric current enters the body, the skin is burned at the entrance wound as well as everywhere along the path until the current grounds and exits the body. In addition to tissues damaged by the heat, significant chemical changes take place in the nervous, cardiovascular, and muscular systems of the body, causing disruption of the body's normal functions and/or even system failure.

Your safety is particularly important when you are called to the scene of an emergency involving electricity. Obviously, you can be fatally injured by coming into contact with power lines. But you can also be fatally injured by touching a patient who is still in contact with a live power line or any other electrical source. For this reason, never attempt to remove someone from an electrical source unless you are specially trained to do so. Likewise, never move a downed power line unless you have the special training and equipment necessary for the job. Before even approaching someone who may still be in contact with a power line or an electrical appliance, make certain the power is turned off. Always assume that any downed power line is live.

Figure 26-24 The human body is a good conductor of electricity. An electrical burn usually occurs when the body, acting as a conductor, completes a circuit.

A burn injury appears where the electricity enters (an entrance wound) and exits (an exit wound) the body. The entrance wound may be quite small **Figure 26-25A**, but the exit wound can be extensive and deep **Figure 26-25B**. Always look for both entrance and exit wounds. There are two dangers specifically associated with electrical burns. First, there may be a large amount of deep tissue injury. Electrical burns are always more severe than the external signs indicate. The patient may have only a small burn to the skin but may have massive damage to the deeper tissues, organs, and the nervous system **Figure 26-26**. The force of the electrical energy can also cause fractures or joint dislocations. Second, the patient may go into cardiac or respiratory arrest from the electric shock; although, if the patient is not in cardiac arrest on your arrival, it is unlikely he or she will do so during transport.

Figure 26-25 Electrical burns, like gunshot wounds, have entrance and exit wounds. **A.** An entrance wound is often quite small. **B.** The exit wound can be extensive and deep.

A, B: © Chuck Stewart, MD.

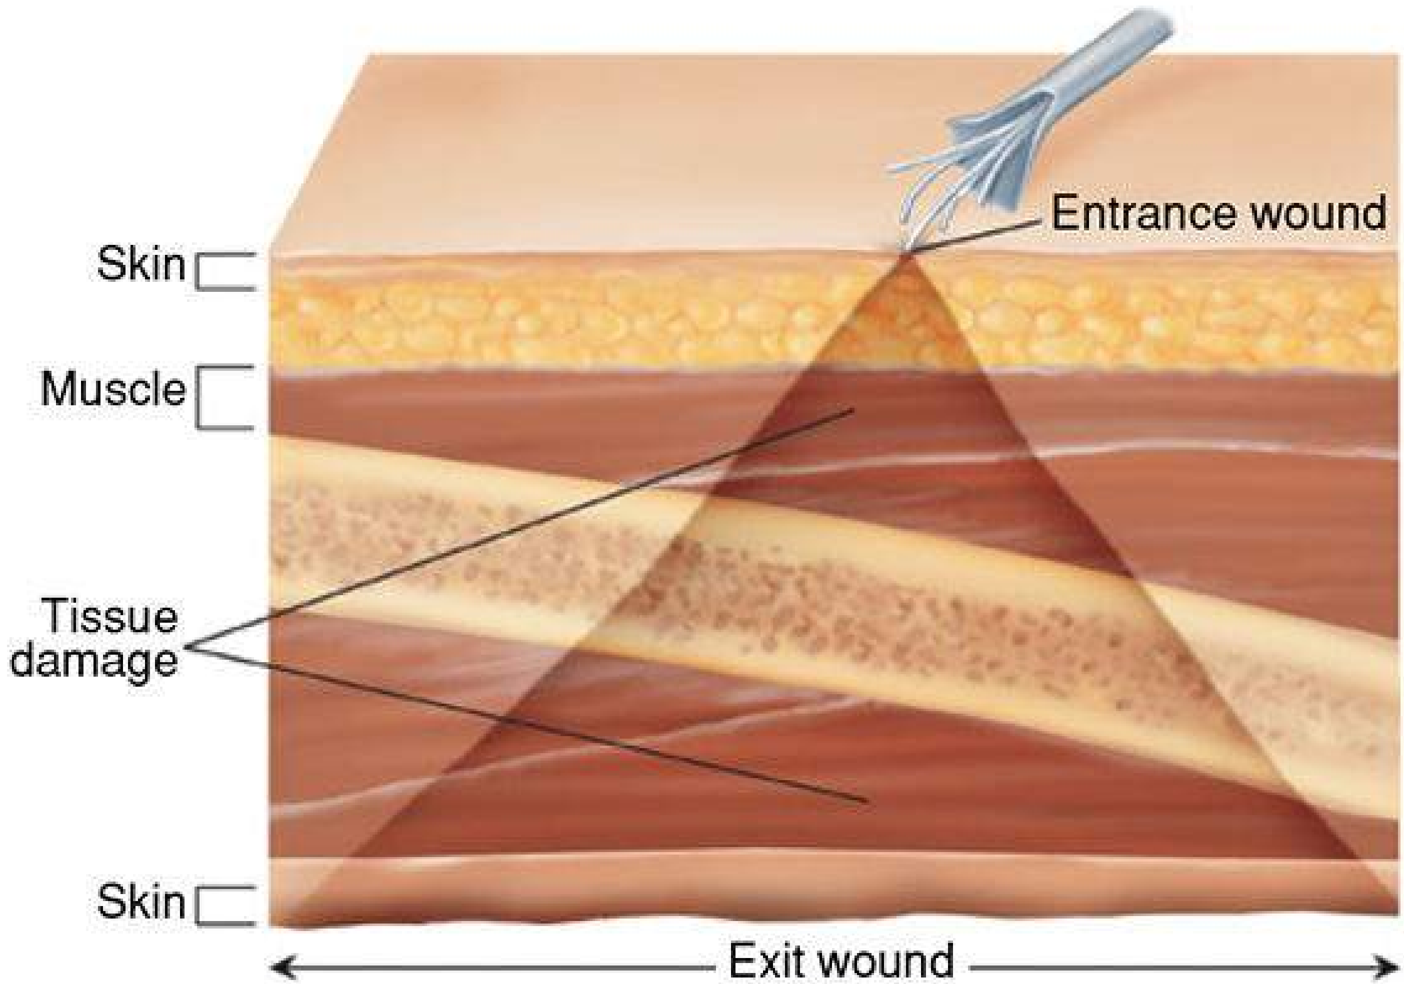

Figure 26-26 External signs of an electrical burn may be deceiving. The entrance wound may be a small burn, whereas the damage to deeper tissue may be massive.

Electrical current can cross the chest and cause cardiac arrest or dysrhythmias. Cardiac arrest can also occur after a lightning strike, which is a form of an electrical burn. If indicated, begin CPR on the patient and apply the automated external defibrillator. Although CPR may need to be quite prolonged in patients with electrical burns, it has a high success rate if started promptly. Be prepared to defibrillate if necessary. If neither CPR nor defibrillation is indicated, give supplemental oxygen, and monitor the patient closely for respiratory and cardiac arrest. Treat the soft-tissue injuries by placing dry, sterile dressings on all burn wounds and splinting suspected fractures. Provide prompt transport; all electrical burns are potentially severe injuries that require further treatment in the hospital.

Taser Injuries

In recent years, law enforcement has increased its use of Tasers. Two small darts (electrodes) that puncture the patient's skin are fired from these weapons. Injuries are generally treated as impaled objects and removed by a physician; although, in some jurisdictions, depending on local protocol, EMTs are permitted to remove these barbs from patients. The barbs are approximately 13 mm in length, and although they produce wounds, they are small and easily managed unless they penetrate the eye.

There are potential complications for the patient when these devices have been used, particularly when the patient is experiencing certain underlying disorders. Considerable attention has been focused on a condition known as **excited delirium**, which is often characterized by extreme agitation, reduced pain sensitivity, hallucinations, persistent struggling, and elevated temperature. This condition is commonly associated with illegal drug ingestion. Excited delirium is a true emergency and warrants assisted ALS response.

Using a Taser in patients with true excited delirium has been previously associated with dysrhythmias and sudden cardiac arrest. Other studies have found that the risk of sudden death is related to the excited delirium condition and is not associated with Taser use. Regardless, be aware of this and be certain you have access to an AED when you respond to calls for patients who have been exposed to Taser shots.

Radiation Burns

Acute radiation exposure has become more than a theoretical issue because the use of radioactive materials has increased in industry and medicine; therefore, you must understand it to effectively manage patients exposed to radiation. Potential threats include incidents related to the use and transportation of radioactive isotopes and intentionally released radioactivity in terrorist attacks. To be effective, first determine if there has been a radiation exposure, and then determine whether ongoing exposure, continues to exist. Increasingly, special response units are equipped with pager-sized radiation detectors, or such detection devices may be provided by other public safety services.

There are three types of ionizing radiation: alpha, beta, and gamma. Alpha particles have little penetrating energy and are easily stopped by the skin. Beta particles have greater penetrating power and can travel much farther in air than alpha particles. They can penetrate the skin but can be blocked by simple protective clothing designed for this purpose. The threat from gamma radiation is directly proportional to its wavelength. This type of radiation is very penetrating and easily passes through the body and solid materials.

Radiation is measured in units of radiation absorbed dose (rad) or radiation equivalent in man (rem): 100 rad = 1 gray (Gy). Small amounts of everyday background radiation are measured in rad; the amount of radiation released in a major incident may be measured in gray. The average human exposure from background radiation is 0.36 rem per year. Mild radiation sickness can be expected with exposures of 1 to 2 Gy (100 to 200 rad), moderate sickness at 2 to 5 Gy, and severe sickness at 4 to 6 Gy. Exposure to more than 8 Gy is immediately fatal.

Most ionizing radiation accidents involve gamma radiation, or x-rays. People who have sustained a radiation exposure generally do not pose a risk to the people around them. However, in some types of incidents—particularly those involving explosions—patients may be contaminated with radioactive particulate matter. It is speculated that after a nuclear explosion, most patients will have sustained some type of trauma in addition to the radiation exposure.

Being exposed to a radiation source does not make a patient contaminated or radioactive. However, when patients have a radioactive source on their body (such as debris from a bomb that dispersed radioactive material), they are contaminated and must be initially cared for by a HazMat responder. Maintain a safe distance and wait for the HazMat team to decontaminate the patient before initiating care. Once decontaminated by the HazMat team, care is often transferred to the EMT. Most contaminants can be removed by simply removing the patient's clothes. Call for additional resources to manage this situation. Once the patient is decontaminated and there is no threat to you, begin treating the ABCs and treat the patient for any burns or trauma.

Irrigate open wounds. Washing should be gentle to avoid further damage to the skin, which could result in additional internal radiation absorption. Irrigate the head and scalp the same way. The ED should be notified as soon as practical if you are transporting a potentially contaminated patient. In contrast with other types of contamination, radioactive particulate matter probably poses a relatively small risk to the provider. Consider providing basic care to the patient before decontamination if you are wearing protective clothing.

Increasing your and the patient's distance from the source by even a few feet may dramatically decrease your exposure. Therefore, it is important to identify the radioactive source and the length of the patient's exposure to it, if this information is available without putting you or your patient at risk for exposure. If not readily available, rely on the HazMat team to obtain this information. Limit your duration of exposure, increase your distance from the source, and attempt to place shielding between yourself and sources of gamma radiation.

With contact radiation burns, decontaminate the wound as if it were a chemical burn to remove any radioactive particulate matter, then treat it as a burn.

Many radioactive isotopes are used in medicine and industry, some of which can be absorbed or have their toxic effects blunted by another substance. Like their radioactive effects, the toxic effects of these isotopes vary. Antidotes may help bind an isotope, enhance its elimination from the body, or reduce the toxic effects on other organs. Such antidotal therapy should be considered only under the guidance of a knowledgeable physician or public health agency.

Dressing and Bandaging

All wounds require bandaging. In most instances, splints help to control bleeding and provide firm support for the dressing. There are many different types of dressings and bandages **Figure 26-27**. You should be familiar with the function and proper application of each.

In general, dressings and bandages have three primary functions:

- To control bleeding
- To protect the wound from further damage
- To prevent further contamination and infection

Sterile Dressings

Universal dressings, conventional 4-inch × 4-inch and 4-inch × 8-inch gauze pads, and assorted small adhesive-type dressings and soft self-adherent roller dressings will cover most wounds. The universal dressing measures 9 inches × 36 inches, is made of thick, absorbent material, and is ideal for covering large open wounds. It also makes an efficient pad for rigid splints. These dressings are available in compact, commercially sterilized packages.

Gauze pads are appropriate for smaller wounds, and adhesive-type dressings are useful for minor wounds. **Occlusive dressings**, made of petroleum (Vaseline) gauze, aluminum foil, or plastic, prevent air and liquids from entering (or exiting) the wound. They are used to cover sucking chest wounds, abdominal eviscerations, penetrating back wounds, and neck injuries.

Figure 26-27 **A.** Many types of sterile dressings are used for covering open wounds, including universal dressings, gauze pads, adhesive dressings, and occlusive dressings. **B.** Bandages keep dressings in place and include soft roller bandages, triangular bandages, and adhesive tape. Splints may also be used to hold dressings in place.

A, B: © Jones & Bartlett Learning. Courtesy of MIEMSS.

Bandages

To keep dressings in place during transport, you can use soft roller bandages, rolls of gauze, triangular bandages, or adhesive tape. The self-adherent, soft roller bandages are probably easiest to use. They are slightly elastic, which makes them easy to apply, and you can tuck the end of the roll into a deeper layer to secure it in place. The layers adhere somewhat but should not be applied too tightly to one another.

Adhesive tape holds small dressings in place and helps secure larger dressings. Some people, however, are allergic to adhesive tape. If you know your patient is allergic, use paper or plastic tape instead.

Do not use elastic bandages to secure dressings. If the injury swells, the bandage may become a tourniquet and cause further damage. Any improperly applied bandage that impairs circulation can result in additional tissue damage or even the loss of a limb. Always check a limb distal to a bandage for signs of impaired circulation and loss of sensation. Air splints and vacuum splints are useful in stabilizing broken extremities, and they can be used with dressings to help control bleeding from soft-tissue injuries.

As discussed in Chapter 25, *Bleeding*, if a wound continues to bleed despite the use of direct pressure, quickly use a tourniquet. Research from the Iraq war has taught us that use of a tourniquet is rarely as harmful to the patient as it was once thought. If you cannot control bleeding from a major vessel in an extremity, a properly applied tourniquet may save a patient's life. Specifically, the tourniquet is useful if a patient is bleeding severely from a partial or complete amputation.

YOU are the Provider — SUMMARY

1. What should be your most immediate priority?

As with any patient, your first priority is to prevent further harm. Although the patient was brought to you wrapped in a blanket, this does not mean that his skin or clothing have stopped burning. First, remove the blanket, to ensure that his clothes are not smoldering and that the burning process has stopped.

If the patient's clothes are still smoldering or if there is any other evidence to indicate the burning process is ongoing, pour sterile water or saline over the affected areas. Alternatively, apply moist, sterile dressings to extinguish the burning areas. These actions not only stop the burning process, they also help relieve pain. If the burning process has stopped, do not apply any water, saline, or moist dressings until you further assess the patient.

2. What is a thermal burn? What are the causes of thermal burns?

A thermal burn is a burn caused by heat—as opposed to radiation, chemicals, or electricity; however, many different situations can cause thermal burns.

Most commonly, thermal burns are caused by an open flame (flame burn), but thermal burns can result whenever the skin is exposed to temperatures higher than 111°F (44°C). In general, the severity of a thermal burn correlates directly with the temperature of the heat source, the amount of heat energy possessed by the object or substance, and the duration of exposure.

Other sources of heat energy, other than fire, include scald burns, which occur from exposure to boiling liquids; contact burns, which occur when a person comes in contact with a heated surface; steam burns, which occur when the body is exposed to superheated gaseous water; and flash burns, which occur when a person is briefly exposed to very intense heat (eg, explosion).

3. What additional information should you obtain from the firefighters who rescued the patient?

It has already been established that the patient was trapped in an enclosed space because the firefighters rescued him from the structure. However, you should determine an approximate length of exposure; this is usually a gross estimate at best.

Determine if the patient was conscious or unconscious when he was found. Conscious patients are often able to extinguish themselves, unless they are completely engulfed in flames. If the patient is unconscious, however, he or she does not have control over the duration of exposure to the fire itself or the quantity of superheated air that he or she inhales.

Determine how the patient was found. Was the patient in an open area of a room or was he or she trapped beneath a collapsed ceiling beam or other heavy structure? Although you should always assess the patient for traumatic injuries, information provided by the firefighters regarding any MOI can help you focus on a particular area (or areas) of the body. Do not assume the patient's injuries are limited to skin burns and toxic gas exposure; the patient may have experienced other injuries (eg, blunt trauma with internal bleeding, head injury) that could be life threatening.

4. How are thermal burns classified? What are the characteristics of each type of burn?

Burns are classified according to their depth—that is, how far the burn injury extends through the layers of the skin (ie, epidermis, dermis). The types of burns you must be able to identify are superficial (first degree), partial-thickness (second degree), and full-thickness (third degree).

Superficial (first-degree) burns involve only the outer layer of the skin—the epidermis. The skin turns red and is often painful, but it does not blister or burn through the epidermis.

Partial-thickness (second-degree) burns involve the epidermis and some portion of the dermis. These burns do not destroy the entire thickness of the skin, nor is the subcutaneous (fatty) tissue injured.

Full-thickness (third-degree) burns extend through all layers of the skin and may involve the subcutaneous layers, muscle, bone, or internal organs. The burned area may appear dry and leathery and may appear white, dark brown, or even charred.

5. What percentage of the patient's body surface area has been burned?

After you identify the depth of a burn, you must rapidly estimate the extent of the burns—that is, the percentage of the patient's body surface area (BSA) that is burned.

Your patient has experienced burns to his anterior torso (chest and abdomen); this represents 18% of his BSA. Additionally, both upper extremities are burned, which represents 18% (9% per extremity) of his BSA. Therefore, *your patient has burns that cover approximately 36% of his BSA*.

6. What factors should you consider to determine the severity of a burn?

When determining the severity of a burn, the two most important factors to consider initially are the depth and extent of the burn.

The American Burn Association classifies burns as being minor, moderate, and severe. However, your local protocols or regional burn center may have slightly different criteria.

Minor burns in an adult include full-thickness burns that cover less than 2% of the BSA, partial-thickness burns that cover less than 15% of the BSA, and superficial burns that cover less than 50% of the BSA. Moderate burns include full-thickness burns that cover between 2% to 10% of the BSA (excluding burns to critical areas of the body), partial-thickness burns that cover 15% to 30% of the BSA, and superficial burns that cover more than 50% of the BSA. Severe burns include *any* full-thickness burn to a critical area of the body, full-thickness burns that cover more than 10% of the BSA to noncritical areas of the body, and partial-thickness burns that cover more than 30% of the BSA.

In addition to the depth and extent of the burn, you must also determine if the burns are located in any critical areas of the body. Critical areas of the body include the face, upper airway, hands, feet, and genitalia.

7. What is the proper treatment of the patient's burns?

Large (greater than 10%) BSA burns should be covered with a dry, sterile, nonadherent dressing (eg, a sterile burn sheet); *your patient has burns that cover approximately 36% of his BSA*. Other than for the purpose of stopping the burning process, do not apply water or saline to large surface area burns. The larger the burn area, the greater the risks of hypothermia, hypovolemia, and infection.

Dry, sterile dressings applied to large surface area burns help maintain body temperature (reduce the risk of hypothermia), prevent further contamination of the burn (reduce the risk of infection), and provide comfort.

Use further treatment to prevent hypothermia (cover the patient with a blanket); closely monitor the patient's airway and ventilation status, and monitor for signs of shock.

8. How has the patient's condition changed? What should you do now?

The patient's breathing is becoming labored. Respiratory distress in a burn patient, especially in a patient without other injuries that would cause breathing difficulties (eg, blunt chest trauma), indicates upper airway swelling secondary to inhaling excessive heat (inhalation injury).

Patients who are trapped in an enclosed space with poor ventilation, especially if they have a loss of consciousness, are at highest risk for an inhalation injury.

Although your patient denies a loss of consciousness, you should still suspect some degree of upper airway swelling because he was in an enclosed space.

If the patient is breathing adequately, continue to administer high-flow oxygen and closely observe the patient. Cool mist or aerosol therapy may help reduce mild airway swelling; however, if this is not available, apply an ice pack to the throat area. If the patient is not breathing adequately (eg, shallow breathing [reduced tidal volume], labored respirations, falling oxygen saturation, decreasing level of consciousness), assist his or her ventilations with a BVM.

Depending on your transport time to the closest appropriate hospital and the availability of ALS resources in your area, you should consider an intercept with an AEMT or paramedic unit. Some patients with inhalation injuries require advanced airway management, such as endotracheal intubation, to protect the airway before it closes completely.

9. What, if any, additional treatment is indicated for this patient?

Continuous, careful monitoring of this patient is essential. Although his condition does not seem to have worsened, it also has not improved. Continue to administer high-flow oxygen, closely monitor the adequacy of his breathing, and be prepared to assist his ventilations. Monitor him for signs of shock and treat accordingly.

Any patient who is experiencing respiratory distress will be anxious. Provide emotional support and let the patient assume a position of comfort; this is usually a full Fowler (90-degree angle) position.

EMS Patient Care Report (PCR)

Date: 10-14-16	**Incident No.:** 012309	**Nature of Call:** Burns		**Location:** 511 Bandera Rd.	
Dispatched: 1500	**En Route:** 1500	**At Scene:** 1500	**Transport:** 1514	**At Hospital:** 1530	**In Service:** 1541

Patient Information

Age: 45 **Sex:** M **Weight (in kg [lb]):** 77 kg (170 lb)	**Allergies:** No known drug allergies **Medications:** None **Past Medical History:** None **Chief Complaint:** Burns to the torso and arms

Narrative

Medic 4 was standing by at the scene of a residential fire when firefighters rescued a 45-year-old man from the burning structure. They presented the patient wrapped in a blanket; he was ambulatory and the burning process was stopped before EMS contact was made. The approximate time of exposure to the burning environment was 8 to 10 minutes. The patient was conscious and alert, his airway was patent, his breathing was adequate, and his face was covered with soot. He reported severe pain to his chest, abdomen, and arms. Immediately moved patient into ambulance, applied high-flow oxygen via nonrebreathing mask, and assessed his burns. Assessment revealed burns that covered approximately 36% of his BSA. Partial-thickness burns were noted to the entire anterior torso, and partial- and full-thickness burns were noted to both of his upper extremities. Additional assessment revealed that his facial hair and the hair just above his hairline were singed; no facial skin burns were noted. The patient denied shortness of breath or any other symptoms other than severe pain from his burns. Secondary assessment did not reveal any other obvious injuries. Patient denies significant past medical history and states he does not take any medications. During the patient's entrapment, he stated he did not have a loss of consciousness. Applied dry, sterile burn sheets to patient's burns, covered him with a blanket for warmth, and began transport to the hospital. En route, notified medical control, who advised us to transport to the ED because the closest burn center was located 75 miles away. Reassessment revealed that the patient's respirations were becoming labored and his voice was becoming hoarse. Continued high-flow oxygen, applied ice pack to the patient's throat area, and continued to monitor his airway and breathing status. Notified the receiving facility of the patient's status and our impending arrival. The patient's vital signs remained stable throughout the duration of the transport, and his oxygen saturation never fell below 95%. Delivered patient to the ED without incident and gave verbal report to the attending physician. Medic 4 returned to service at 1541.**End of report**

Prep Kit

Ready for Review

- The skin protects the body by keeping pathogens out and water in and assisting in body temperature regulation.
- There are three types of soft-tissue injuries:
  - Closed injuries (Soft-tissue damage occurs beneath the skin or mucous membrane but the surface remains intact.)
  - Open injuries (There is a break in the surface of the skin or the mucous membrane, exposing deeper tissue to potential contamination.)
  - Burns (The soft tissue receives more energy than it can absorb without injury; the source of this energy can be thermal, toxic chemicals, electricity, or radiation.)
- Closed soft-tissue injuries are characterized by a history of blunt trauma, pain at the site of injury, swelling beneath the skin, and discoloration. Contusions, hematomas, and crushing injuries are classified as closed injuries. Treat a closed soft-tissue injury by applying the mnemonic RICES: *Rest, Ice, Compression, Elevation*, and *Splinting*.
- Open injuries differ from closed injuries in that the protective layer of skin is damaged. Abrasions, lacerations, avulsions, and penetrating wounds are classified as open injuries. Treat an open soft-tissue injury by applying direct pressure with a sterile bandage using a roller bandage, and splint the extremity. Use a tourniquet when necessary to control bleeding.
- It is generally easier to assess an open injury than it is to assess a closed injury because you can see the injury.
- Burns are serious and painful soft-tissue injuries caused by heat (thermal), chemicals, electricity, and radiation.
- Burns are classified primarily by the depth and extent of the burn injury and the body area involved.
- Burns are considered to be superficial, partial-thickness, or full-thickness based on the depth involved.
- When providing emergency care for burns, do the following:
  - Use standard precautions to protect yourself from potentially contaminated body fluid and to protect the patient from potential infection.
  - Ensure you have cooled the burned area to prevent further cellular damage.
  - Remove jewelry and constrictive clothing; never attempt to remove any synthetic material that may have melted into the burned skin.
  - Ensure an open and clear airway, provide high-flow oxygen, and be alert to signs and symptoms of inhalation injury such as difficulty breathing, stridor, or wheezing.
  - Place sterile dressings over the burn areas; to prevent hypothermia, cover the patient with a clean blanket. Provide prompt transport.
- Small animal and human bites can lead to serious infection and must be evaluated by a physician. Small animals can carry rabies.
- Dressings and bandages are designed to control bleeding, protect the wound from further damage, prevent further contamination, and prevent infection.

Vital Vocabulary

abrasion Loss or damage of the superficial layer of skin as a result of a body part rubbing or scraping across a rough or hard surface.

amputation An injury in which part of the body is completely severed.

avulsion An injury in which soft tissue is torn completely loose or is hanging as a flap.

burns Injuries in which soft-tissue damage occurs as a result of thermal heat, frictional heat, toxic chemicals, electricity, or nuclear radiation.

closed injuries Injuries in which damage occurs beneath the skin or mucous membrane but the surface of the skin remains intact.

compartment syndrome Swelling in a confined space that produces dangerous pressure; may cut off blood flow or damage sensitive tissue.

contact burn A burn caused by direct contact with a hot object.

contamination The presence of infective organisms or foreign bodies such as dirt, gravel, or metal.

contusion A bruise from an injury that causes bleeding beneath the skin without breaking the skin.

crush syndrome Significant metabolic derangement that develops when crushed extremities or body parts remain trapped for prolonged periods. This can lead to renal failure and death.

crushing injury An injury that occurs when a great amount of force is applied to the body.

dermis The inner layer of the skin, containing hair follicles, sweat glands, nerve endings, and blood vessels.

ecchymosis Discoloration associated with a closed wound; signifies bleeding.

epidermis The outer layer of skin that acts as a watertight protective covering.

evisceration The displacement of organs outside the body.

excited delirium A serious behavioral condition in which a person exhibits agitated behavior combined with disorientation, hallucinations, or delusions; also called agitated delirium or exhaustive mania.

fascia The fiberlike connective tissue that covers arteries, veins, tendons, and ligaments.

flame burn A burn caused by an open flame.

flash burn A burn caused by exposure to very intense heat, such as in an explosion.

full-thickness (third-degree) burns Burns that affect all skin layers and may affect the subcutaneous layers, muscle, bone, and internal organs, leaving the area dry, leathery, and white, dark brown, or charred.

hematoma Blood collected within the body's tissues or in a body cavity.

impaled objects Objects that penetrate the skin but remain in place.

incision A sharp, smooth cut in the skin.

laceration A deep, jagged cut in the skin.

mucous membranes The linings of body cavities and passages that are in direct contact with the outside environment.

occlusive dressings Dressings made of petroleum (Vaseline) gauze, aluminum foil, or plastic that prevent air and liquids from entering or exiting a wound.

open injuries Injuries in which there is a break in the surface of the skin or the mucous membrane, exposing deeper tissue to potential contamination.

partial-thickness (second-degree) burns Burns that affect the epidermis and some portion of the dermis but not the subcutaneous tissue, characterized by blisters and skin that is white to red, moist, and mottled.

penetrating wound An injury resulting from a sharp, piercing object.

rabid Infected with rabies.

rule of nines A system that assigns percentages to sections of the body, allowing calculation of the amount of skin surface involved in the burn area.

scald burn A burn caused by hot liquids.

steam burn A burn caused by exposure to hot steam.

superficial (first-degree) burns Burns that affect only the epidermis, characterized by skin that is red but not blistered or actually burned through.

thermal burns Burns caused by heat.

Assessment *in Action*

You are dispatched to a bar to respond to a fight. The police have cleared the scene and it is safe for you to enter. You see a man, conscious and alert. His face is mottled with blisters and abrasions, and he has blood on his shirt. He tells you he was trying to stop the fight when he was hit in the face with scalding hot coffee and then he fell backward into a chair. Physical examination shows a jagged laceration measuring approximately 2 inches on his abdomen.

It is still bleeding, and you notice bruising on the right lateral chest. Vital signs are stable.

1. What is the classification of this burn?

   A. Superficial
   B. Partial-thickness
   C. Full-thickness
   D. Thermal

2. The priority in treating this patient is to:

   A. clean any open wounds.
   B. take vital signs.
   C. stop the burning process.
   D. keep the airway open.

3. What kind of burn is this?

   A. Inhalation burn
   B. Thermal burn
   C. Radiation burn
   D. Chemical burn

4. According to the rule of nines, what percentage of the patient's skin surface is burned?

   A. 4.5%

B. 7.5%
C. 9%
D. 18%

5. What is the priority for treating an open wound on the patient's abdomen?

   A. Clean it.
   B. Flush it with sterile saline.
   C. Probe it.
   D. Stop the bleeding.

6. Which of the patient's soft-tissue injuries is least likely to result in infection?

   A. Contusion on the right lateral chest
   B. Abdominal laceration
   C. Burns to the face
   D. Abrasions to the face

7. Is this a severe burn? Why or why not?

8. What is the rule of nines?

9. What are the steps to take to control bleeding?

10. How should you treat a closed injury?

CHAPTER
27

Face and Neck Injuries

National EMS Education Standard Competencies

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Diseases of the Eyes, Ears, Nose, and Throat

Recognition and management of
› Nosebleed (pp 965–967)

Trauma

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

Head, Facial, Neck, and Spine Trauma

› Recognition and management of:
  • Life threats (pp 950–956)
  • Spine trauma (Chapter 28, *Head and Spine Injuries*)
› Pathophysiology, assessment, and management of:
  • Penetrating neck trauma (pp 950–956, 970–972)
  • Laryngotracheal injuries (pp 950–956, 971–972)
  • Spine trauma (Chapter 28, *Head and Spine Injuries*)
  • Facial fractures (pp 950–956, 969–970)

- Skull fractures (Chapter 28, *Head and Spine Injuries*)
- Foreign bodies in the eyes (pp 950–960)
- Dental trauma (pp 950–956, 970)

Knowledge Objectives

1. Describe the anatomy and physiology of the head, face, and neck; include major structures and specific important landmarks of which EMTs must be aware. (pp 947–950)
2. Describe the factors that may cause the obstruction of the upper airway following a facial injury. (pp 950–951)
3. Discuss the different types of facial injuries and patient care considerations related to each one. (pp 950–951)
4. Explain the emergency care of a patient who has sustained face and neck injuries; include assessment of the patient, review of signs and symptoms, and management of care. (pp 950–956)
5. Explain emergency medical care of a patient with soft-tissue wounds of the face and neck. (pp 955–956)
7. Describe the three different causes of a burn injury to the eye and patient management considerations related to each one. (pp 959–961)
8. Explain emergency medical care of a patient with injuries of the nose. (pp 965–967)
9. Explain the emergency medical care of a patient with injuries of the ear, including lacerations and foreign body insertions. (pp 967–969)
10. Explain the physical findings and emergency care of a patient with a facial fracture. (pp 969–970)
11. Explain the emergency medical care of the patient with dental and cheek injuries; include how to deal with an avulsed tooth. (p 970)
12. Explain the emergency medical care of a patient with an upper airway injury caused by blunt trauma. (pp 970–971)
13. Explain the emergency medical care of the patient with a penetrating injury to the neck; include how to control regular and life-threatening bleeding. (pp 971–972)

Skills Objectives

1. Demonstrate the removal of a foreign object from under a patient's upper eyelid. (pp 956–958, Skill Drill 27-1)
2. Demonstrate the stabilization of a foreign object that has been impaled in a patient's eye. (pp 959–960, Skill Drill 27-2)
3. Demonstrate irrigation of a patient's eye using a nasal cannula, bottle, or basin. (pp 960–962)
4. Demonstrate the care of a patient who has a penetrating eye injury. (p 962)
5. Demonstrate how to control bleeding from a neck injury. (pp 971–972, Skill Drill 27-3)

Introduction

The face and neck are particularly vulnerable to injury because of their relatively unprotected positions on the body. Soft-tissue injuries and fractures to the bones of the face are common and vary greatly in severity. Some are potentially life threatening, and many leave disfiguring scars if not treated properly. Penetrating trauma to the neck may cause severe bleeding. An open injury may allow an air embolism to enter the circulatory system. If a hematoma forms in this area, it may stop or slow blood flow to the brain, causing a stroke. With appropriate prehospital and hospital care, a patient with a seemingly devastating injury can have a surprisingly good outcome.

As an EMT, your objectives when treating a patient with face and neck injuries include prevention of further injury, particularly to the cervical spine, managing any acute airway problems, and controlling bleeding. This chapter first reviews the anatomy of the head and neck and then examines the factors that can produce upper airway obstruction. A discussion follows that includes emergency medical care of soft-tissue wounds of the face, nose, and ear; facial fractures; penetrating injuries of the neck; and dental injuries.

Anatomy and Physiology

The head is divided into two parts: the cranium and the face. The cranium, or skull, contains the brain, which connects to the spinal cord through the foramen magnum, a large opening at the base of the skull. The most posterior portion of the cranium is called the occiput. On each side of the cranium, the lateral portions are called the temples or temporal regions. Between the temporal regions and the occiput lie the parietal regions. The forehead is called the frontal region. Just anterior to the ear, in the temporal region, you can feel the pulse of the superficial temporal artery.

The face is composed of the eyes, ears, nose, mouth, and cheeks. Six bones—the nasal bone, the two maxillae (upper jaw bones), the two zygomas (cheek bones), and the mandible (jaw bone)—are the major bones of the face **Figure 27-1**.

The orbit of the eye is composed of the lower edge of the frontal bone of the skull, the zygoma, the maxilla, and the nasal bone. The bony orbit protects the eye from injury. By viewing the face from the side, you can see the eyeball recessed in the orbit. Only the proximal third of the nose—the bridge—is formed by bone. The remaining two-thirds are composed of cartilage.

The exposed portion of the ear is composed entirely of cartilage that is covered by skin. The external, visible part of the ear is called the **pinna** **Figure 27-2**. The ear lobes are the fleshy portions at the bottom of each ear. The **tragus** is a small, rounded, fleshy bulge immediately anterior to the ear canal. The superficial temporal artery can be palpated just anterior to the tragus. About 1 inch posterior to the external opening of the ear is a prominent bony mass at the base of the skull called the **mastoid process**.

The jaw is the lower border of the mouth, where the tongue and 32 teeth are located. Motion of the mandible occurs at the **temporomandibular joint**, which lies just in front of the ear on either side of the face. Below the ear and anterior to the mastoid process, the angle of the mandible is easily palpated.

The neck also contains many important structures. It is supported by the cervical spine, or the first seven vertebrae in the spinal column (C1 through C7). The spinal cord exits from the foramen magnum and lies within the spinal canal formed by the vertebrae. The upper part of the esophagus and the trachea lie in the midline of the neck. The carotid arteries are found on either side of the trachea, along with the jugular veins and several nerves.

YOU are the Provider — PART 1

At 1926 hours, you are dispatched to the parking lot of a convenience store at 1505 Eagle Rock Drive for a patient who was allegedly assaulted. You and your partner respond to the scene, which is located about 3 miles away. Law enforcement personnel, who are on scene, advise you that the scene has been secured, and that your patient, a young man, is conscious but has severe trauma to his face.

1. What should be your most immediate concern after receiving this initial patient information?
2. What should your initial actions consist of when you arrive at the scene?

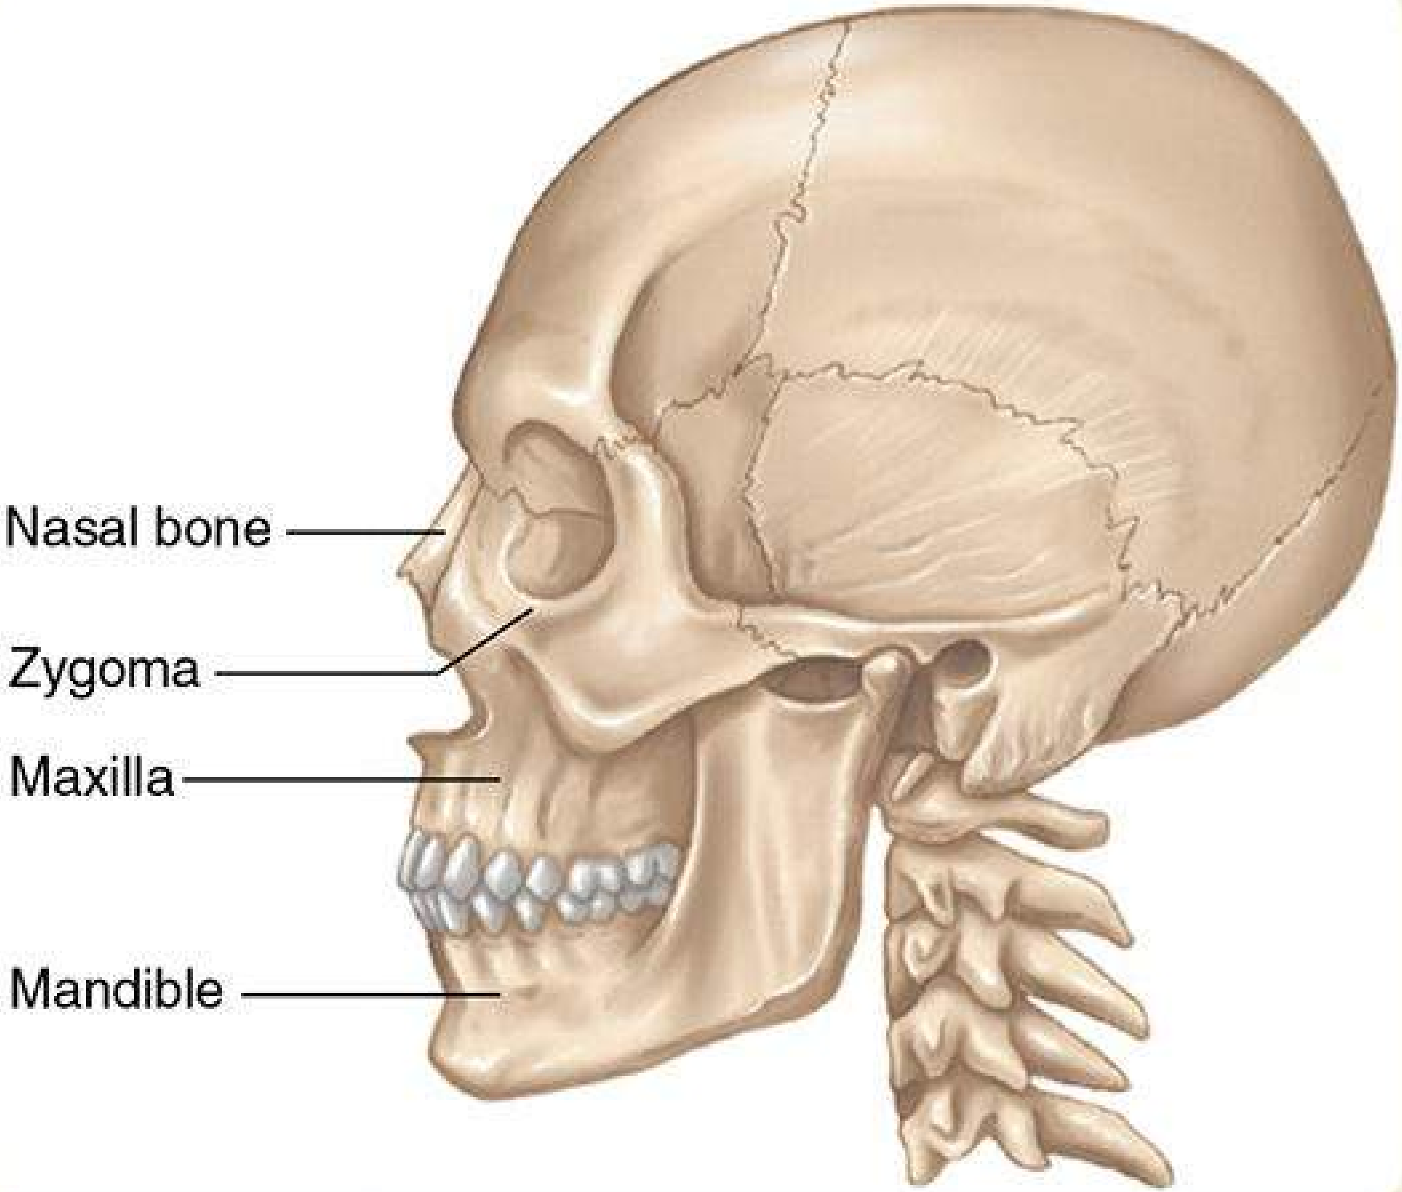

Figure 27-1 The face is composed of six bones: the nasal bone, two maxillae, two zygomas, and the mandible.

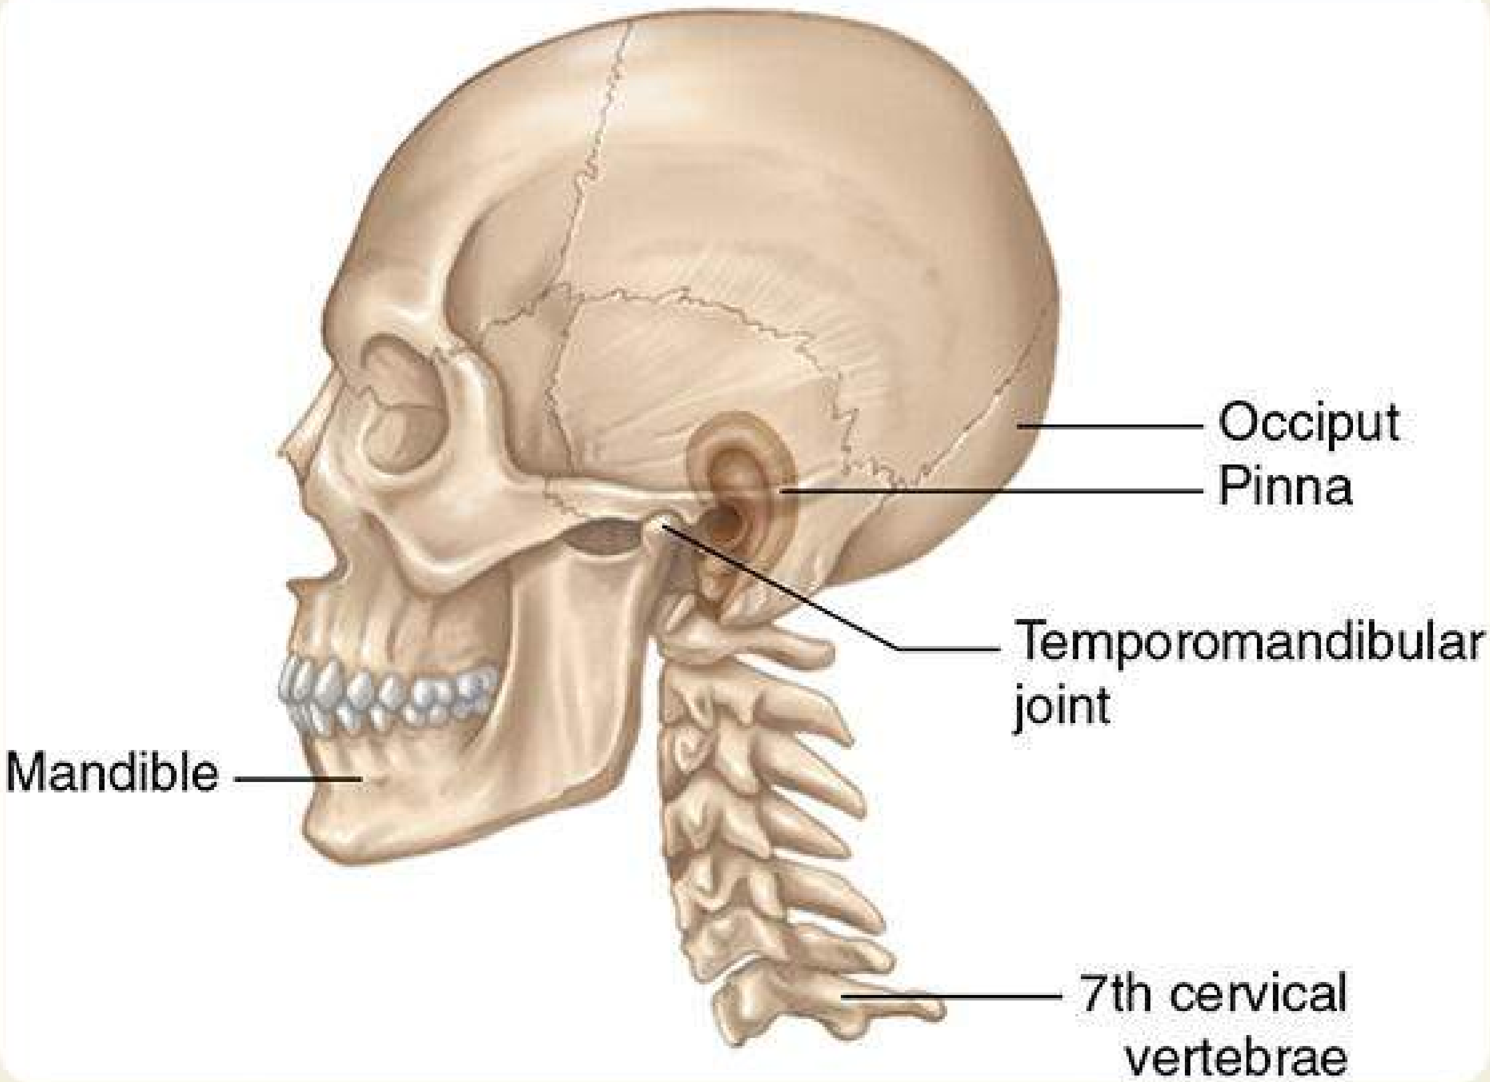

Figure 27-2 Specific landmarks of the head and neck include the pinna, the mandible, the occiput, the seventh cervical vertebra, and the temporomandibular joint.

Several useful landmarks can be palpated and seen in the neck **Figure 27-3**. The most obvious is the firm prominence in the center of the anterior surface, commonly known as the Adam's apple. Specifically, this prominence is the upper part of the larynx, formed by the thyroid cartilage. It is more prominent in men than in women. The other portion of the larynx is the cricoid cartilage, a firm ridge of cartilage (the only complete circular cartilage structure of the trachea) below the thyroid cartilage, which is somewhat more difficult to palpate. Between the thyroid cartilage and the cricoid cartilage in the midline of the neck is a soft depression, the cricothyroid membrane. This is a thin sheet of connective tissue (fascia) that joins the two cartilages Figure 27-4. The cricothyroid membrane is covered at this point only by skin.

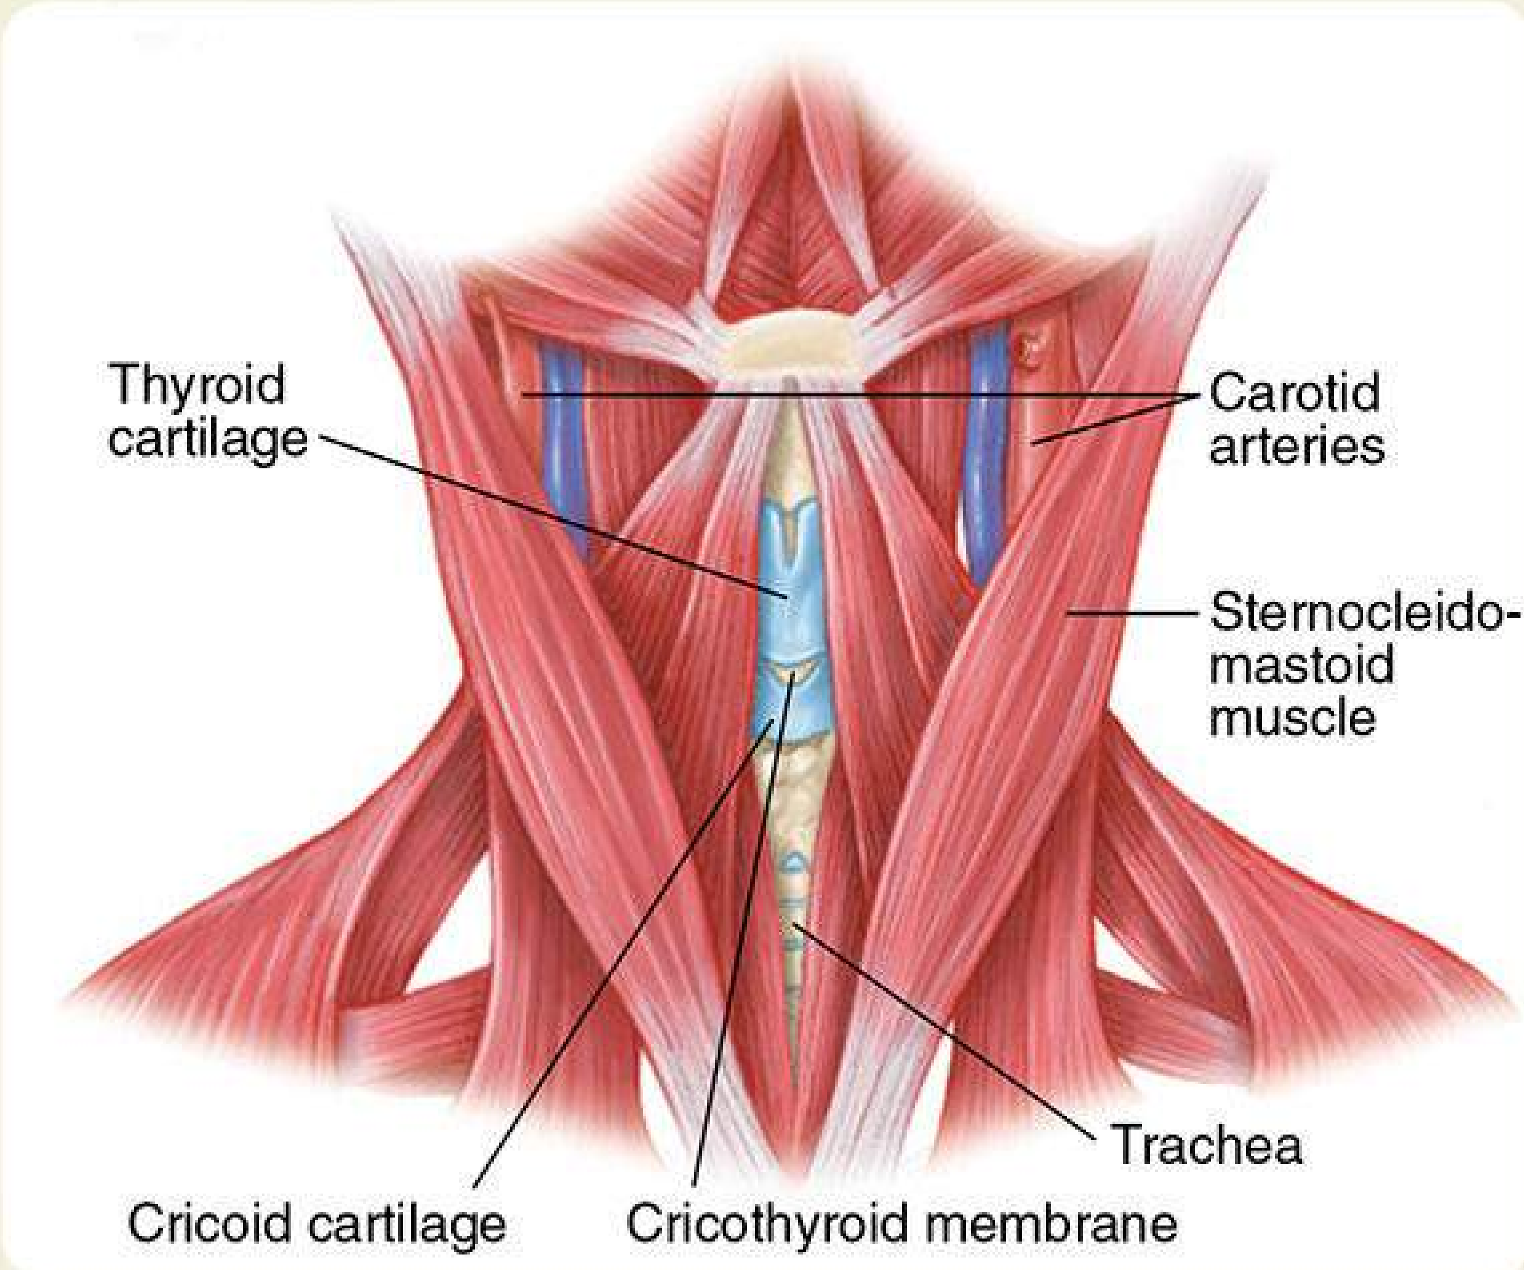

Figure 27-3 Important landmarks in the neck include the cricoid cartilage, the thyroid cartilage, the carotid arteries, the cricothyroid membrane, and the sternocleidomastoid muscles.

Below the larynx, several additional firm ridges are palpable in the anterior midline. These ridges are the cartilage rings of the trachea. The trachea connects the oropharynx and the larynx with the main air passages of the lungs (the bronchi). On either side of the lower larynx and the upper trachea lies the thyroid gland. Unless it is enlarged, this gland is usually not palpable.

Pulsations of the carotid arteries are easily palpable in a groove approximately 0.5 inch lateral to the larynx. Lying immediately adjacent to these arteries, but not palpable, are the internal jugular veins and several important nerves. Lateral to these vessels and nerves lie the **sternocleidomastoid muscles**. These muscles originate from the mastoid process of the cranium and insert into the medial border of each collarbone and the sternum at the base of the neck. They allow movement of the head.

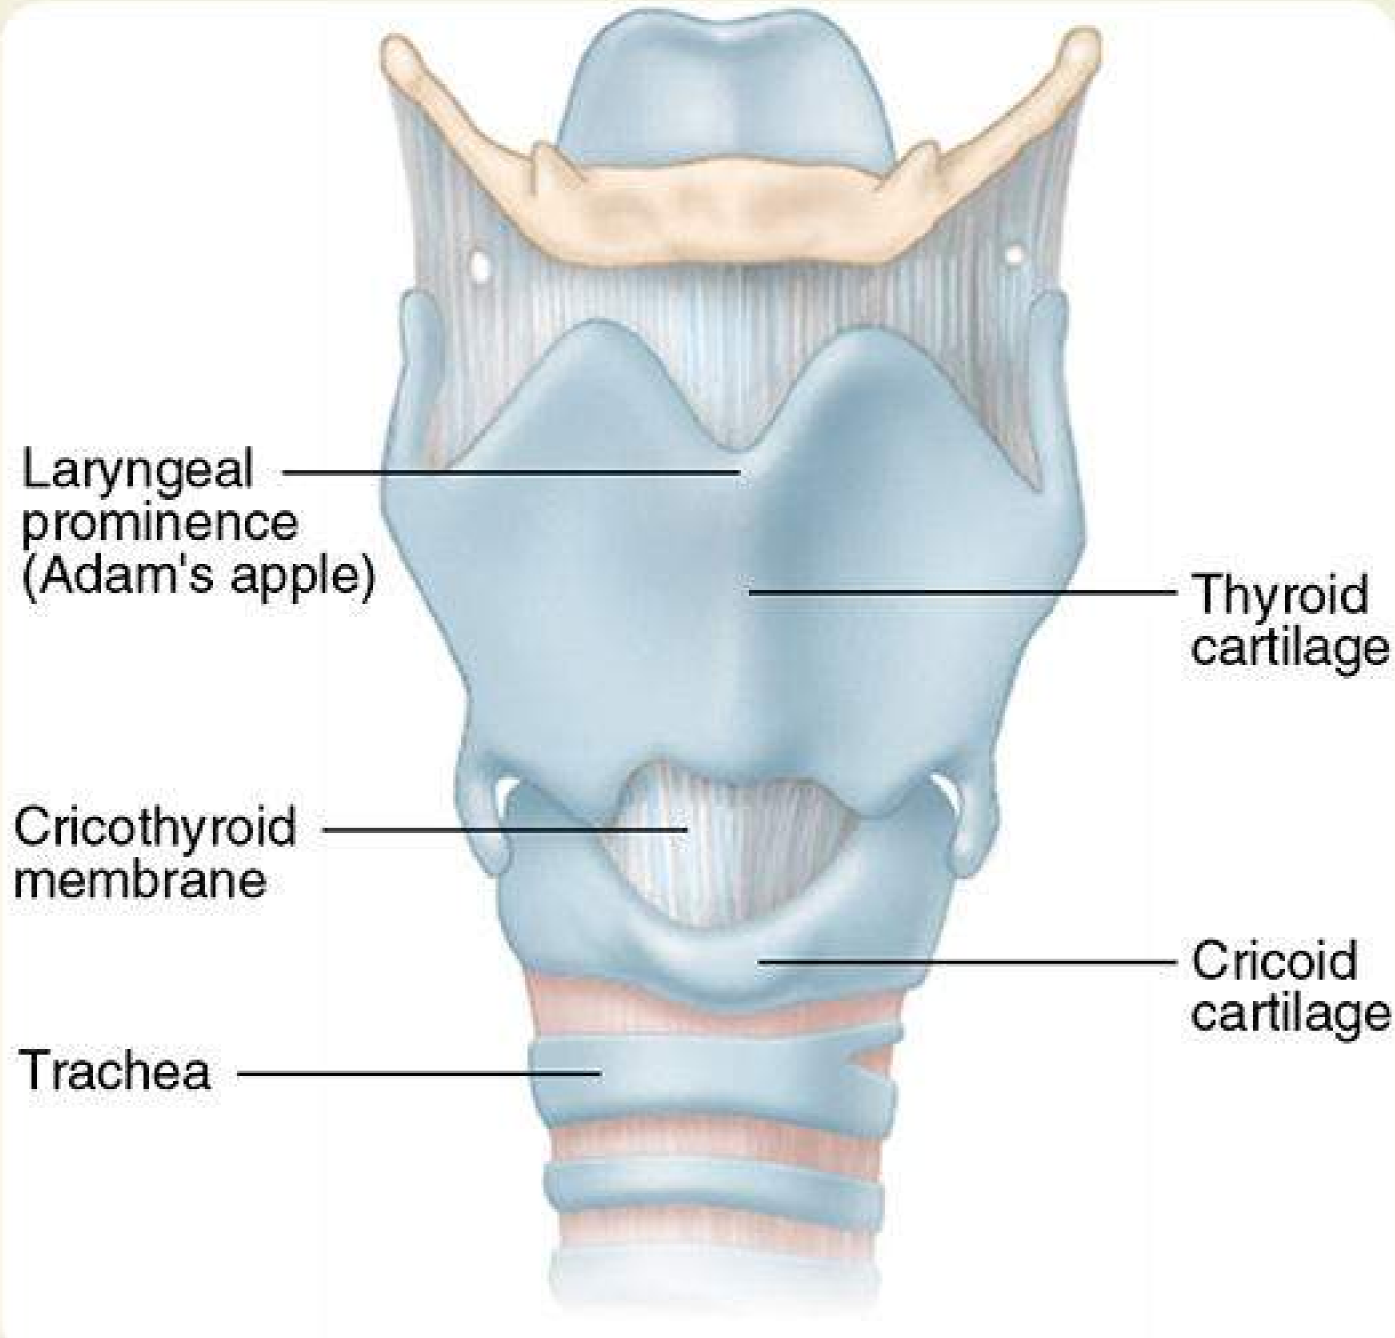

Figure 27-4 The larynx.

A series of bony prominences lie posteriorly, in the midline of the neck. They are the spines of the cervical vertebrae. The lower cervical spines are more prominent than the upper ones. They are more easily palpable when the neck is in flexion. At the base of the neck posteriorly, the most prominent spine is the seventh cervical vertebra.

The eye is globe-shaped, approximately 1 inch in diameter, and located within a bony socket in the skull called the orbit Figure 27-5. The orbit is composed of the adjacent bones of the face and skull; the orbit forms the base of the floor of the cranial cavity, and directly above it are the frontal lobes of the brain. In the adult, more than 80% of the eyeball is protected within this bony orbit. Between and below the orbits are the nasal bone and the sinuses, respectively. Therefore, any severe injury to the face or head can potentially damage the eyeball or the muscles attached to the eyeball that cause the eye to move.

The Eye

The eyeball, or **globe**, keeps its global shape as a result of the pressure of the fluid contained within its two chambers. The clear, jellylike fluid near the back of the eye is called the vitreous humor. In front of the lens is a clear fluid called the aqueous humor, named for its watery appearance; in Latin, *aqua* means water. In penetrating injuries of the eye, aqueous humor can also leak out, but with time and appropriate medical treatment, the body can make more.

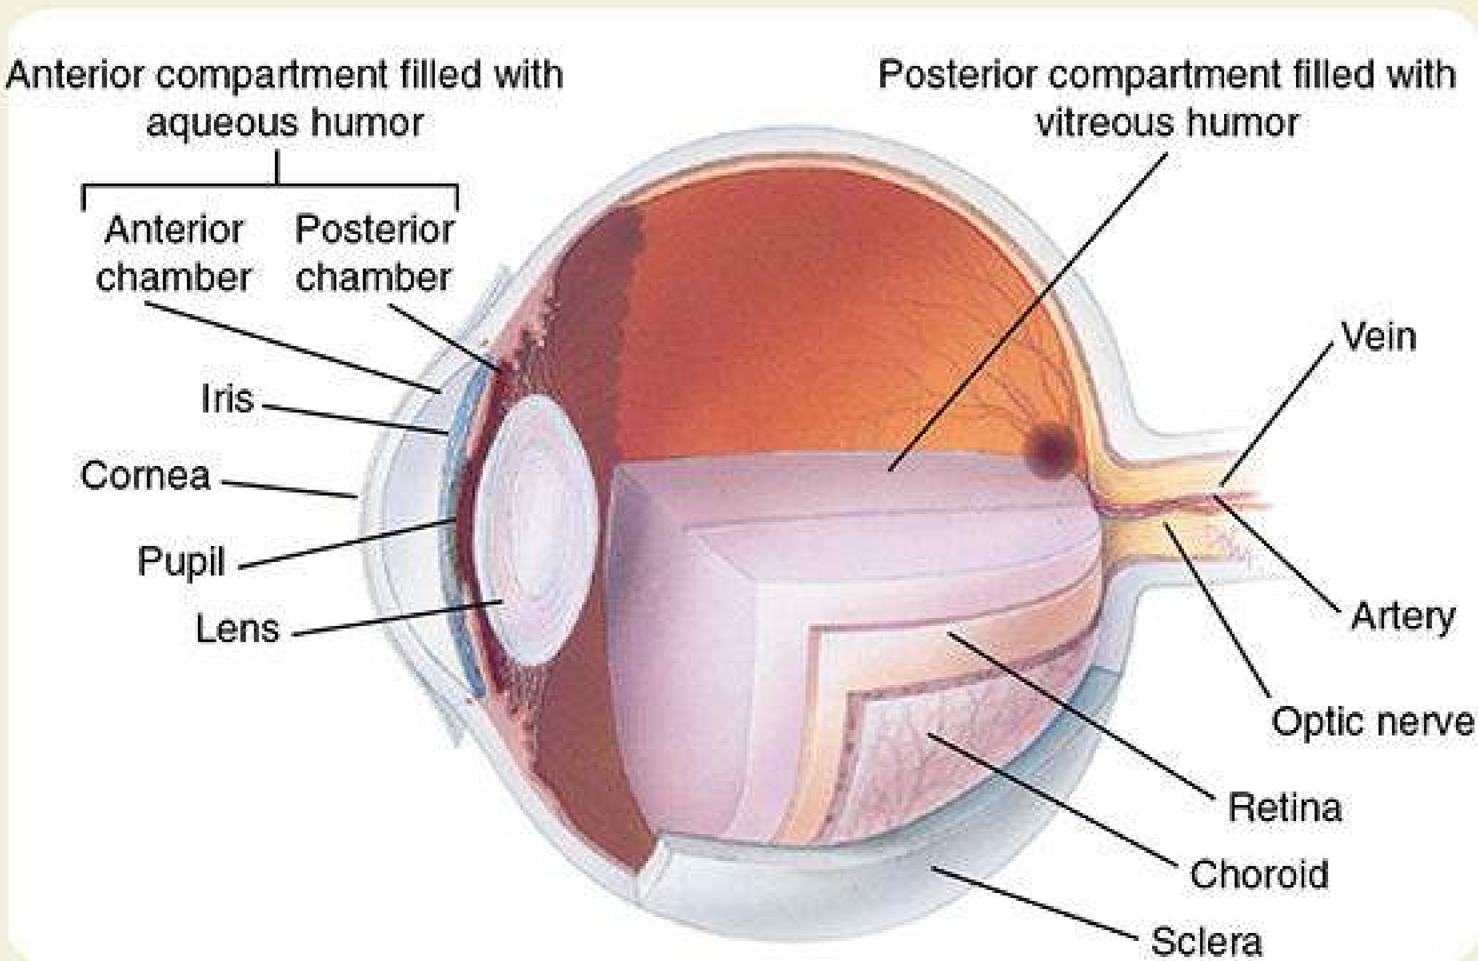

Figure 27-5 The major components of the eye.

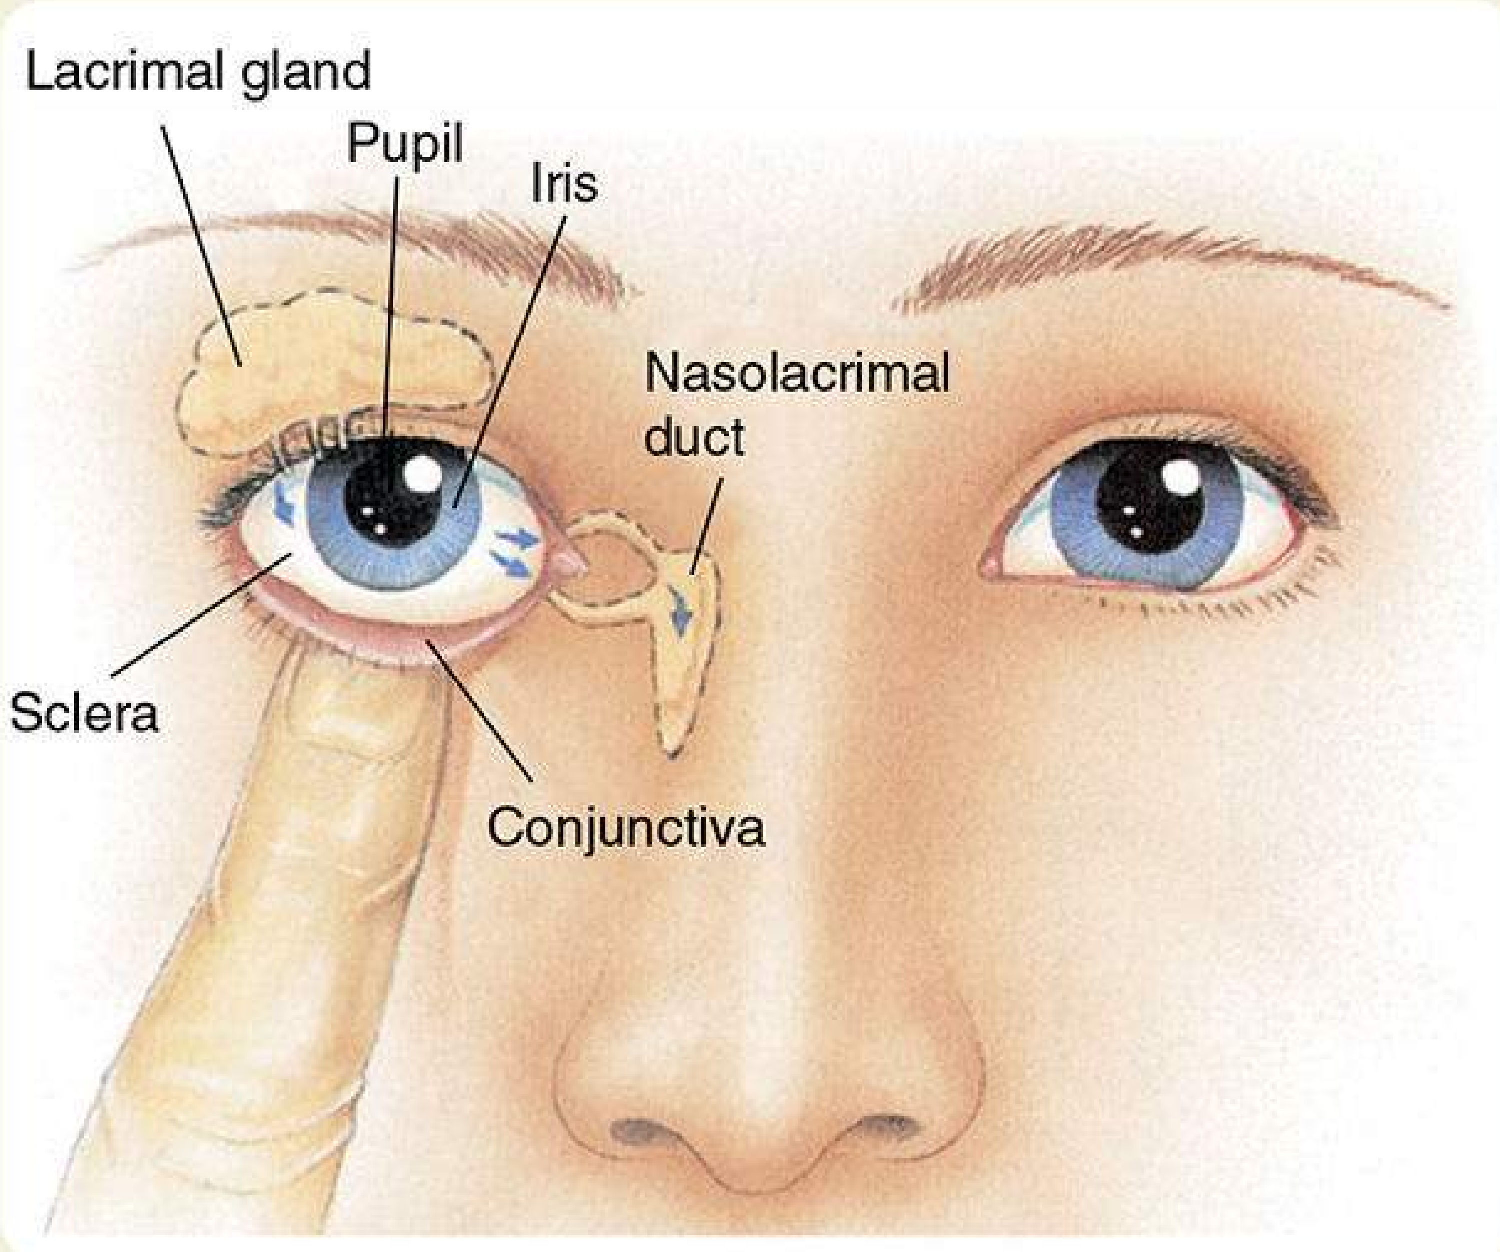

Figure 27-6 The lacrimal system consists of tear glands and ducts. Tears act as lubricants and keep the front of the eye from drying out.

The inner surface of the eyelids and the exposed surface of the eye itself, which are covered by a delicate membrane, the **conjunctiva**, are kept moist by fluid produced by the **lacrimal glands**, often called tear glands **Figure 27-6**. Humans blink unconsciously many times per minute. This action sweeps fluid from the lacrimal glands over the surface of the eye, cleaning it. The tears drain on the inner side of the eye through two lacrimal (tear) ducts into the nasal cavity. This is why, when people cry, they sometimes need to blow their nose.

The white of the eye, called the **sclera**, extends over the surface of the globe. This is extremely tough, fibrous tissue that helps maintain the eye's globular shape and protect the more delicate inner structures. On the front of the eye, the sclera is replaced by a clear, transparent membrane called the **cornea**, which allows light to enter the eye. A circular muscle lies behind the cornea with an opening in its center. Like the shutter in a camera, this muscle adjusts the size of the opening to regulate the amount of light that enters the eye. This circular muscle and surrounding tissue are called the **iris**. The iris is pigmented, giving the eye its characteristic brown, green, or blue color.

The opening in the center of the iris, which allows light to move to the back of the eye, is called the **pupil**. Normally, the pupil appears black. Like the opening in a camera, the pupil becomes smaller in bright light and larger in dim light. The pupil also becomes smaller and larger when the person is looking at objects near at hand and farther away; these adjustments occur almost instantaneously. Normally, the pupils in both eyes are equal in size. Some people are born with pupils that are not equal (**anisocoria**); however, particularly in unconscious patients, unequal pupil size may indicate serious injury or illness of the brain or eye.

Behind the iris is the **lens**. Like the lens of a camera, this lens focuses images on the light-sensitive area at the back of the globe, called the **retina**. Within the retina are numerous nerve endings, which respond to light by transmitting nerve impulses through the **optic nerve** to the brain. In the brain, the impulses are interpreted as vision.

The retina is nourished by a layer of blood vessels between it and the sclera at the back of the globe. This layer is called the choroid. If, as sometimes happens, the retina detaches from the underlying choroid and sclera, the nerve endings are not nourished, and the patient experiences blindness. This may be partial blindness, depending on how much of the retina is separated. This condition is called **retinal detachment**.

Words of Wisdom

The eye can see objects directly in front (central line vision) and objects to the side (peripheral vision).

Injuries of the Face and Neck

Injuries about the face and neck can often lead to partial or complete obstruction of the upper airway. Several factors may contribute to the obstruction. Bleeding from facial injuries can be very heavy, producing large blood clots in the upper airway. These clots can lead to complete obstruction, particularly in a patient who is not fully conscious. In particular, direct injuries to the nose and mouth, the larynx, or the trachea are often the source of significant bleeding and/or respiratory compromise. You may need to suction the airway if you are unable to control the bleeding. In addition, the injuries may cause loosened teeth or dentures to become dislodged into the throat where they may be swallowed or aspirated.

YOU are the Provider — PART 2

When you arrive at the scene, you find the patient, a 30-year-old man, sitting on the ground. He is conscious and alert and tells you, "They hurt me bad!" His face is swollen and covered with blood, he keeps spitting out small amounts of blood from his mouth, and his voice is hoarse. As your partner manually stabilizes his head, you perform a primary assessment.

Recording Time: 0 Minutes	
Appearance	Face is covered with blood; appears anxious
Level of consciousness	Conscious and alert
Airway	A small amount of blood in the mouth, which he is spitting out
Breathing	Increased rate; adequate depth
Circulation	Radial pulses, increased rate and strong; skin is pink, warm, and dry

3. Does this patient have a patent airway? How can you tell?
4. What should be your initial treatment priorities for this patient?

Figure 27-7

Facial hematoma.

The airway may also be affected when the patient's head is turned to the side, as often is done when the patient has an altered level of consciousness or is unconscious. Other factors that interfere with normal respirations include possible injuries to the brain and/or cervical spine that may be associated with facial injuries. If the great vessels in the neck are injured, significant bleeding and pressure on the upper airway are common; these can result in airway obstruction as well.

Depending on the mechanism of injury, there may be a cervical spine injury. If there is significant impact to the face, suspect accompanying cervical spine injury and follow your agency's protocol for cervical injuries.

▶ Soft-Tissue Injuries

Soft-tissue injuries of the face and neck are very common. Because the face and neck are extremely vascular, swelling from soft-tissue injuries in this area may be more severe than in other injured parts of the body. The skin and underlying tissues in these areas have a rich blood supply, so bleeding from penetrating injuries may be heavy. Even minor soft-tissue wounds of the face and neck may bleed profusely. A blunt injury that does not break the skin may cause a break in a blood vessel wall, leading blood to collect under the skin; this is called a hematoma **Figure 27-7**. In some situations, a flap of skin is peeled back, or avulsed, from the underlying muscle and fascia **Figure 27-8**.

Dental Injuries

Mandible (lower jaw) fractures are relatively common because of the prominence of the mandible itself. These fractures are second only to nasal fractures in frequency. Most of these fractures are the result of vehicle collisions and assaults. If your patient has a mandibular fracture, then consider the major force necessary to cause that fracture—there is a strong probability your patient will have additional facial trauma and/or cervical injuries. Signs of a mandibular fracture include a misalignment of the teeth, numbness of the chin, and an inability to open the mouth. The patient will most likely have swelling, bruising, and loosened or missing teeth.

Figure 27-8 A major avulsion injury is characterized by a large flap of skin that is peeled back from the underlying muscle and tissue.

Maxillary fractures are predominantly found after blunt-force, high-energy impacts such as an unrestrained driver striking the steering wheel, a fall, or a direct blow from an object such as a pipe. The signs include massive facial swelling, instability of the facial bones, and misalignment of the teeth.

Fractured and avulsed teeth are common following facial trauma. Dental injuries may be associated with motor vehicle crashes or an assault. Always assess the patient's mouth following a facial injury, especially if your examination reveals fractured or avulsed teeth. Teeth fragments (or even whole teeth) can become an airway obstruction and should be removed from the patient's mouth immediately.

Patient Assessment

Scene Size-up

As you arrive on the scene, observe for hazards and threats to the safety of the crew, bystanders, and the patient. Assess the impact of hazards on patient care and address those hazards. Assess for the potential for violence and assess for environmental hazards.

Patients who are conscious and supine and have oral or facial bleeding may protect their airway by coughing, projecting the blood at you. Therefore, standard precautions require eye protection and a face mask. Also, put several pairs of gloves in your pocket for easy access in the event your gloves tear or there are multiple patients with bleeding.

If your response is to a motor vehicle crash, you may be confronted with more than one patient in a vehicle. Determine the number of patients and consider if you need additional or specialized resources on the scene.

As you observe the scene, look for indicators of the mechanism of injury (MOI). This assessment helps you develop an early index of suspicion for underlying injuries in the patient who has sustained a significant MOI. As you put together information from dispatch and your observations of the scene, consider how the MOI produced the injuries expected. Common MOI for face and neck injuries include motor vehicle collisions, sports, falls, penetrating trauma, and blunt trauma. In motor vehicle collisions, the probability of injury increases if the vehicle rolled over or came to an abrupt stop when striking an immovable object, such as a tree. Injuries sustained during sports participation may include a player without a helmet who was struck by a baseball or two players who sustained a helmet-to-helmet collision in football.

Primary Assessment

As you approach the patient, look for important indicators to alert you to the seriousness of the patient's condition. Is the patient interacting with the environment or lying still, making no sounds? Does the patient have any apparent life threats such as significant bleeding? How is the patient's skin color? The general impression will help you develop an index of suspicion for serious injuries and determine your sense of urgency for medical intervention.

Injuries to the face and throat may be very obvious, such as bleeding and significant swelling, but may also be hidden under collars and hats. Because of the likelihood of respiratory distress with these injuries, they should be recognized as early as possible.

As with any injury with life-threatening bleeding, control the blood loss with direct pressure. Always consider the need for manual spinal stabilization and check for responsiveness using the AVPU scale.

Ensure that the patient has a clear and patent airway. If the patient is unresponsive or has a significantly altered level of consciousness, consider inserting a properly sized oropharyngeal airway. The use of a nasopharyngeal airway is controversial, as many believe that inserting a nasopharyngeal airway into the nare of a patient with facial or head trauma carries the risk of introducing the device into the cranial vault and brain tissue. However, recent research suggests this risk is extremely small. As always, be aware of and follow your local protocols.

Quickly assess for adequacy of breathing. Palpate the chest wall for DCAP-BTLS. If penetrating trauma is discovered, place an occlusive dressing on the wound. Maintain the airway, provide supplemental oxygen, and initiate bag-valve mask (BVM) ventilation if necessary. Check for breath sounds and provide rapid transport to the hospital without delay if breath sounds are abnormal. Splinting or otherwise attempting to restrict chest wall motion is not indicated as it is ineffective and can actually impair air exchange in the lungs.

Words of Wisdom

Face and throat injuries increase the need for airway and breathing maintenance, so do not hesitate to place a nonrebreathing mask over facial injuries. The seal may not be as easy to maintain, but airway and breathing take priority over soft-tissue injuries.

Quickly assess the pulse rate and quality; determine the skin condition, color, and temperature; and check the capillary refill time. Significant bleeding is an immediate life threat. If the patient has obvious life-threatening bleeding, you must control it quickly.

If the patient you are treating has an airway or a breathing problem or significant bleeding, you must consider quickly transporting the patient to the hospital for treatment. Stabilization and maintenance of an airway and breathing and controlling bleeding can be very difficult in patients with facial or neck injuries. Avoid delays in transport and consider advanced life support backup if the transport time is long. A patient with signs and symptoms of internal bleeding must be transported quickly to the appropriate hospital for treatment by a physician. Internal bleeding in face and throat injuries may compromise blood flow to the brain. Bleeding from major vessels of the throat can have a serious impact on the patient's airway. The condition of a patient with visible significant bleeding or signs of significant internal bleeding may quickly become unstable. Treatment is directed at quickly addressing life threats and providing rapid transport to the closest appropriate hospital. Signs such as tachycardia, tachypnea, low blood pressure, weak pulse, and cool, moist, pale skin are signs of hypoperfusion and imply the need for rapid transport. The patient who has a significant MOI but whose condition appears stable should also be transported promptly to the closest appropriate hospital. Remember that any significant blow to the face or throat should increase your suspicion of spinal or brain injury. Be alert to these signs and reconsider your priority and transport decision if they develop.

Even if the patient has no signs of hypoperfusion or other life-threatening injuries, there is the possibility of eye injuries, which are considered serious. Therefore, the patient should be transported to the hospital as quickly and as safely as possible. In some situations, surgery and/or restoration of circulation to the eye will need to be accomplished within 30 minutes or permanent blindness may result. Consider transporting the patient with serious, isolated eye injuries to an eye care specialty center depending on local protocol. Do not delay transport of a seriously injured patient, particularly one with significant bleeding even if controlled, to take a patient's history or perform a secondary assessment. Further assessment can continue during transport.

History Taking

After the life threats have been managed during the primary assessment, investigate the chief complaint or history of present illness. Obtain a medical history and be alert for injury-specific signs and symptoms, as well as any pertinent negatives such as no pain or no loss of sensation.

Next, obtain a SAMPLE history from your patient. If the patient is not responsive, attempt to obtain the SAMPLE history from friends or family members who may be present.

In an unresponsive patient you will only be able to notice the signs of the patient's injuries. Any other information will need to be obtained by someone who is knowledgeable about the patient. Keep in mind that the information you obtain may or may not be accurate and may be incomplete. The person providing the information may not be able to give you the actual names of the patient's medications but might be able to provide some pertinent medical history and possibly known allergies.

Secondary Assessment

The secondary assessment is a more detailed, comprehensive examination of the patient that is used to uncover injuries that may have been missed during the primary assessment. In some instances, such as a critically injured patient or a short transport time, you may not have time to conduct a secondary assessment.

If there is significant trauma that likely affects multiple systems, start with an assessment of the entire body looking for DCAP-BTLS to be sure that you have found all life threats and injuries. When this is completed, perform a detailed examination of specific areas. However, do not delay transport to complete a thorough physical examination.

In the responsive patient who has an isolated injury with a limited MOI, consider focusing your physical examination on the isolated injury, the patient's chief complaint, and the body region affected, which, in this case, is the face and throat. Ensure that control of bleeding is maintained and note the location of the injury. Inspect open wounds for any foreign matter and stabilize impaled objects.

During the physical examination, use both your eyes and hands. Your eyes will be looking for swelling, deformities of the bones, contusions, and discoloration whereas your hands will be gently palpating the face, looking and feeling for any abnormalities such as deformity or tenderness. Ask yourself the following questions:

1. Do the facial bones seem to be in alignment?
2. Does the nasal bone seem to deviate from the midline?
3. Note any variations from the normal facial examination; is there any facial drooping?
4. Does one eye appear to be lower than the other? If so, this is an indication of an orbital fracture.
5. Does the mandible appear to deviate toward one side or the other?

If your patient is responsive, explain exactly what you are doing and what you are looking for. Your discovery of an abnormality may actually be an old injury that the patient can tell you more about.

Assess all underlying systems. This should include the neurologic system, including brain and major nerves; sensory organs, including the eyes and nose; respiratory system, including mouth, nose, sinuses, and airway; and circulatory system, particularly focusing on the carotid arteries and jugular veins.

When you are evaluating the eyes, start on the outer aspect of the eye and work your way in toward the pupils. Examine the eye for any obvious foreign matter. Your patient may relay this information to you also ("I have something in my eye."). Visual acuity, or the clarity of the patient's vision in each eye, is considered the vital sign of the eye. Quickly assess the patient's visual acuity by gently covering one eye and holding fingers up at arm's length in front of the open eye. Test for the ability to see fingers in both the injured and uninjured eye and document your findings. Note any discoloration of the eye, bleeding in the iris area, or redness. Look for eye symmetry because asymmetry is a possible indication of a brain injury.

Look at each pupil for equal size and reaction to light. If the pupils are not symmetric, ask the patient if he or she has had any previous eye surgeries or injuries. Previous surgery or injury, rather than brain injury, may be the root cause of the pupils not appearing the same. Cataract surgery can cause unequal pupils, but when you have a patient with a suspected head injury or ocular injury, anisocoria (unequal pupils in dim light) may be present. Determine whether the unequal pupils are caused by physiologic or pathologic issues. Use of over-the-counter eye drops can change pupil size, and certain asthma inhalers can have the same effect if inadvertently sprayed into the eye. Brain injury, nerve disease, glaucoma, and meningitis are all possible causes of unequal pupils.

Does the patient have the ability to follow your finger from side to side as well as up and down? Can the patient read normal print? Does the patient report blurry vision in either eye? Is there a new sensitivity to light?

Assess vital signs to obtain a baseline so that you can observe any changes a patient may display during treatment. A systolic blood pressure reading of less than 100 mm Hg with a weak, rapid pulse and cool, moist skin that is pale or gray should alert you to the presence of hypoperfusion in a patient who may have significant bleeding. Remember, you must be concerned with visible bleeding and unseen bleeding inside a body cavity. With facial and throat injuries, baseline information about the rate and quality of respirations and pulse is very important, as is monitoring throughout patient care.

In addition to hands-on assessment, use monitoring devices to quantify your patient's oxygenation and circulatory status. You may also use noninvasive methods to monitor the blood pressure. It is recommended that you always assess the patient's first blood pressure manually with a sphygmomanometer (blood pressure cuff) and stethoscope.

YOU are the Provider — PART 3

As your partner continues to manually stabilize his head, you perform a secondary assessment of the entire body, which reveals bruising and mild swelling to the anterior part of the neck, directly over the trachea. The remainder of your assessment does not reveal any obvious injuries. You apply a cervical collar and assess his vital signs. One of the police officers is asked to retrieve the long backboard and other spinal immobilization equipment.

The patient tells you that he was struck in the face with a steel pipe. After he fell to the ground, he was kicked in the face and throat several times. His face is severely swollen, three of his front teeth are missing, and he tells you that it "doesn't feel right" when he closes his mouth.

Recording Time: 5 Minutes	
Respirations	22 breaths/min; adequate depth
Pulse	118 breaths/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	132/68 mm Hg
Oxygen saturation (Spo_2)	97% (on oxygen)

5. On the basis of the mechanism of injury, what type of injuries should you suspect and assess for?

Reassessment

Repeat the primary assessment. Reassess vital signs and the chief complaint. Continually reassess the adequacy of the patient's airway, breathing, and circulation. Recheck patient interventions. Are the treatments you provided for problems with the ABCs still effective? This is particularly important in patients with facial or neck injuries because of the ease in which injuries can affect associated systems, such as the respiratory (airway and breathing), circulatory, and nervous systems. The patient's condition should be reassessed at least every 5 minutes.

Provide complete spinal immobilization to any patient with suspected spinal injuries. Spinal injuries should be suspected any time there is significant trauma to the face or neck. Maintain an open airway, be prepared to suction the patient, and consider an oropharyngeal airway. Whenever you suspect significant bleeding, provide high-flow oxygen. Oxygen and airway maintenance are important for all patients with face and neck injuries. If needed, provide assisted ventilation using a BVM with high-flow oxygen.

Control any significant visible bleeding. If the patient has signs of hypoperfusion, treat the patient aggressively for shock and provide rapid transport to the appropriate hospital. Do not delay transport of a seriously injured trauma patient to complete nonlifesaving treatments in the field, such as splinting extremity fractures. Instead, complete these treatments en route to the hospital. If there is no cervical spine injury suspected, the patient may be more comfortable in the sitting position during transport.

In your documentation, describe the MOI and the position in which you found the patient when you arrived at the scene. Document the method used to remove the patient from the vehicle, for example, "prolonged extrication." In patients with severe external bleeding, it is important to recognize, estimate, and report the amount of blood loss that has occurred and how rapidly or how much time has passed since the bleeding started. This can be a challenge for you, especially if the surface the patient is on is wet or absorbs fluids or the environment is dark. Inform the hospital personnel about all of the injuries involving the patient's head and neck. Specialists may need to be called to manage injuries involving the eyes, ears, teeth, mouth, sinuses, larynx, esophagus, or large vessels. These specialists are not always in the hospital, especially during the evening or night, or in smaller hospitals, so informing emergency department personnel of all injuries involving the face and throat can save valuable time.

Emergency Medical Care

The emergency care of soft-tissue injuries to the face and neck is the same as treatment of soft-tissue injuries elsewhere on the body. You should assess the ABCs and care for any life threats first. Remember also to follow standard precautions in all cases.

In the absence of life-threatening bleeding, your first step is to open and clear the airway. Securing and maintaining a patent airway is paramount. Remember that blood draining into the throat can produce vomiting and airway obstruction; therefore, the patient may need frequent suctioning. Take appropriate precautions if you suspect that the patient has sustained a cervical spine injury; be sure to avoid moving the neck. Use the jaw-thrust maneuver to open the patient's airway, and then suction the mouth. Once the patient is immobilized in a cervical collar and on a backboard, you can turn the backboard to one side to allow any blood or vomitus to drain out of the mouth rather than pool in the pharynx and obstruct the airway.

Control bleeding by applying direct manual pressure with a dry, sterile dressing. Use roller gauze, wrapped around the circumference of the head, to hold a pressure dressing in place **Figure 27-9**. Do not apply excessive pressure if there is a possibility of an underlying skull fracture. When an injury exposes the brain, eye, or other structures, cover the exposed parts with a moist, sterile dressing to protect them from further damage. For injuries in which the skin is not broken, apply ice locally to help control the swelling of bruised tissues.

Figure 27-9 Use roller gauze, wrapped around the circumference of the head, to hold a pressure dressing in place.

For soft-tissue injuries around the mouth, always check for bleeding inside the mouth. Broken teeth and lacerations to the tongue may cause profuse bleeding and obstruction of the upper airway **Figure 27-10**. Often, the patient will swallow the blood from lacerations inside the mouth, so the hemorrhage may not be apparent. You should also inspect the inside of the mouth for bleeding and hidden injuries in patients who have sustained facial trauma. Remember that patients who swallow blood are prone to vomiting.

Figure 27-10 Soft-tissue injuries around the mouth can be associated with profuse bleeding inside the mouth and obstruction of the airway.

Figure 27-11 If avulsed skin is still attached, place the flap in a position that is as close to normal as possible, and hold it in place with a dry, sterile dressing.

Often, physicians will be able to graft a piece of avulsed skin back into the appropriate position. For this reason, if you find portions of avulsed skin that have become separated, wrap them in a sterile dressing, place them in a plastic bag, and keep them cool. Never place tissue directly on ice because freezing will destroy the tissue and make it unusable. Deliver the bag labeled with the patient's name to the emergency department along with the patient. In many avulsion injuries, the skin will still be attached in a loose flap **Figure 27-11**. Place the flap in a position that is as close to normal as possible, and hold it in place with a dry, sterile dressing. These steps will help to increase the patient's chances of having his or her normal appearance restored.

Emergency Medical Care for Specific Injuries

Injuries of the Eyes

Eye injuries are common, particularly in sports. An eye injury can produce severe, lifelong complications, including blindness. Proper emergency treatment will minimize pain and may very well help to prevent a permanent loss of vision.

In a normal, uninjured eye, the entire circle of the iris is visible. The pupils are round, usually equal in size, and react equally when exposed to light **Figure 27-12**. Both eyes move together in the same direction when following your moving finger. After an injury, pupil reaction or shape and eye movement are often disturbed. Any of these conditions should cause you to suspect an injury of the globe or its associated tissues. Remember, though, that abnormal pupil reactions sometimes are a sign of brain injury rather than eye injury.

Treatment starts with a Always perform your examination using standard precautions, taking great care to avoid aggravating any problems. You are looking for specific abnormalities or conditions that may suggest the nature of the injury **Figure 27-13**. For example, blunt or penetrating injuries can produce swollen or lacerated eyelids. Bleeding soon after irritation or injury can result in a bright red conjunctiva. A damaged cornea quickly loses its smooth, wet appearance.

Foreign Objects

Large objects are prevented from penetrating the eye by the protective orbit that surrounds it. However, moderately sized and smaller foreign objects of many different types can enter the eye and cause significant damage. Even a very small foreign object, such as a grain of sand lying on the surface of the conjunctiva, may produce severe irritation **Figure 27-14**. The conjunctiva becomes inflamed and red—a condition known as **conjunctivitis**—almost immediately, and the eye begins to produce tears in an attempt to flush out the object. Irritation of the cornea or conjunctiva causes intense pain. The patient may have difficulty keeping the eyelids open, because the irritation is further aggravated by bright light.

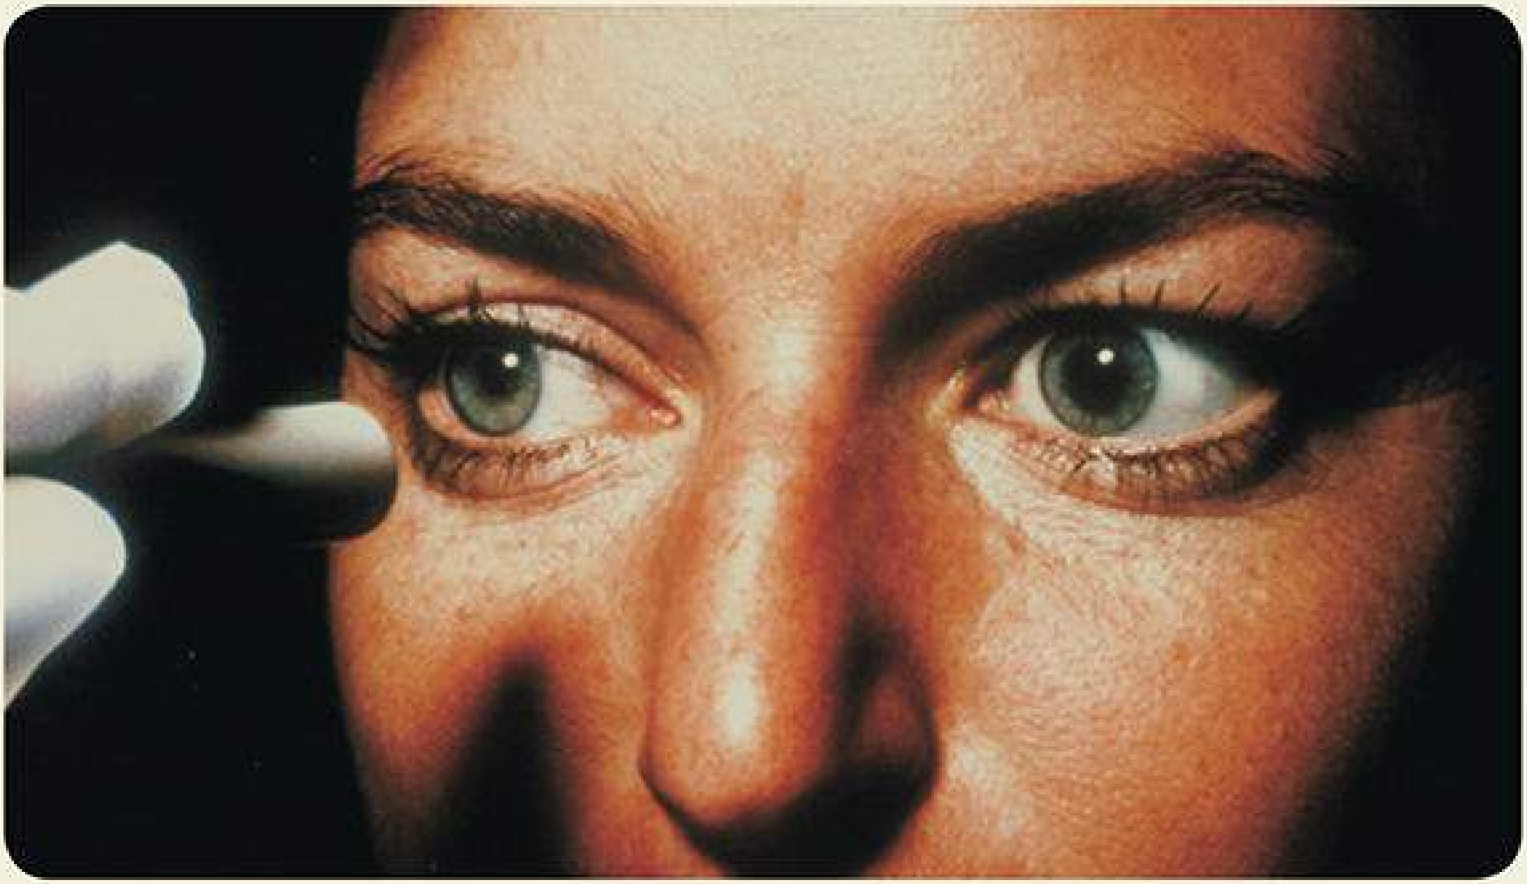

Figure 27-12 Normally, the pupils are round, equal in size, and equally reactive when exposed to light. The pupils shown here appear unequal.

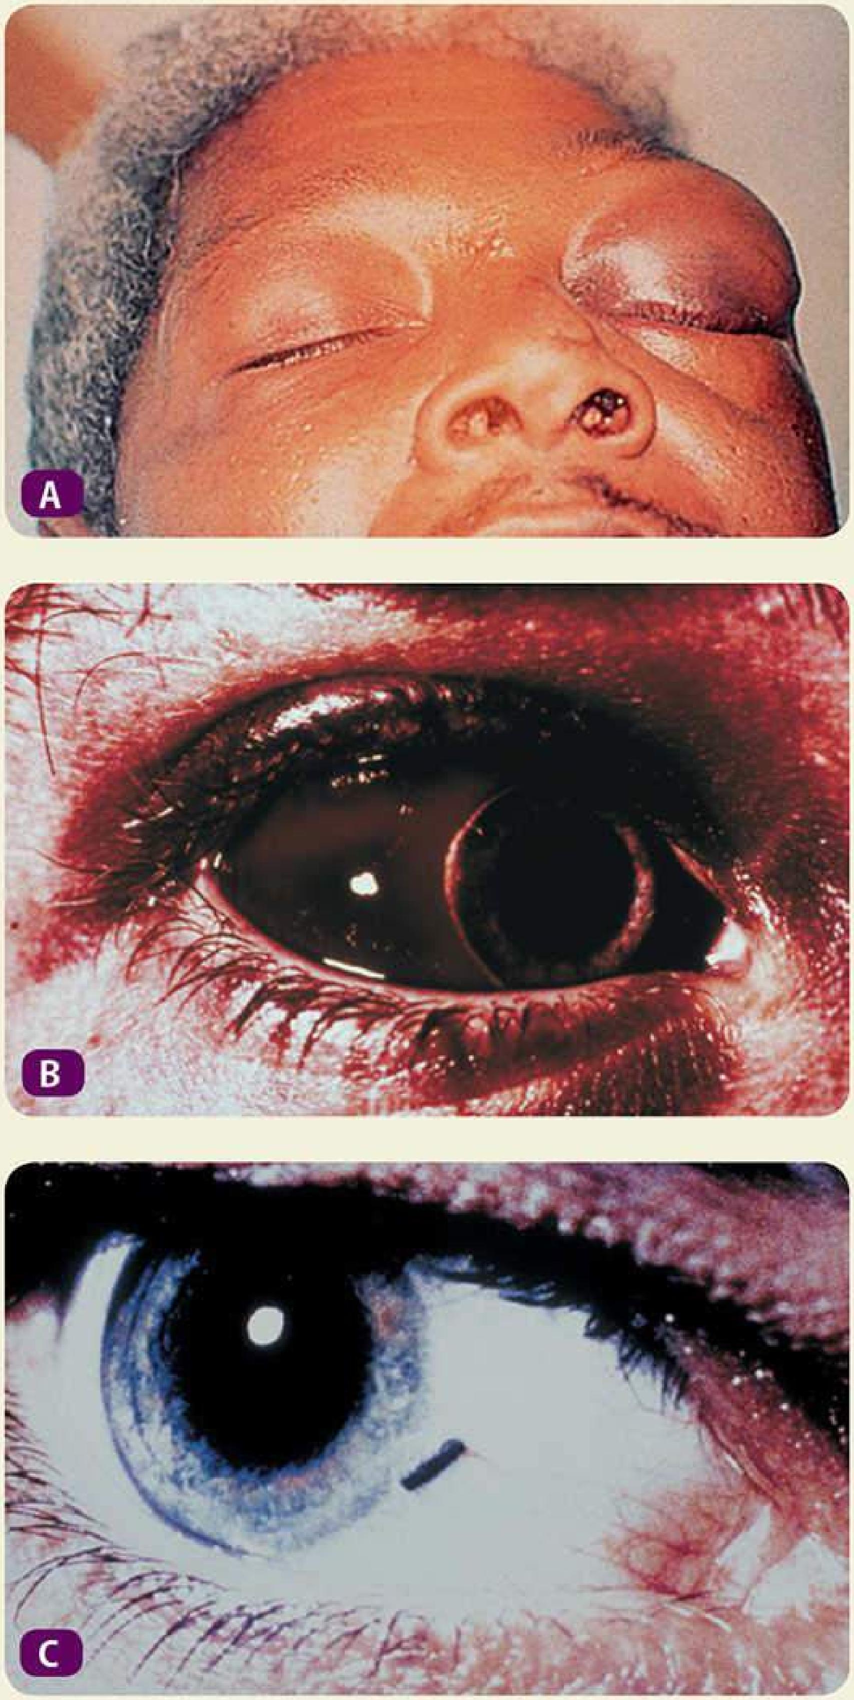

Figure 27-13 Injuries to the eyes are easily detected by swelling **(A)**, bleeding **(B)**, and the presence of foreign objects in the eye **(C)**.

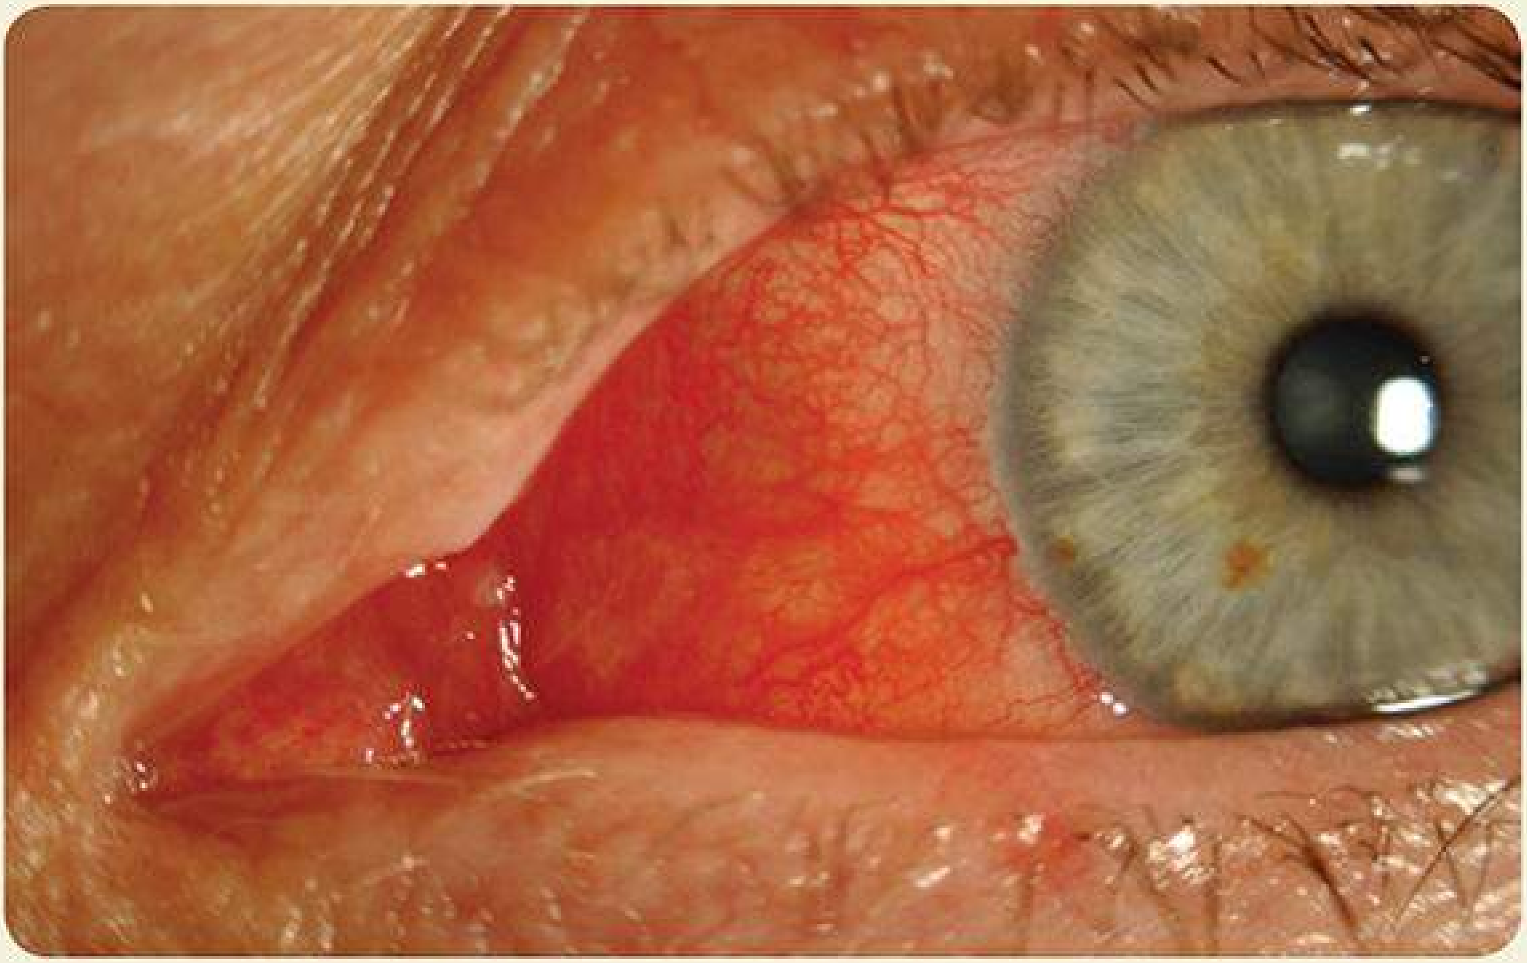

Figure 27-14 Conjunctivitis is often associated with the presence of a foreign object in the eye.

Courtesy of John T. Halgren, MD., University of Nebraska Medical Center.

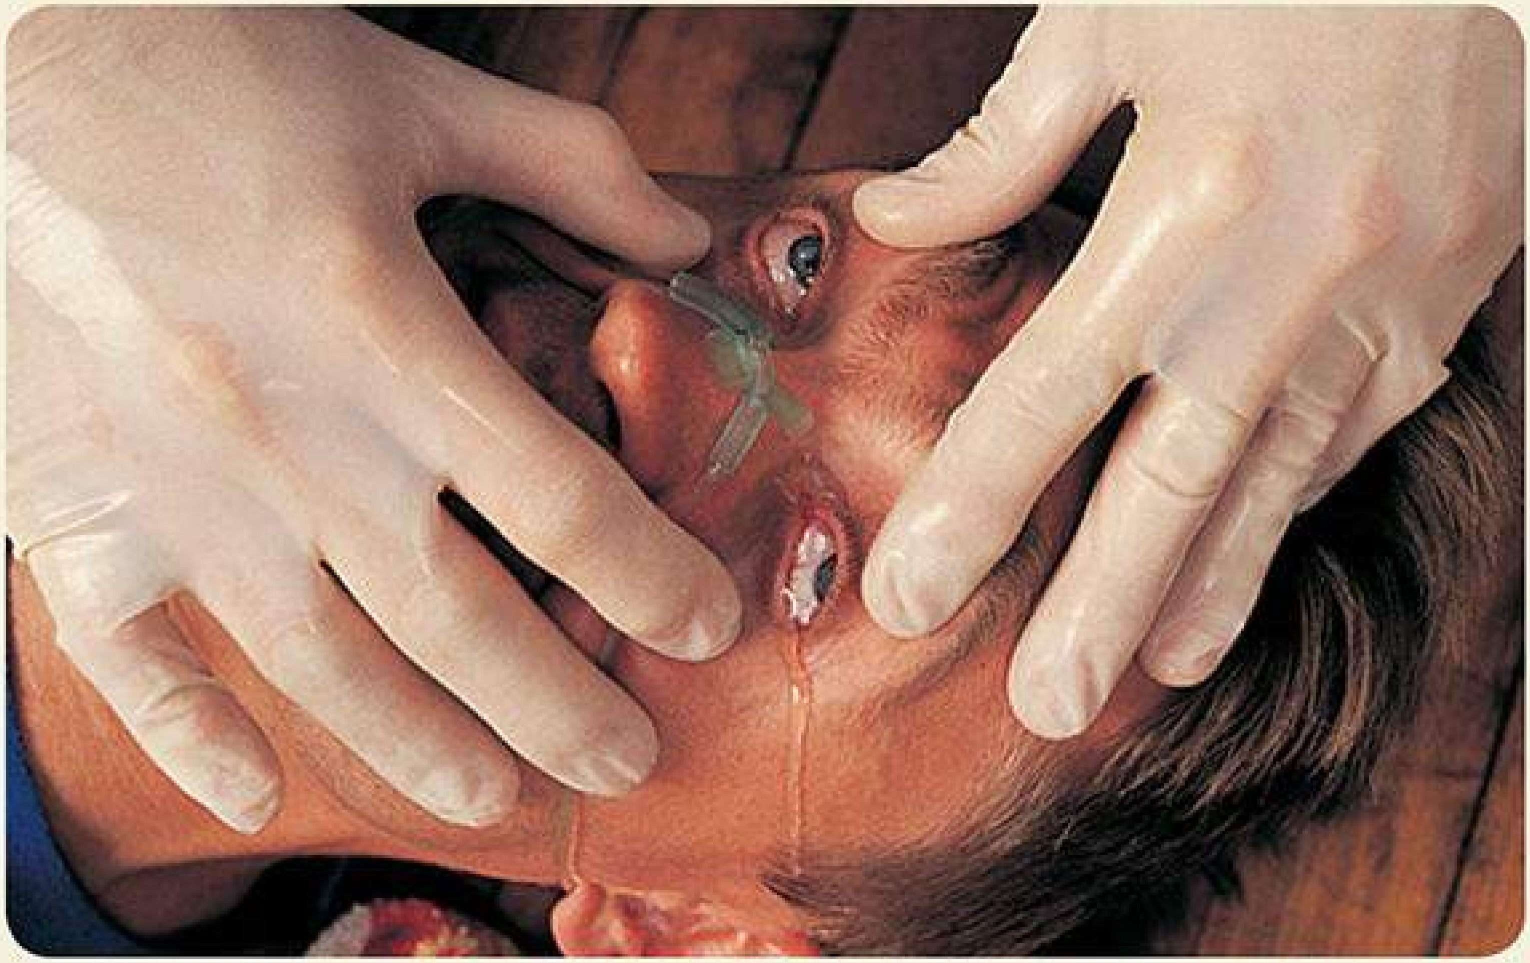

Figure 27-15 One method of irrigation is to direct saline into the injured eye using a round nasal airway or cannula. Always flush from the nose side of the eye toward the outside to avoid flushing material into the other eye.

If a small foreign object is lying on the surface of the patient's eye, you should use a normal saline solution to gently irrigate the eye. Irrigation with a sterile saline solution will frequently flush away loose, small particles. If a small bulb syringe is available, you can use this, or a nasal airway or cannula, to direct the saline into the affected eye Figure 27-15. Always flush from the nose side of the eye toward the outside to avoid flushing material into the other eye. After it has been flushed away, a foreign body will often leave a small abrasion on the surface of the conjunctiva. For this reason, the patient will report irritation even when the particle itself is gone. It is always a good idea to transport the patient to the hospital for further assessment to ensure appropriate medical care to the affected eye.

Gentle irrigation usually will not wash out foreign bodies that are stuck to the cornea or lying under the upper eyelid. To examine the undersurface of the upper eyelid, pull the lid upward and forward. If you spot a foreign object on the surface of the eyelid, you may be able to remove it with a moist, sterile, cotton-tipped applicator **Skill Drill 27-1**. Never attempt to remove a foreign body that is stuck to the cornea.

1. Tell the patient to look down while you grasp the lashes of the upper eyelid with your thumb and index finger. Gently pull the eyelid away from the eyeball **Step 1**.
2. Gently place a cotton-tipped applicator horizontally along the center of the outer surface of the upper eyelid **Step 2**.
3. Pull the eyelid forward and up, which causes it to roll or fold back over the applicator, exposing the undersurface of the eyelid **Step 3**.
4. If you see a foreign object on the surface of the eyelid, gently remove it with a moistened, sterile, cotton-tipped applicator **Step 4**.

Skill Drill 27-1 Removing a Foreign Object From Under the Upper Eyelid

© Jones & Bartlett Learning. Courtesy of MIEMSS.

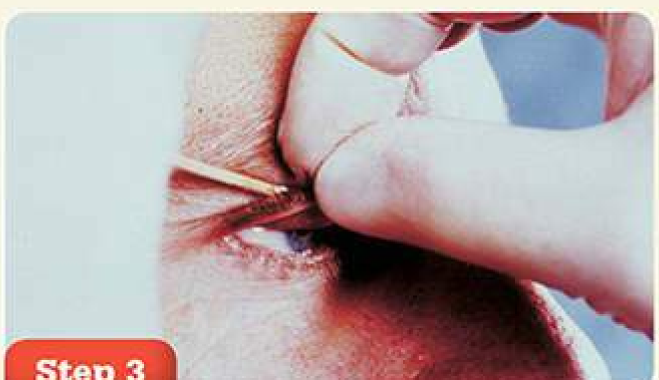
Step 1

Have the patient look down, grasp the upper lashes, and gently pull the lid away from the eye.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 2

Place a cotton-tipped applicator on the outer surface of the upper lid.



© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 3

Pull the lid forward and up, folding it back over the applicator.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 4

Gently remove the foreign object from the eyelid with a moistened, sterile, cotton-tipped applicator.

Foreign bodies ranging in size from a pencil to a sliver of metal may be impaled in the eye **Figure 27-16**. These objects must be removed by a physician. Your care involves stabilizing the object and preparing the patient for transport to definitive care. The greater the length of the foreign object you can see sticking out of the eye, the more important stabilization becomes in avoiding further damage. Bandage the object in place to support it. Cover the eye with a moist, sterile dressing, and then surround the object with a doughnut-shaped collar made from roller gauze or a small gauze pack. Follow the steps in **Skill Drill 27-2**:

Figure 27-16 Any number of objects can become impaled in the eye. **A.** Fishhook. **B.** Sharp, metal sliver. **C.** Knife blade.

1. Begin to prepare the doughnut ring by wrapping a 2-inch gauze roll circumferentially around your fingers and thumb enough times to make a thick dressing layer. You can adjust the inner diameter of what will become the ring by spreading your fingers or squeezing them together Step 1.
2. Remove the gauze from your hand and wrap the remainder of the gauze roll radially around the ring that you have created Step 2.
3. Work your way around the ring until you have wrapped all the way around it and finished the "doughnut" Step 3.
4. Carefully place the ring over the eye and impaled object, without bumping the object. You can then stabilize the object and the gauze collar with a roller bandage surrounding the head. Bandage both the injured and uninjured eyes to minimize eye movement and prevent further damage to the globe because when one eye moves, so does the other. Transport to an appropriate medical facility for treatment Step 4.

Sometimes, a variety of types of large and small foreign bodies, particularly small metal fragments, become completely embedded within the eye itself. The patient may not even be aware of the cause of the problem. Suspect such an injury when the history includes metal work (such as hammering, exposure to splinters, grinding, vigorous filing) and when there are other signs of ocular injury. When you see or suspect an impaled object in the eye, bandage both eyes with soft, bulky dressings to prevent further injury to the affected eye. Your bandage should be loose enough to hold the eyelid closed but not cause pressure on the eye itself. Using this technique prevents sympathetic motion (the movement of one eye causing both eyes to move), which may cause additional damage to the injured eye. This type of injury must be handled by an ophthalmologist on an urgent basis. X-rays and special equipment may be required to find the foreign body.

Burns of the Eye

Chemicals, heat, and light rays all can burn the delicate tissues, such as the cornea, often causing permanent damage. Your role is to stop the burn and prevent further damage.

Skill Drill 27-2 Stabilizing a Foreign Object Impaled in the Eye

Step 1

To prepare a doughnut ring, wrap a 2-inch roll around your fingers and thumb seven or eight times. Adjust the diameter by spreading your fingers or squeezing them together.

Step 2

Remove the gauze from your hand and wrap the remainder of the gauze roll radially around the ring that you have created.

Step 3

Work around the entire ring to form a doughnut.

Step 4

Place the dressing over the eye and impaled object to hold the impaled object in place, and then secure it with a roller bandage.

Chemical Burns. Chemical burns, usually caused by acid or alkaline solutions, require immediate emergency care Figure 27-17. This consists of flushing the eye with water or a sterile saline irrigation solution. If sterile saline is not available, you can use any clean water.

The idea is to direct the greatest amount of irrigating solution or water into the eye as gently as possible Figure 27-18. Because opening the eye spontaneously may cause the patient pain, you may have to force the lids open to irrigate the eye adequately. Ideally, you will use a bulb or irrigation syringe, a nasal cannula, or some other device that will allow you to control the flow. In some circumstances, you may have to resort to pouring water into the eye by holding the patient's head under a gently running faucet. You can even have the patient immerse his or her face in a large pan or basin of water and rapidly blink the affected eyelid. If only one eye is affected, care must be taken to avoid contaminated water from getting into the unaffected eye.

Be sure to flush from the inner corner of the affected eye toward the outside corner. Never flush from the outside corner as this may cause the substance to contaminate the unaffected eye. If the burn was caused by an alkali or a strong acid, irrigate the eye continuously for 20 minutes. Follow local protocols on whether to try to irrigate while transporting or to stay on scene until flushing is complete. Strong acids and all alkaline solutions can penetrate deeply, requiring a prolonged flush. Again, always take care to protect the uninjured eye and prevent irrigation fluid from running into it.

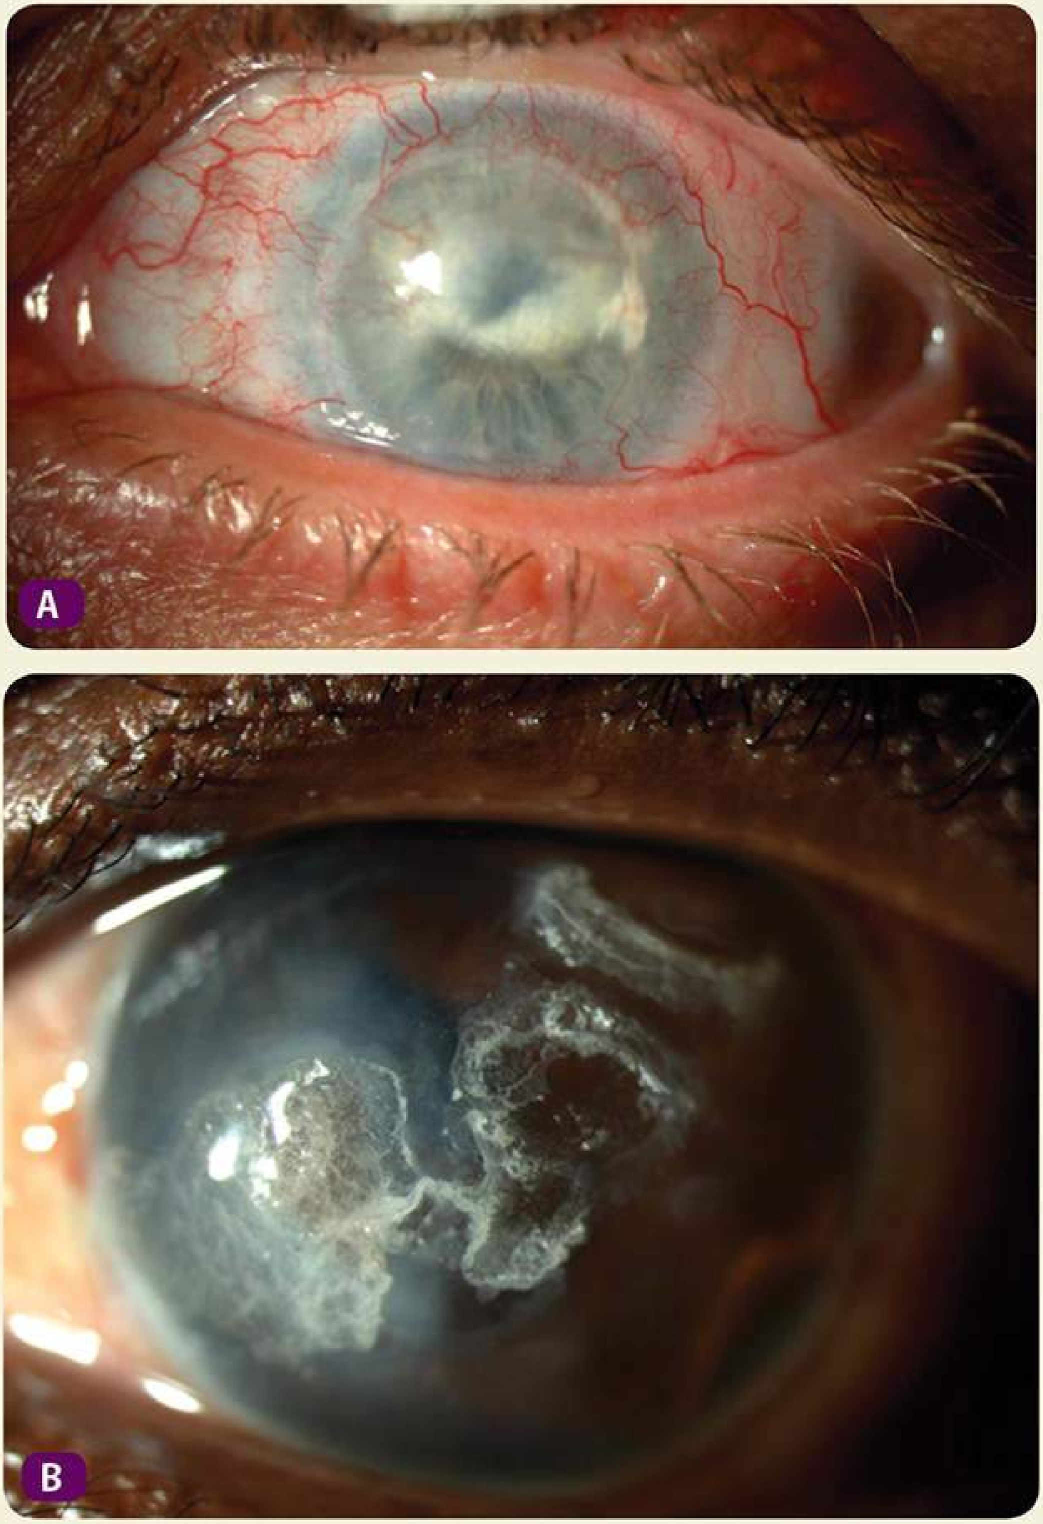


Figure 27-17 **A.** Chemical burns typically occur when an acid or alkali is splashed into the eye. **B.** This figure shows a chemical burn from lye, an alkaline solution. Because lye can continue to damage the eye even when diluted, fast action is needed.

After you have completed irrigation, apply a clean, dry dressing to cover the eye, and transport the patient promptly to the hospital for further care **Figure 27-19**. If the irrigation can be carried out satisfactorily in the ambulance, it should be done during transport to save time.

Thermal Burns. When a patient is burned on the face during a fire, the eyes usually close rapidly because of the heat. This reaction is a natural reflex to protect the eye from further injury. However, the eyelids remain exposed and are frequently burned **Figure 27-20**. Burns of the eyelids require very specialized care. It is best to provide prompt transport for these patients without further examination. First, however, you should cover both eyes with a sterile dressing moistened with sterile saline. You may apply eye shields over the dressing.

Words of Wisdom

With thermal burns to the face, inhalation burns may also occur.

Light Burns. Infrared rays, eclipse light (if the patient has looked directly at the sun), and laser burns all can cause significant damage to the sensory cells of the eye when rays of light become focused on the retina. Retinal injuries that are caused by exposure to extremely bright light are generally not painful but may result in permanent damage to vision.

Superficial burns of the eye can result from ultraviolet rays from an arc welding unit, light from prolonged exposure to a sun lamp, or reflected light from a bright, snow-covered area (snow blindness). This kind of burn often is not painful at first but may become so 3 to 5 hours later, when the damaged cornea responds to the injury. Severe conjunctivitis usually develops, with redness, swelling, and excessive tear production. You can ease the pain from these corneal burns by covering each eye with a sterile, moist pad and an eye shield. Have the patient lie down during transport to the hospital, and protect him or her from further exposure to bright light.

The patient should be examined by a physician as soon as possible.

Lacerations

Lacerations of the eyelids require very careful repair to restore appearance and function **Figure 27-21**. Bleeding may be heavy, but it usually can be controlled by gentle, manual pressure. If there is a laceration of the globe itself, apply no pressure to the eye. Compression can interfere with the blood supply to the back of the eye and result in loss of vision from damage to the retina. Furthermore, pressure may squeeze the vitreous humor, iris, lens, or even the retina out of the eye and cause irreparable damage or blindness.

Figure 27-18 The following are four ways to effectively irrigate the eye. **A.** Nasal cannula. **B.** Shower. **C.** Bottle. **D.** Basin. Remember, you must protect the uninjured eye from the irrigating solution to prevent exposure of the unaffected eye to the substance.

Figure 27-19 Apply a clean, dry dressing to cover the eye after you have finished irrigation.

Follow these three important guidelines in treating penetrating injuries of the eye:

1. Never exert pressure on or manipulate the injured eye (globe) in any way.
2. If part of the eyeball is exposed, gently apply a moist, sterile dressing to prevent drying.
3. Cover the injured eye with a protective metal eye shield, cup, or sterile dressing. Apply soft dressings to both eyes, and provide prompt transport to the hospital.

On rare occasions following a serious injury, the eyeball may be displaced out of its socket. Do not attempt to reposition it. Simply cover the eye and stabilize it with a moist, sterile dressing Figure 27-22. Remember to cover both eyes to prevent further injury because of sympathetic movement. Have the patient lie in a supine position en route to the hospital to prevent further loss of fluid from the eye.

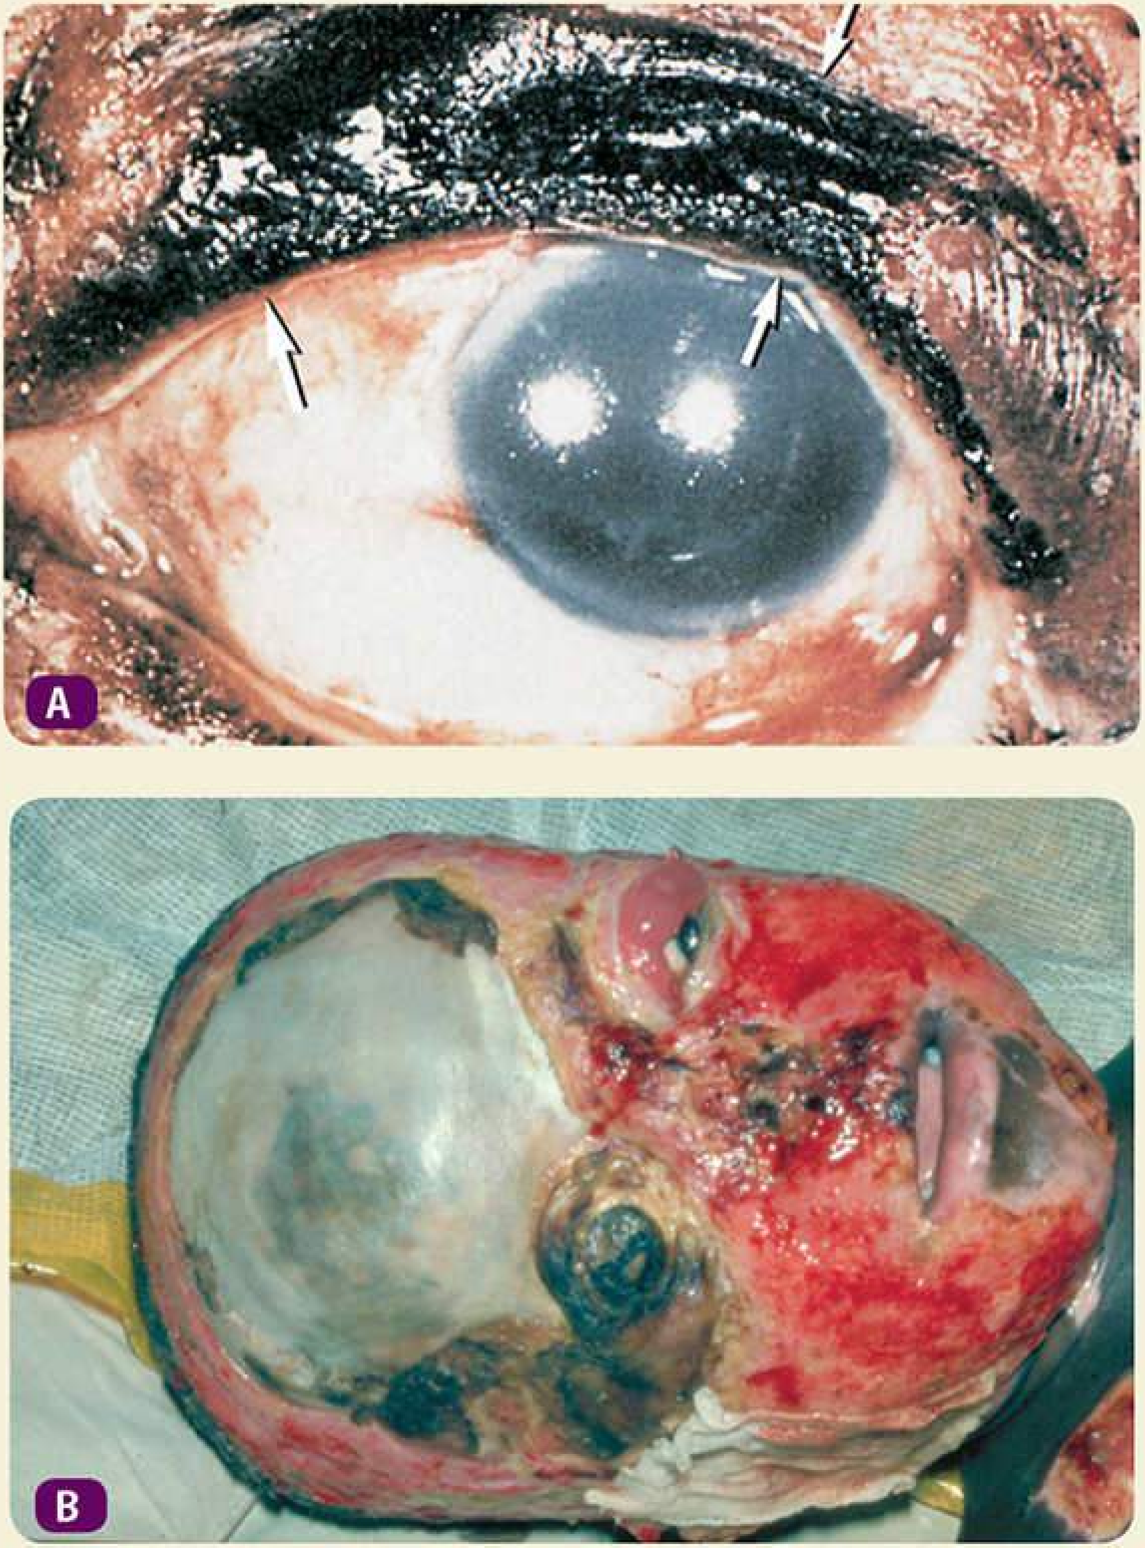

Figure 27-20 Thermal burns occasionally cause significant damage to the eyelids. **A.** Arrows show some full-thickness burns. **B.** Burns of the eyelids require immediate hospital care.

Blunt Trauma

Blunt trauma can cause a number of serious eye injuries. These range from the ordinary "black eye," a result of bleeding into the tissue around the orbit, to a severely damaged globe **Figure 27-23**. You may see an injury called hyphema, or bleeding into the anterior chamber of the eye, that obscures part or all of the iris **Figure 27-24**. This injury is common in blunt trauma and may seriously impair vision. Twenty-five percent of hyphemas are globe injuries, a serious injury to the eye. Cover the eye to protect it from further injury and provide transportation to the hospital for further medical evaluation.

Blunt trauma can also cause a fracture of the orbit, particularly of the bones that form its floor and support the globe. This injury is called a **blow-out fracture**. The fragments of fractured bone can entrap some of the muscles that control eye movement, causing double vision **Figure 27-25**. Any patient who reports pain, double vision, or decreased vision following a blunt injury about the eye should be placed on a stretcher and transported promptly to the emergency department. Protect the eye from further injury with a metal shield; cover the other eye to minimize movement on the injured side.

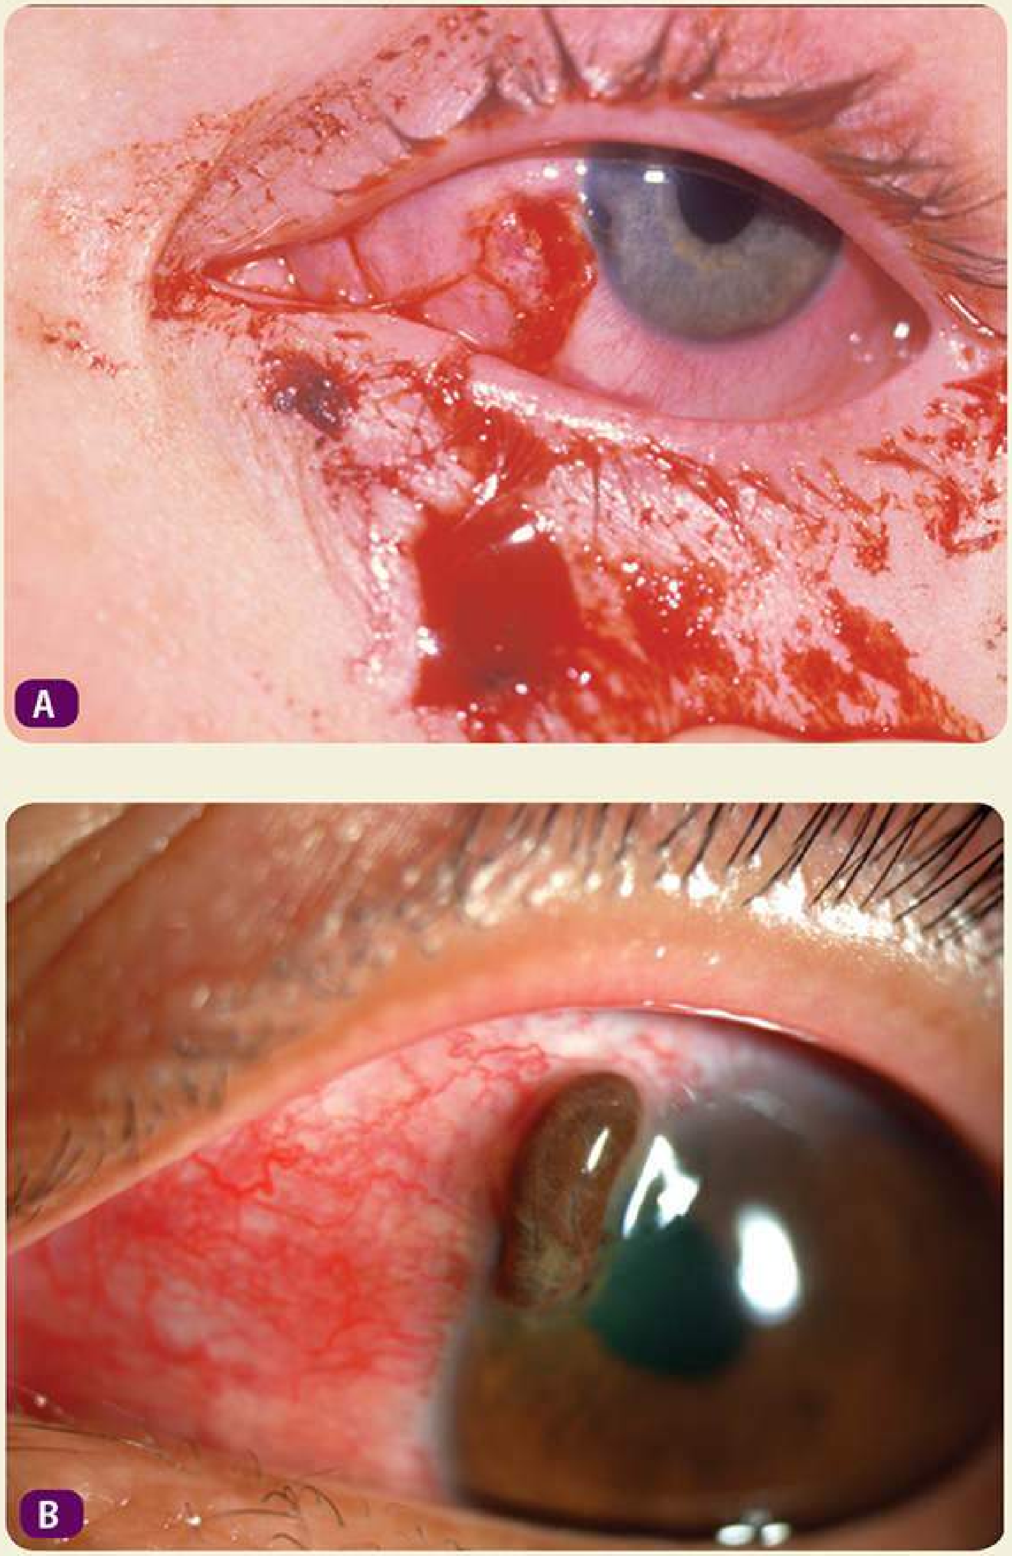

Figure 27-21 Lacerations are serious injuries that require prompt transport. **A.** Although bleeding can be heavy, never exert pressure on the eye. **B.** Pressure may squeeze the vitreous humor, iris, lens, or even the retina out of the eye.

A: © Chris Barry/Phototake; B: Paul Whitten/Science Source.

Another possible result of blunt eye injury is retinal detachment. This injury is often seen in sports, especially boxing. It is painless but produces flashing lights, specks, or "floaters" in the field of vision and a cloud or shade over the patient's vision. Because the retina is separated from the nourishing choroid, this injury requires prompt medical attention to preserve vision in the eye.

Eye Injuries Following Head Injury

Abnormalities in the appearance or function of the eyes often occur following a closed head injury. Any of the following eye findings should alert you to the possibility of a head injury:

- One pupil larger than the other Figure 27-26
- The eyes not moving together or pointing in different directions
- Failure of the eyes to follow the movement of your finger as instructed
- Bleeding under the conjunctiva, which obscures the sclera (white portion) of the eye
- Protrusion or bulging of one eye

Record any of these observations, along with the time that you make them. For an unconscious patient, remember to keep the eyelids closed; drying of the ocular tissue can cause permanent injury and may result in blindness. Cover the lids with moist gauze, or hold them closed with clear tape. Normal tears will then keep the tissues moist.

Blast Injuries

The signs and symptoms of blast injuries range from severe pain and loss of vision to foreign bodies within the globe. Before responding to patients after the blast, first ensure that the scene is safe.

Management of blast injuries to the eye depends on the severity of the injury. If there is a foreign body within the globe, do not attempt to remove it. Use a clean cup or similar item to protect the area. If only one eye is injured, follow local protocol, which may include covering the other eye to eliminate sympathetic motion. Patients with a sudden loss or decrease of vision will need to be verbally instructed on what actions are taking place around them. If the patient has severe swelling or a hematoma to the eyelid, do not attempt to force the eyelid open to examine the eye because this increases the pressure already present within the globe.

Contact Lenses and Artificial Eyes

Small, hard contact lenses usually are tinted, making them relatively easy to see. Large, soft contact lenses are clear and can be very difficult to see. In general, you should not attempt to remove either kind of lens from a patient. You should never attempt to remove a lens from an eye that has been—or may have been—injured because manipulating the lens can aggravate the problem. The only time that contact lenses should be removed immediately in the field is in the case of a chemical burn of the eye. In this situation, the lens can trap the chemical and make irrigation difficult.

YOU are the Provider — PART 4

After applying full spinal immobilization, you place the patient onto the stretcher and load him into the ambulance. You recovered his teeth and placed them in a commercial tooth-saver container. While you reassess the interventions you have performed thus far, your partner reassesses the patient's vital signs.

Recording Time: 11 Minutes	
Level of consciousness	Conscious and alert
Respirations	20 breaths/min; adequate depth
Pulse	108 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	128/62 mm Hg
Spo_2	98% (on oxygen)

Reassessment of the patient's mouth reveals that it is clear of blood. You begin transport to a trauma center, which is located 15 miles away. En route, the patient tells you that he is becoming nauseated. You call in your radio report and give an estimated time of arrival of 18 to 20 minutes.

6. What should you do if this patient begins to vomit?

7. How should you treat a patient with active oral bleeding *and* inadequate ventilation?

If it is necessary to remove a hard contact lens, use a small suction cup, moistening the end with saline **Figure 27-27A**. To remove soft lenses, place one to two drops of saline in the eye **Figure 27-27B**, gently pinch it between your gloved thumb and index finger, and lift it off the surface of the eye **Figure 27-27C**. Place the contact lens in a container filled with sterile saline solution to prevent damage to the contact lens. Always advise the emergency department staff if a patient is wearing contact lenses.

Figure 27-22 An injury that exposes the brain, eye, or other structures **(A)** should be covered with a moist, sterile dressing to prevent further damage **(B)**.

Occasionally, you may find yourself caring for a patient who is wearing an eye prosthesis (an artificial eye). Many people are surprised to find that it can be difficult to distinguish a prosthesis from a natural eye. You should suspect an eye of being artificial when it does not respond to light, move in concert with the opposite eye, or appear quite the same as the opposite eye. If you think that a patient may have an artificial eye but you are not sure, go ahead and ask about it. Although no harm will be done if you care for an artificial eye as you would a normal one, you need to clearly understand the patient's eye function.

Figure 27-23 The typical "black eye" is caused by bleeding into the tissue around the orbit.

Injuries of the Nose

Nosebleeds (epistaxis) are a common problem that can occur spontaneously or from trauma. One of the most common causes of nosebleeds is digital trauma (picking the nose with a finger). Nosebleeds are further classified into anterior and posterior epistaxis. Anterior nosebleeds usually originate from the area of the septum and bleed fairly slowly. These are usually self-limited and resolve quickly. Posterior nosebleeds are usually more severe and often cause blood to drain into the patient's throat, causing nausea and vomiting. Trauma to the face and skull that results in a basilar skull fracture often will cause the posterior wall of the nasal cavity to become unstable. Attempting to place a nasopharyngeal airway in a patient with a suspected basilar skull fracture or with facial injuries is controversial because many believe that insertion may permit the airway to enter through the unstable wall of the nasal cavity into the cranial vault. However, recent research suggests this risk is extremely small. As always, be aware of and follow your local protocols.

The nose often takes the brunt of deliberate physical assaults and car crashes. Blunt injuries to the nose caused by a fist or a dashboard may be associated with fractures and soft-tissue injuries of the face, head injuries, and/or injuries to the cervical spine. Penetrating injuries to the nose can be seen when air guns and BB pellets are fired from a close range, resulting in pellets lodging in the nasal septum and sinuses. Another type of penetrating injury to the nose is a self-inflicted one that occurs when a person attempts to insert a foreign body into the nose, such as a pencil.

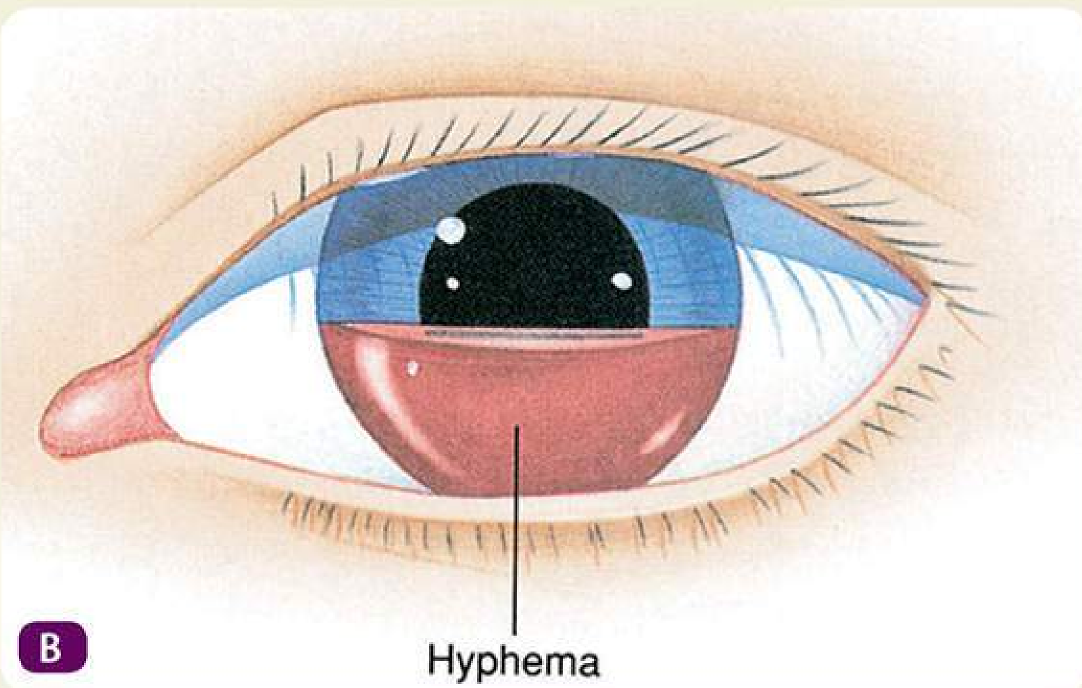

Figure 27-24 **A.** A hyphema, characterized by bleeding into the anterior chamber of the eye, is common following blunt trauma to the eye. This condition may seriously impair vision and should be considered a sight-threatening emergency. **B.** Illustration of hyphema.

Figure 27-25 A patient with a blow-out fracture may not move his or her eyes together because of muscle entrapment. Therefore, the patient sees double images of any object.

Figure 27-26 Variation of pupil size may indicate a head injury.

When you are assessing injuries involving the nose, it helps to picture the inside of the nose itself **Figure 27-28**. The nasal cavity is divided into two sections or chambers by the nasal septum, which is made of cartilage. Within each nasal chamber, there are layers of bone called the **turbinates**, which are covered with a moist lining. Both chambers have a superior turbinate, a middle turbinate, and an inferior turbinate. As a person breathes, air moves through the nasal chambers and is humidified as it passes over the turbinates. Directly above the nose are the frontal sinuses and, on either side, the orbit of the eye.

All of these structures should be assessed for injury. In patients with severe injury, there may also be injury to the cervical spine. Keep in mind that cerebrospinal fluid (CSF) may escape down through the nose (or ears) following a fracture at the base of the skull. If blood or drainage contains CSF, a characteristic staining of the dressing will occur. This can be seen by using a piece of gauze to absorb blood that is flowing from the nose or ears. If CSF is present, the blood will be surrounded by a lighter ring of fluid. This is often called the halo test.

You can control bleeding from abrasions and lacerations to the nose by applying a sterile dressing. If the patient is bleeding heavily from the nose, this is most likely caused by significant trauma and you must consider cervical spine injury. The patient should not be moved if the airway can be managed in the patient's present position. For a nontrauma patient who is bleeding from the nose, you should place the patient in a sitting position, leaning forward, and pinch his or her nostrils together **Figure 27-29**. For a detailed discussion of the care for epistaxis, see Chapter 25, *Bleeding*.

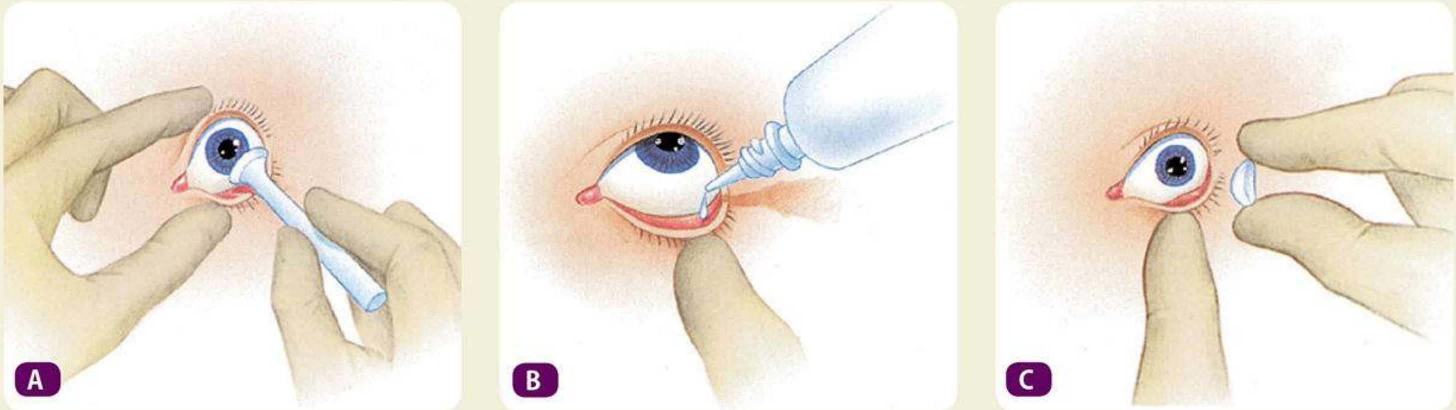

Figure 27-27 Removing contact lenses should be limited to patients with chemical burn injuries to the eye. **A.** To remove hard contact lenses, use a specialized suction cup moistened with sterile saline solution. **B.** To remove soft contact lenses, instill one or two drops of saline or irrigating solution. **C.** Next, pinch off the lens with your gloved thumb and index finger.

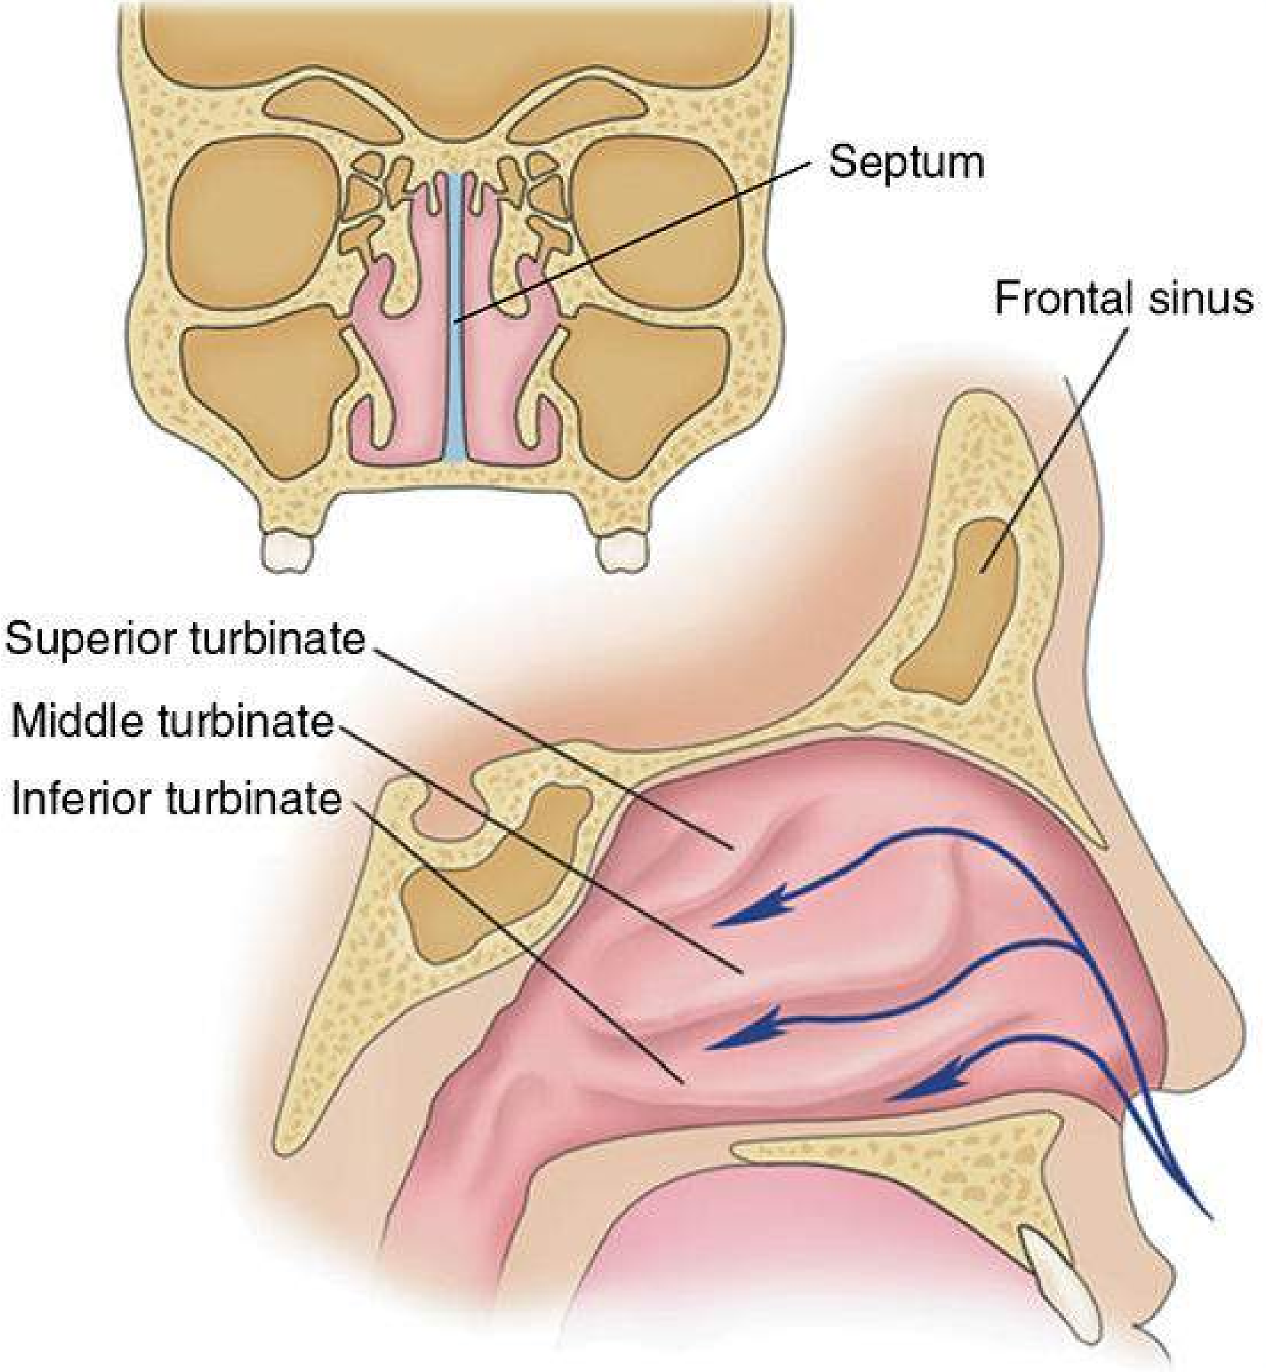

Figure 27-28 The nose has two chambers, divided by the septum. Each chamber is composed of layers of bone called turbinates. Above the nose are the frontal sinuses and, on either side, the orbit of the eye.

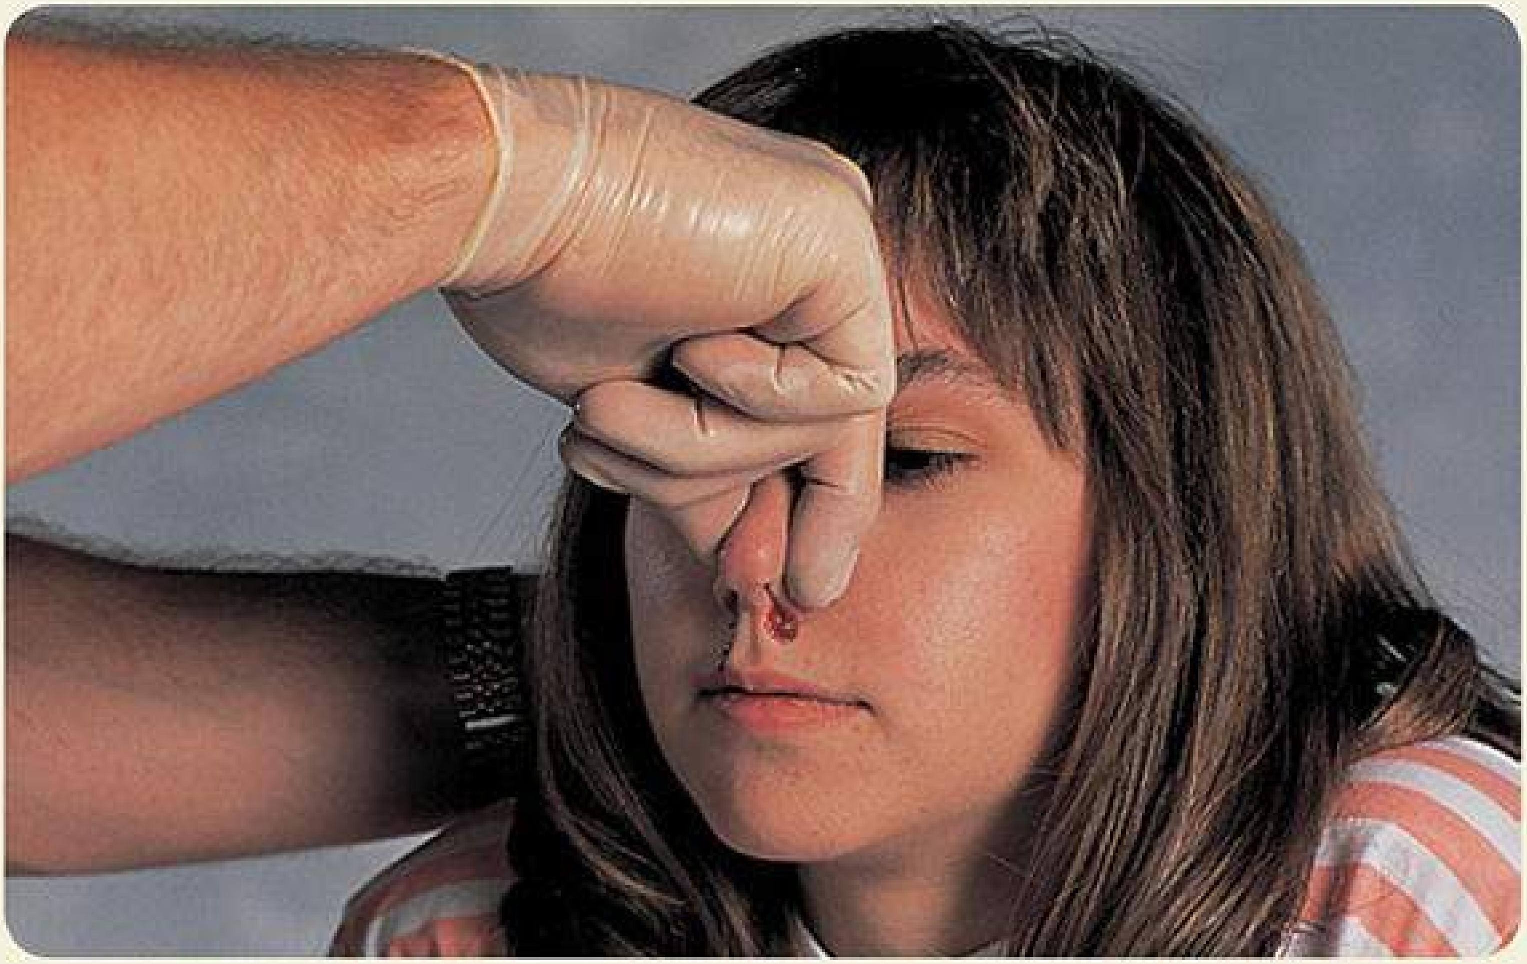

Figure 27-29 Control bleeding from the nose by pinching the nostrils together.

Injuries of the Ear

The ear is a complex organ that is associated with hearing and balance. The ear is divided into three parts **Figure 27-30**. The external ear is composed of the pinna, or auricle, which is the part lying outside of the head, and the **external auditory canal**, which leads in toward the **tympanic membrane**, or eardrum. The middle ear contains three small bones (the hammer, anvil, and stirrup) that move in response to sound waves hitting the tympanic membrane. This is the mechanism by which sounds are heard and differentiated. The middle ear is connected to the nasal cavity by the **eustachian tube**, which is the internal auditory canal. This connection permits equalization of pressure in the middle ear when external atmospheric pressure changes. The inner ear is composed of bony chambers filled with fluid. As the head moves, so does the fluid. In response, fine nerve endings within the fluid send impulses to the brain indicating the position of the head and the rate of change of position.

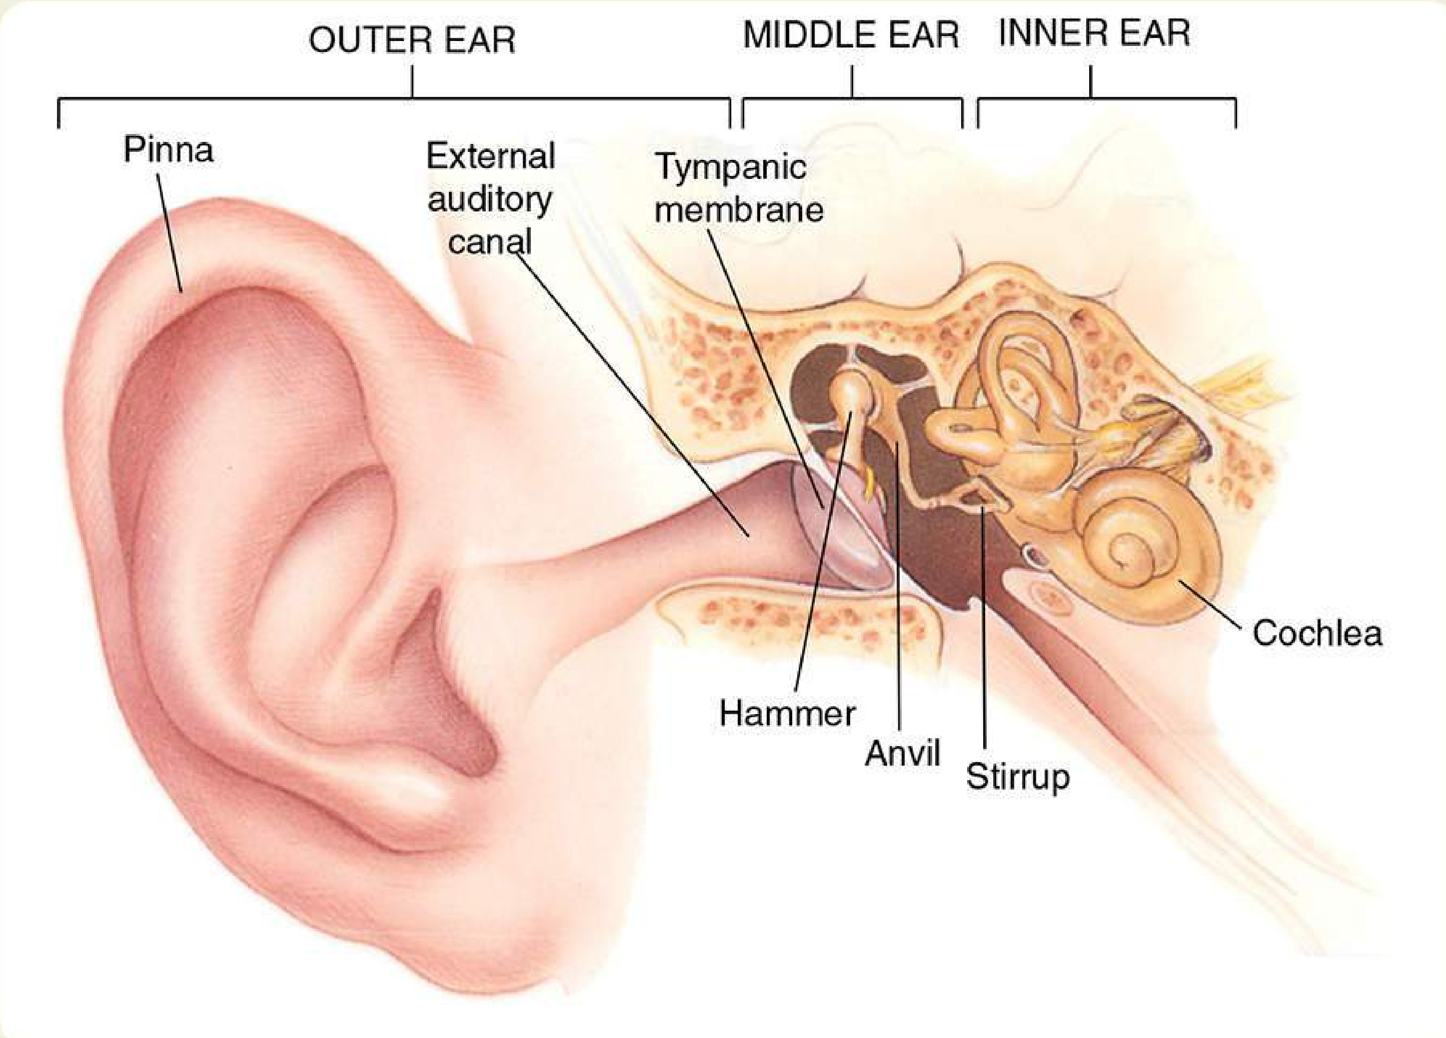

Figure 27-30 The ear has three principal parts: the external, or outer, ear, composed of the pinna, external auditory canal, and tympanic membrane; the middle ear, including the hammer, anvil, and stirrup; and the inner ear, composed of bony chambers filled with fluid.

YOU are the Provider — PART 5

You reassess the patient en route, including his vital signs, and note that his breathing is becoming increasingly labored. His airway remains clear of secretions and blood, but his neck appears to be more swollen than it was during previous assessments.

Recording Time: 16 Minutes	
Level of consciousness	Conscious and alert; anxious
Respirations	26 breaths/min; labored
Pulse	124 beats/min; strong and regular
Skin	Cool and moist; perioral cyanosis is developing
Blood pressure	122/58 mm Hg

Spo_2	88% (on oxygen)

The hospital staff are notified of the change in the patient's condition. The nurse tells you to bring him straight to the trauma room on your arrival.

8. What is the most likely cause of your patient's labored breathing?

9. What adjustments, if any, should you make to your current treatment?

Ears are often injured, but they usually do not bleed very much. If local pressure does not control the bleeding, you can apply a roller dressing **Figure 27-31**. First, however, you should place a soft, padded dressing between the back of the ear and the scalp because bandaging the ear against the tender underlying scalp can be extremely painful for the patient. In the case of an ear avulsion, you should wrap the avulsed part in a moist, sterile dressing and put it in a plastic bag labeled with the patient's name. Keep the avulsed part cool and transport to the hospital with the patient. Often, avulsed tissue from the ear can be reattached.

Figure 27-31 **A.** A major laceration of the ear. **B.** Proper treatment includes use of a soft, sterile pad behind the ear, between it and the scalp. Then wrap a roller gauze dressing around the head to include the entire ear.

Sudden changes in pressure created by a blast wave may rupture one or both tympanic membranes. Patients with a ruptured tympanic membrane will often report severe ear pain, difficulty hearing, or ringing in the affected ear. The tympanic membrane may also be perforated by insertion of objects (like a cotton swab) too far into the ear. Any patient with a suspected tympanic membrane injury should be transported to the hospital for a more detailed evaluation.

The external auditory canal is a favorite place for children to place foreign bodies such as peanuts or candy. All such items should be removed by a physician in the emergency department. Never try to manipulate the foreign body because you may press it further into the auditory canal and cause permanent damage to the tympanic membrane.

Again, note any clear fluid coming from the ear of a severely injured patient because this may indicate a fracture at the base of the skull.

Facial Fractures

Fractures of the facial bones typically result from blunt impact. For example, the patient's head collides with a steering wheel or windshield in an automobile crash or is hit by a baseball bat or pipe in an assault. You should assume that any patient who has sustained a direct blow to the mouth or nose has a facial fracture. Other clues to the possibility of fracture include bleeding in the mouth, inability to swallow or talk, absent or loose teeth, and/or loose or movable bone fragments. Patients may also report that "it doesn't feel right" when they close their jaw, signaling an irregularity of bite.

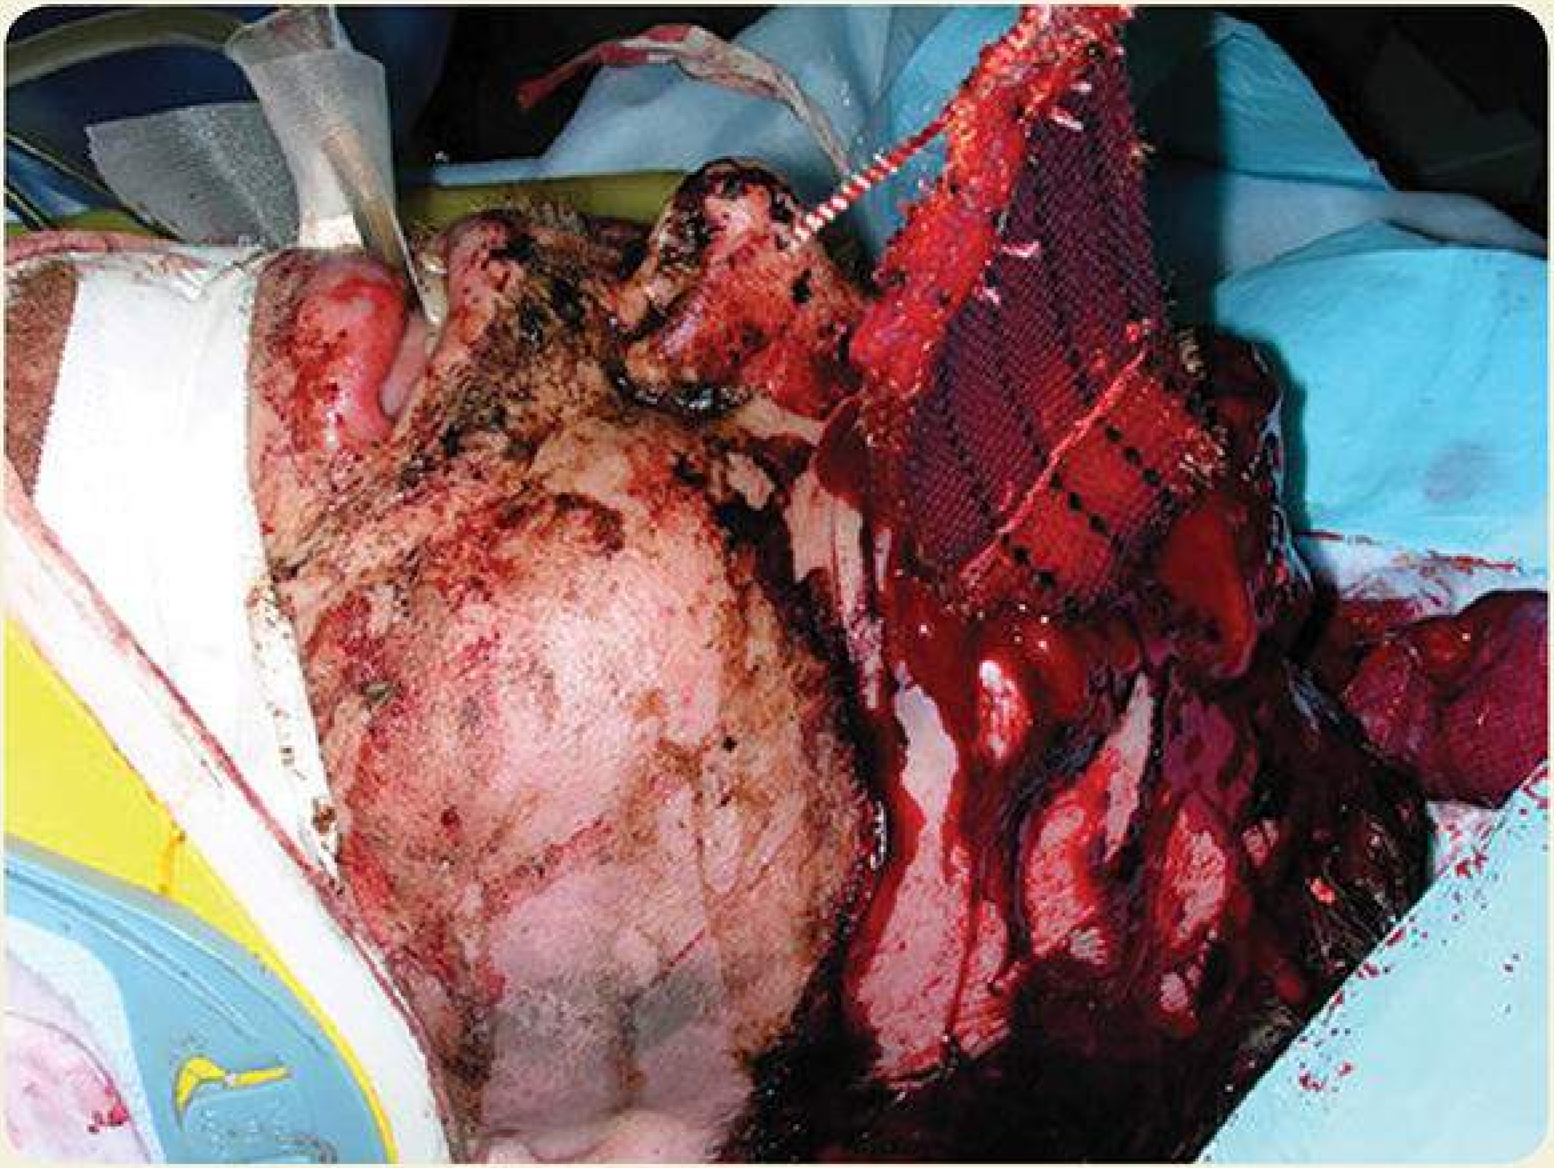

Figure 27-32 Bleeding following a crushing injury to the face can be life threatening because, in addition to the external hemorrhage, blood clots in the airway can cause a complete obstruction.

© Chuck Stewart, MD.

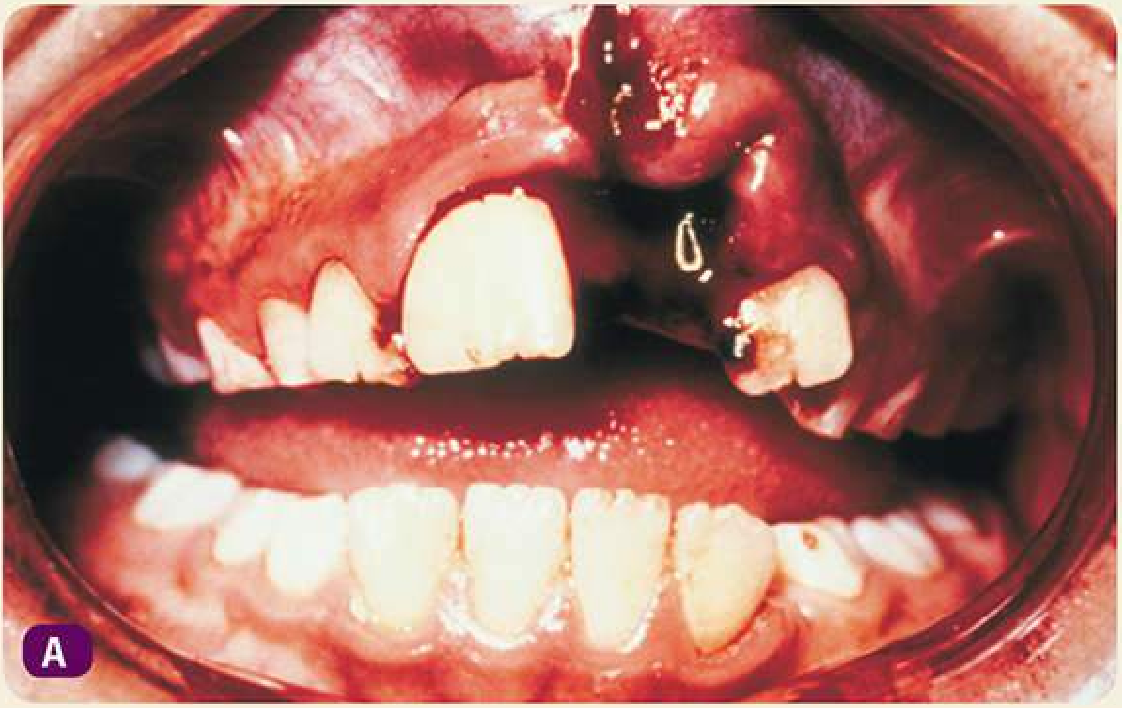
Facial fractures alone are not acute emergencies unless there is serious bleeding; however, they are an indication of significant blunt force trauma applied to that region of the body. Serious bleeding from a facial fracture can be life threatening. In addition to external hemorrhage, there is the danger of blood clots lodging in the upper airway and causing an obstruction Figure 27-32. Fractures around the face and mouth can also produce deformity and loose bone fragments. However, plastic surgeons can repair the damage if the injuries are treated within 7 to 10 days of the injury. Be sure to remove and save loose teeth or bone fragments from the mouth; it is often possible to reimplant them **Figure 27-33**. Remove any loose dentures or dental bridges to protect against airway obstruction. The removal of dentures will affect the shape of the patient's jaw.

Another source of potential airway obstruction is swelling, which can be extreme within the first 24 hours after injury. If you notice swelling during assessment or at any time while the patient is in your care, check for airway obstruction.

Dental Injuries

Dental injuries can be traumatic to a patient. Not only is the injury itself traumatic, but the patient's permanent teeth may also be lost—affecting everything from eating to smiling. Keep this in mind when providing care.

Bleeding will occur whenever a tooth is violently displaced out of its socket; therefore, apply direct pressure to stop the bleeding. To keep the airway patent, perform suctioning if needed. Also keep in mind that cracked or loose teeth are possible airway obstructions; therefore, suctioning may be necessary.



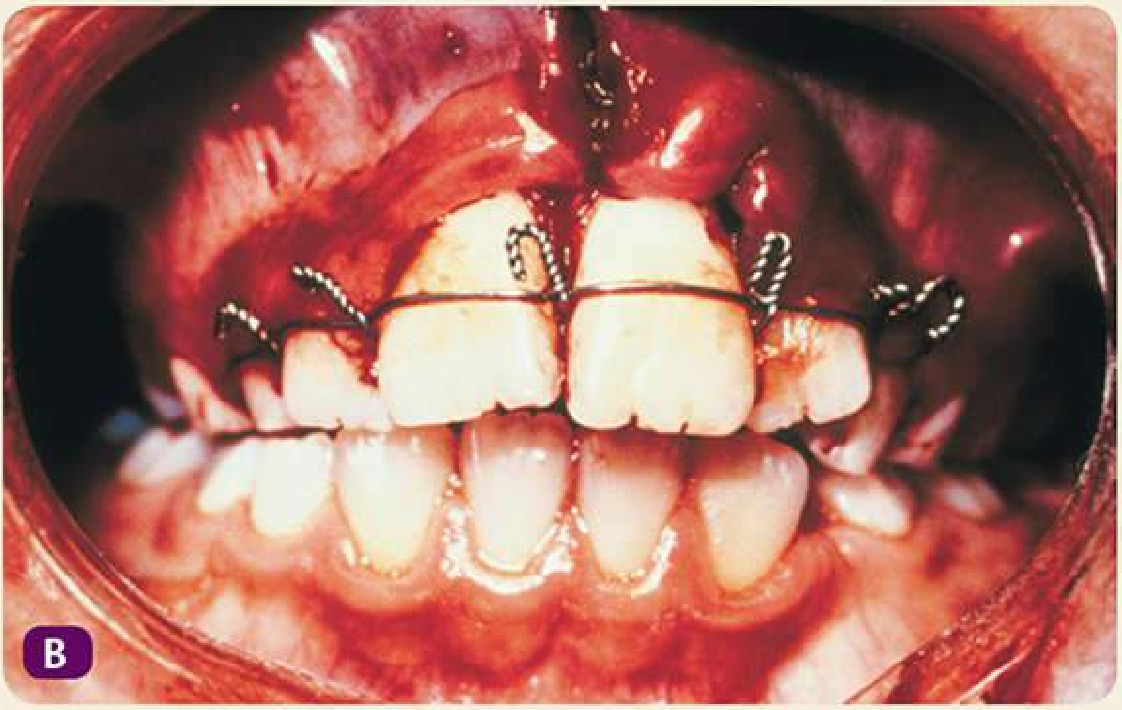


Figure 27-33 **A.** Save any lost teeth or bone fragments following an injury to the mouth. **B.** Even with traumatic loss of a tooth, the possibility of successful reimplantation is very good, especially if the tooth is stored in an appropriate tooth-storage solution, cold milk, or sterile saline.

When dealing with an avulsed tooth, handle it by its crown and not by the root. When transporting the patient, bring along the tooth, placing it in a special tooth storage solution if available in your supplies, or in cold milk or sterile saline. There are also commercially available kits that may be used by your agency. Be familiar with how the kit is used before you encounter a patient with dental trauma. Notify the receiving facility about the avulsed tooth because reimplantation is recommended within 20 minutes to 1 hour after the trauma.

Injuries of the Cheek

You may encounter an object that is impaled in the patient's cheek. If you are unable to control the bleeding and it is compromising the patient's airway, consider removing the impaled object if possible and provide direct pressure on the inside and outside of the cheek. The amount of bandaging should not be so overwhelming that it occludes the mouth and makes it difficult for the patient to breathe.

Injuries of the Neck

The neck contains many structures that are vulnerable to injury by blunt trauma, such as from a steering wheel in a car crash, or by penetrating injury, such as a stab or gunshot wound. These structures include the upper airway, the esophagus, the carotid arteries and jugular veins, the thyroid cartilage or Adam's apple, the cricoid cartilage, and the upper part of the trachea. Any injury to the neck is serious and should be considered life threatening until proven otherwise in the emergency department.

Blunt Injuries

Any crushing injury of the upper part of the neck is likely to involve the larynx or trachea. Examples include a collision with a steering wheel, an attempted suicide by hanging, and a clothesline injury sustained while riding a bicycle. Once the cartilages of the upper airway and larynx are fractured, they do not spring back to their normal position. This type of fracture can lead to loss of voice, difficulty swallowing, severe and sometimes fatal airway obstruction, and leakage of air into the soft tissues of the neck **Figure 27-34**. The presence of air in the soft tissues produces a characteristic crackling sensation called **subcutaneous emphysema**. If you feel this sensation when you palpate the neck, you should maintain the airway as best you can and provide immediate transport. Be aware that complete airway obstruction can develop very rapidly in these patients as a result of swelling or bleeding into the underlying tissues. It may be very difficult to manage the airway in patients with these injuries; therefore, ALS support either by air or during an intercept may be necessary. Some patients will require a surgical airway at the hospital. An incident involving an injury to the throat may also have caused a cervical spinal injury; therefore, spinal immobilization may be needed.

Penetrating Injuries

Penetrating injuries to the neck can cause profuse bleeding from laceration of the great vessels in the neck—the carotid arteries or the jugular veins **Figure 27-35**. Injuries to the carotid and jugular vessels in the neck can cause the body to bleed out, also known as exsanguination. Injuries to these large vessels may also allow air to enter the circulatory system. If a vein has been punctured, air may be sucked through it to the heart, a clinical situation called an **air embolism**. A large amount of air in the right atrium and right ventricle of the heart can lead to cardiac arrest. The airway, the esophagus, and even the spinal cord can be damaged by a penetrating injury.

Figure 27-34 Fractures of the larynx or trachea can cause air to leak from the airway into the subcutaneous tissues. The presence of air in the soft tissues produces a crackling sensation called subcutaneous emphysema.

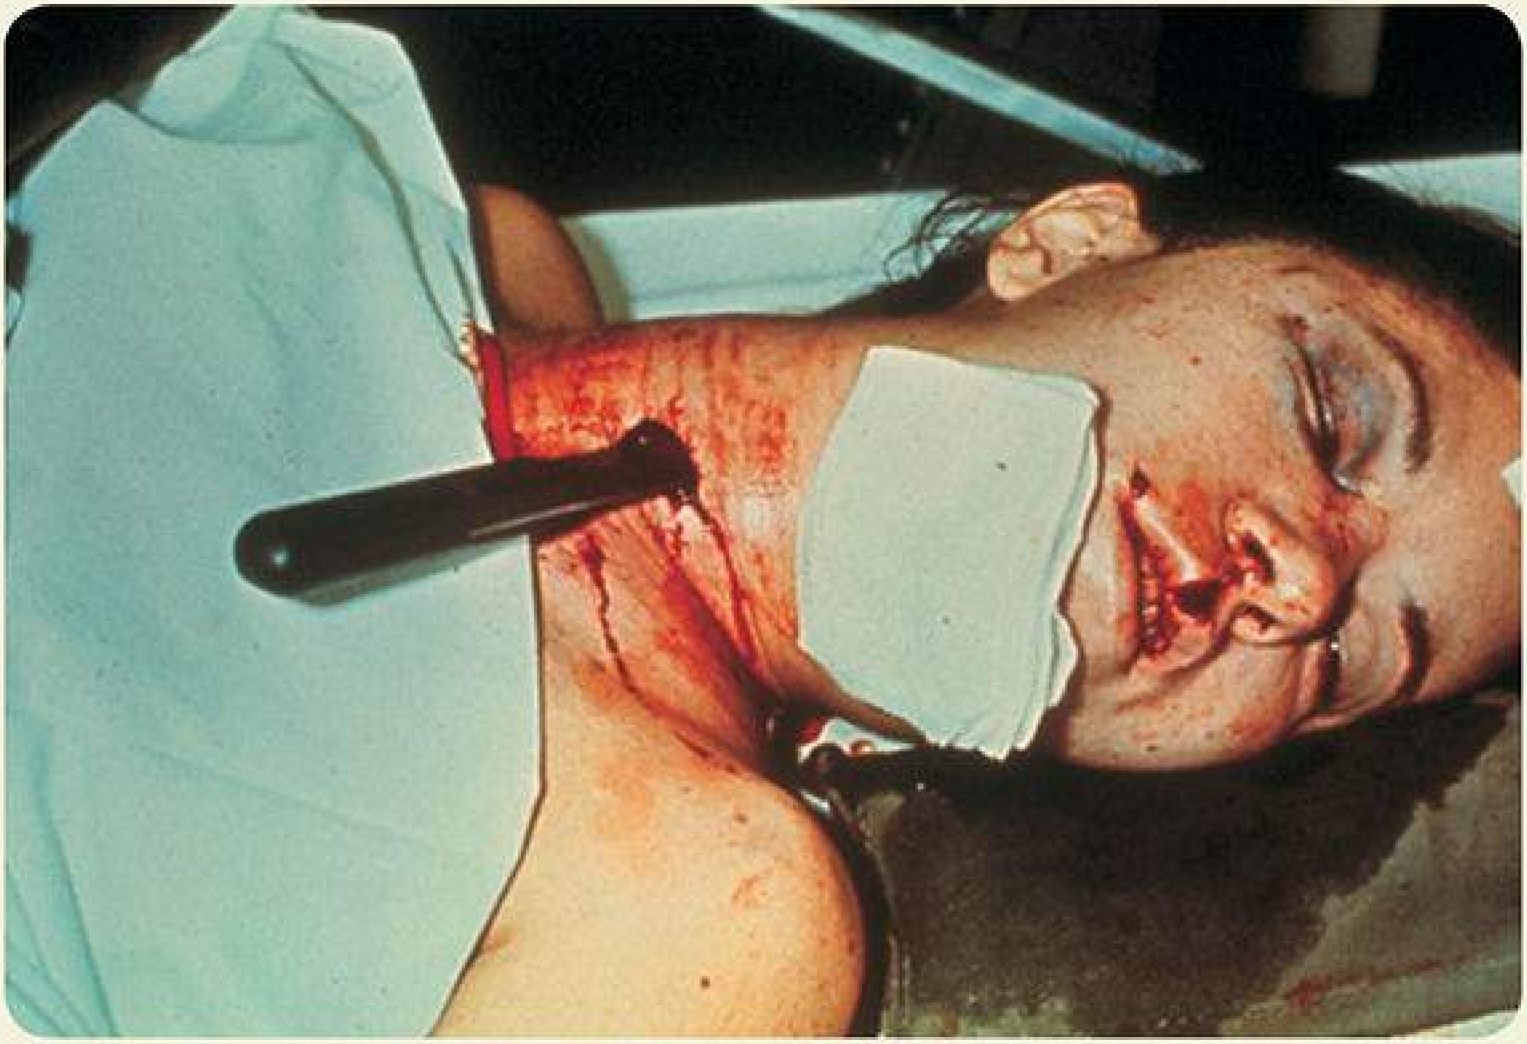

Figure 27-35 Penetrating injuries to the neck can result in profuse bleeding if a carotid artery or jugular vein is damaged.

Direct pressure over the bleeding site will control most neck bleeding. Follow the steps in Skill Drill 27-3:

1. Apply direct pressure to the bleeding site using a gloved fingertip if necessary to control bleeding Step 1.
2. Apply a sterile occlusive dressing to ensure that air does not enter a vein or artery Step 2.
3. Secure the dressing in place with roller gauze, adding more dressings if needed.
4. Wrap the gauze around and under the patient's shoulder. To avoid possible airway and circulation problems, do not wrap the gauze around the neck.

Despite the use of these measures, the tissues within the neck may still continue to bleed and compress the upper airway, so you should look for signs of airway obstruction.

You might find it necessary to apply pressure both above and below the penetrating wound to control life-threatening bleeding from the carotid artery (above) and the jugular vein (below). You may also need to treat the patient for shock.

If indicated, maintain cervical spine immobilization, and with the patient fully immobilized to a backboard, provide prompt transport. Ensure that the airway remains open en route, and apply high-flow oxygen.

Laryngeal Injuries

Blunt force trauma to the larynx can occur when an unrestrained driver strikes the steering wheel or when a snowmobile rider or off-road biker strikes a clothesline or a fixed wire strung across a property line. The larynx becomes crushed against the cervical spine, resulting in soft-tissue injury, fractures, and/or separation of the fascia that connects the thyroid and cricoid cartilages. These strangulation injuries can also be found in either intentional or unintentional hangings. Any time there is suspected injury to the larynx, you should suspect possible cervical spine injury.

Open injuries to the larynx can occur as a result of a stabbing or penetration by a similar object. Penetrating and impaled objects should not be removed unless they interfere with cardiopulmonary resuscitation. Stabilize all impaled objects if they are not obstructing the airway (see Chapter 26, *Soft-Tissue Injuries*).

Skill Drill 27-3 Controlling Bleeding From a Neck Injury

Step 1

Apply direct pressure to the bleeding site using a gloved fingertip if necessary to control bleeding.

Step 2

Apply a sterile occlusive dressing to ensure that air does not enter a vein or artery.

Significant injuries to the larynx pose an immediate risk of airway compromise because of disruption of the normal passage of air, soft-tissue swelling, or aspiration of blood. The signs and symptoms of larynx injuries include respiratory distress, hoarseness, pain, difficulty swallowing (dysphagia), cyanosis, pale skin, sputum in the wound, subcutaneous emphysema, bruising on the neck, hematoma, or bleeding.

To manage a laryngeal injury, provide oxygenation and ventilation. Apply a cervical collar, but avoid the use of rigid collars because they may cause further damage to the soft tissues.

YOU are the Provider — SUMMARY

1. What should be your most immediate concern after receiving this initial patient information?

The presence of severe facial trauma should immediately increase your index of suspicion for potential airway and ventilation compromise, including partial or complete upper airway obstruction. Direct trauma to the nose and mouth can be a source of significant bleeding. Severe swelling and bleeding can occur in the oropharynx. Crushing injuries to the larynx and trachea are associated with a high incidence of airway and ventilation compromise. The risk of upper airway obstruction is significantly higher if the patient has a decreased level of consciousness and is unable to expel blood from the mouth on his or her own. Also, if the patient swallows large amounts of blood, the risks of vomiting and subsequent aspiration are high.

Dislodged teeth can fall to the back of the throat and be aspirated into the lungs or complicate obstruction of the upper airway. Crushing injuries to the throat should increase your index of suspicion for a spinal injury. In addition, when trauma is severe enough to fracture facial bones, the possibility of an underlying closed head injury should be considered as well.

2. What should your initial actions consist of when you arrive at the scene?

First, conduct a scene size-up. Although law enforcement personnel have advised you that the scene is secure, you must still remain aware of your surroundings at all times. Your patient has been assaulted, which means that the perpetrator, if he or she is not in custody, could return to the scene. Ascertain the total number of patients and call for additional resources if you think you will need them.

As you are approaching the patient, form a general impression.

As you make physical contact with the patient, introduce yourself and manually stabilize his head. Next, assess the status of the patient's airway. If he can talk to you, he has no *immediate* airway problems, although this can quickly change. If there is any blood in his oropharynx, remove it with suction. If he is conscious and alert, consider allowing him to suction his own mouth. Follow standard precautions, including protective facial wear.

After ensuring a patent airway, assess the quality of the patient's breathing and intervene at once. If he is breathing adequately, administer high-flow oxygen via a nonrebreathing mask. If he has signs of inadequate breathing (eg, fast or slow rate, shallow breathing [reduced tidal volume]), assist his ventilations.

Complete your primary assessment by assessing the rate and quality of his radial and carotid pulses and looking for and immediately controlling any severe external bleeding. If signs of shock are present, begin immediate shock treatment.

3. Does this patient have a patent airway? How can you tell?

Since the patient is conscious, alert, and talking, he has a patent airway—at least, for the time being. Although he has blood in his mouth, he is able to keep his own airway clear by spitting it out. The patient's voice is hoarse; this should concern you because it could indicate upper airway swelling or a crushing injury to the structures of the anterior neck (ie, trachea, larynx).

At this point in the primary assessment, you have not yet determined if he has any injuries that could affect his level of consciousness, such as a closed head injury. Therefore, you must pay meticulous attention to his mental status and be prepared to suction the blood from his mouth. If he has a loss of consciousness, he will not be able to maintain his airway and you need to be prepared to intervene immediately. *Regardless of the situation, a patient's airway must remain patent at all times!*

4. What should be your initial treatment priorities for this patient?

The goal of the primary assessment is to *find and quickly treat* problems associated with the ABCs. Further assessment and treatment must focus on injuries or conditions that will kill your patient *first*.

Your patient has severe facial trauma and his voice is hoarse. Although he is able to maintain his own airway right now, do not assume that he will be able to continue to do this until you get him to a hospital. Closely monitor his airway and ventilation status!

Your partner is providing manual stabilization of the patient's head based on the assumption that trauma significant enough to cause massive facial trauma can just as easily fracture or dislocate a spinal vertebra.

Apply high-flow oxygen via a nonrebreathing mask, but closely monitor his airway for continued oral bleeding. It may be necessary to occasionally remove the oxygen mask, allow him to expel any blood from his mouth, and then reapply the mask. If he remains conscious and can easily follow commands, you can allow him to hold the rigid suction catheter and suction the blood from his mouth himself.

Carefully monitor the patient's level of consciousness and breathing adequacy, keep his airway clear of blood, and be prepared to assist his ventilations.

5. On the basis of the mechanism of injury, what type of injuries should you suspect and assess for?

On the basis of your assessment, the patient's injuries appear to be isolated to his face and anterior part of the neck. However, a more in-depth assessment by a physician is needed to rule out occult injuries. Facial swelling, which is common following blunt force facial trauma, can make assessment difficult.

On the basis of the mechanism of injury, you should be suspicious for facial bone fractures and injury to his trachea and/or larynx. Indicators of facial fractures include oropharyngeal bleeding, loose or absent teeth, difficulty talking or swallowing, and loose or obviously movable bone fragments. Your patient's report that it "doesn't feel right" when he tries to close his mouth signals an irregular bite (dental malocclusion) and is a sign of a mandibular fracture. This is a significant finding because it takes a lot of force to fracture the mandible!

Any crushing injury to the anterior part of the neck is likely to involve the larynx or trachea. During your assessment, you detected bruising and swelling of the throat, and the patient's voice is hoarse. These are red flag indicators of significant anterior neck trauma. Suspect fracture of the trachea if you detect subcutaneous emphysema, a crackling sensation that is felt when palpating the soft tissues of the neck.

Fractures of the zygomas (cheek bones) often present with a flattened appearance of the cheek bones; however, if the face is severely swollen, this may not be grossly apparent.

When caring for a patient with blunt facial trauma, assess the ability of the patient to move his or her eyes in all directions. Inability of the patient to look up (paralysis of upward gaze) suggests an orbital (blowout) fracture, in which case a bone fragment has entrapped one of the oculomotor nerves.

A closed head injury cannot be ruled out. During your assessment, you should look in and behind the ears. Bruising over the mastoid bone (Battle sign) indicates a basilar skull fracture. Blood that is draining from the ears may contain cerebrospinal fluid. This is also an indicator of a basilar skull fracture. Blood or fluid drainage from the nose is also a sign of an underlying skull fracture.

Sudden hyperextension of the head during trauma can cause fractures or dislocations of the vertebrae of the cervical spine. Provide full spinal immobilization when caring for a patient with significant blunt facial trauma.

6. What should you do if this patient begins to vomit?

If aspiration occurs, the risk of mortality increases significantly so you *must* have a plan of action to prevent aspiration while transporting a patient who is supine and immobilized on a backboard.

If the patient begins to vomit, *immediately* place him on his side to allow vomitus to drain from his mouth. It is imperative that you protect the patient's airway, but as you turn the entire backboard onto its side, you must also avoid aggravating any possible spinal injury by ensuring that the patient is properly immobilized.

While the patient is on his side, suction his mouth to remove any remaining vomitus that did not drain with gravity. Before returning the patient to a supine position, make sure that *all* vomitus and other secretions are removed from his mouth!

7. How should you treat a patient with active oral bleeding and inadequate ventilation?

Not only is the patient's airway in immediate jeopardy from obstruction from blood clots and aspiration, but inadequate ventilation will result in hypoxia and may lead to respiratory or cardiopulmonary arrest. Therefore, you must treat both problems simultaneously.

If blood has pooled in the patient's mouth, immediately place the patient onto his or her side to allow the blood to drain from the mouth. Suction the airway for up to 15 seconds. Then assist the patient's ventilations for 2 minutes.

Continue this alternating pattern of suctioning for 15 seconds and assisting ventilations for 2 minutes as needed, until the bleeding in the oropharynx is minimal or stops altogether. Regardless of the situation, the patient's airway must remain patent at all times and adequate ventilation must be ensured.

Patients with this type of airway and ventilation predicament would benefit from advanced airway management, especially if they are unconscious. Paramedics can intubate the patient, thus isolating the trachea and preventing aspiration, while manually ventilating the patient with a BVM attached to the endotracheal tube. Request an ALS ambulance, if possible, when caring for patients with this type of complex airway and breathing problem.

8. What is the most likely cause of your patient's labored breathing?

Reassessment reveals that his airway remains clear of blood. However, the anterior part of his neck is more swollen so you should suspect that his upper airway is swelling—most likely because of injury to his trachea or larynx, thus making it increasingly difficult for him to breathe. His oxygen saturation of 88%, even with high-flow oxygen, reflects significant hypoxemia, and perioral cyanosis (cyanosis around the mouth) is developing.

It is important to note that not all patients with significant injuries deteriorate at the scene. Many of them deteriorate en route to the hospital or shortly after you arrive at the hospital. Therefore, it is critical to *frequently reassess* any patient with injuries that could jeopardize airway patency and impair ventilation.

9. What adjustments, if any, should you make to your current treatment?

Your patient's ventilation status has clearly deteriorated. You should consider assisting his ventilations with a BVM and high-flow oxygen. Try to assist the patient's breathing, but do not be too aggressive. If he becomes combative and pushes the BVM away from his face, reapply the nonrebreathing mask and carefully monitor his breathing.

If he tolerates assisted ventilation, use extreme caution. Although you must maintain adequate minute volume, a tracheal or laryngeal injury can be exacerbated by aggressive positive-pressure ventilation. Squeeze the BVM just enough to improve the amount of tidal volume with each breath; observe for visible chest rise.

You should *not* use any type of mechanical ventilation device, such as a flow-restricted, oxygen-powered ventilation device, when ventilating a patient with tracheal or laryngeal trauma. These devices deliver oxygen under high pressure and can cause further injury to patients with fractures of the trachea or larynx.

Narrative

Ambulance 12 dispatched to the scene of an assault. The scene was secured by law enforcement prior to EMS arrival. On arrival at the scene, found the patient, a 30-year-old male, sitting on the ground; his face was covered with blood and his face was swollen. He was conscious but appeared anxious. He was spitting out small amounts of blood from his mouth, but was maintaining his own airway; his breathing was adequate. Manual c-spine stabilization was applied as patient was assessed further. He stated that he was struck across the face with a steel pipe, fell to the ground, and was kicked in the face and throat. He denies loss of consciousness. Applied high-flow oxygen via nonrebreathing mask and suctioned the patient's mouth as needed to remove blood. Secondary assessment revealed severe swelling of the entire face, and bruising and mild swelling of the anterior part of the neck. Patient states that it "doesn't feel right" when he tries to close his mouth. No gross evidence of head or c-spine injury was noted during secondary assessment. Recovered pt's teeth and placed them in a commercial tooth-saver container. Applied full spinal immobilization, placed patient onto stretcher, loaded him into the ambulance, and began transport to the hospital. Reassessment en route revealed that his airway was free of blood or other secretions and his vital signs were stable. After radio report was called to receiving facility, patient became more anxious and nauseated and began experiencing respiratory distress. Immediate reassessment revealed that his airway remained free of blood or other secretions, but the anterior part of his neck appeared more swollen than in previous assessments. Further reassessment revealed that he was developing perioral cyanosis, and his oxygen saturation decreased significantly. Began assisting the patient's ventilations with a BVM and high-flow oxygen; he was initially resistant, but became more compliant with coaching. Notified hospital of patient status change. Continued to assist patient's ventilations and monitor his airway status for the duration of the transport. Noted improvement in patient's oxygen saturation and skin condition with assisted ventilation. Delivered patient to the emergency department staff and gave verbal report to the attending physician. Ambulance 12 cleared the hospital and returned to service at 2021 hrs.**End of report**

Prep Kit

Ready for Review

- Soft-tissue injuries and fractures of the bones of the face and neck are common and vary in severity.
- In face and neck injuries, your priorities are to prevent further injury to the cervical spine, manage the airway and ventilation of the patient, and control bleeding.
- Airway compromise may be caused by heavy bleeding into the airway, swelling in and around the structures of the airway located in the face and neck, and injuries to the central nervous system that interfere with normal respiration.
- To control heavy bleeding from soft-tissue injuries to the face, use direct pressure with a dry, sterile dressing. If brain tissue is exposed, use a moist, sterile dressing.
- Always check for bleeding inside the mouth because this may produce airway obstruction.
- Open the airway using the jaw-thrust maneuver (when indicated), and clear the airway in all patients with facial injuries.
- Save avulsed pieces of skin and tissue, and transport them with the patient for possible reattachment at the hospital.
- Maintain a high index of suspicion for patients with unequal pupils—this sign may indicate an illness or an injury to the brain. Remember, some people are born with one pupil larger than the other. During your assessment, ask your patient whether he or she normally has unequal pupils.
- Foreign bodies on the surface of the eye should be irrigated gently with normal saline solution. Always flush from the region of the eye closest to the nose toward the outside, away from the midline.
- If a foreign body is on the underside of the eyelid, remove it gently with a cotton-tipped applicator. Never remove foreign bodies stuck to the cornea.
- Chemicals, heat, and light rays can all cause burn injury to the eyes, resulting in permanent damage.
- Be alert to clear fluid draining from the ears or nose. This may indicate a basilar skull fracture.
- Blunt and penetrating trauma to the neck can produce life-threatening injuries. Palpate the neck for signs of subcutaneous emphysema. In patients with this sign, complete airway obstruction may develop in minutes.
- If bleeding is present from a penetrating injury, direct pressure over the site will usually control most forms of bleeding.
- Be alert to the possibility of an air embolism from an open neck injury. Place an occlusive dressing over the site, and provide direct pressure.

Vital Vocabulary

air embolism The presence of air in the veins, which can lead to cardiac arrest if it enters the heart.

anisocoria Naturally occurring uneven pupil size.

blow-out fracture A fracture of the orbit or of the bones that support the floor of the orbit.

conjunctiva The delicate membrane that lines the eyelids and covers the exposed surface of the eye.

conjunctivitis Inflammation of the conjunctiva.

cornea The transparent tissue layer in front of the pupil and iris of the eye.

eustachian tube A branch of the internal auditory canal that connects the middle ear to the oropharynx.

external auditory canal The ear canal; leads to the tympanic membrane.

globe The eyeball.

iris The muscle and surrounding tissue behind the cornea that dilate and constrict the pupil, regulating the amount of light that enters the eye; pigment in this tissue gives the eye its color.

lacrimal glands The glands that produce fluids to keep the eye moist; also called tear glands.

lens The transparent part of the eye through which images are focused on the retina.

mastoid process The prominent bony mass at the base of the skull about 1 inch posterior to the external opening of the ear.

optic nerve A cranial nerve that transmits visual information to the brain.

pinna The external, visible part of the ear.

pupil The circular opening in the middle of the iris that admits light to the back of the eye.

retina The light-sensitive area of the eye where images are projected; a layer of cells at the back of the eye that changes the light image into electric impulses, which are carried by the optic nerve to the brain.

retinal detachment Separation of the retina from its attachments at the back of the eye.

sclera The tough, fibrous, white portion of the eye that protects the more delicate inner structures.

sternocleidomastoid muscles The muscles on either side of the neck that allow movement of the head.

subcutaneous emphysema A characteristic crackling sensation felt on palpation of the skin, caused by the presence of air in soft tissues.

temporomandibular joint The joint formed where the mandible and cranium meet, just in front of the ear.

tragus The small, rounded, fleshy bulge that lies immediately anterior to the ear canal.

turbinates Layers of bone within the nasal cavity.

tympanic membrane The eardrum, which lies between the external and middle ear.

Assessment *in Action*

You are dispatched to a motor vehicle crash on a rural road where a single vehicle is up on an embankment. The vehicle has front-end damage and a starred windshield. The unrestrained driver is lying supine in the road; the police report that they found the patient outside of the vehicle. He is unconscious and has obvious facial bleeding. Examination reveals a hematoma and depression of the left temporal area, both eyes are black and blue, and one pupil is dilated, whereas the other is normal. The patient has blood coming from the nose and mouth, and palpation reveals subcutaneous emphysema around the clavicles and chest area. The patient's breathing is labored, and the pulse is rapid and thready.

1. What is the priority for this patient?

   A. Perform spinal immobilization.
   B. Assess the vital signs.
   C. Provide rapid transport.
   D. Assess the airway, breathing, and circulation.

2. How should you manage this patient's airway?

   A. Give oxygen via a nasal cannula at 4 L/ min.
   B. Give oxygen via a nonrebreathing mask at 15 L/min.
   C. Suction the airway and assist with ventilations with a BVM.
   D. Suction the airway and give 100% oxygen via a nonrebreathing mask.

3. The unequal pupils most likely indicate what type of injury?

   A. Brain
   B. Skull
   C. Chest
   D. Spinal

4. What type of airway adjunct should be used to maintain a patent airway in this patient?

   A. Nasopharyngeal airway
   B. Gastric airway
   C. Oropharyngeal airway
   D. Endotracheal airway

5. When subcutaneous emphysema is found, what substance has accumulated under the skin?

   A. Blood
   B. Air
   C. Both blood and air
   D. Cerebrospinal fluid

6. Which of the following best describes hyphema?

   A. Bleeding in the interior chamber of the brain
   B. Bleeding in the oropharynx
   C. Bleeding in the posterior thorax
   D. Bleeding in the anterior chamber of the eye

7. Which of the following fractures is associated with bruising around the ears and blood coming from the nose?

   A. Basilar skull fracture
   B. Orbit fracture
   C. Mandibular fracture
   D. Maxilla fracture

8. A hematoma is:

   A. a form of cancer affecting red blood cells.
   B. an entrapment of air and blood in the airway.
   C. a collection of blood within the tissues.
   D. a rupture of the eye.

9. Why does this patient need rapid transport?

10. In patients with head injuries, cerebrospinal fluid (CSF) may escape from the skull. What test can you use to determine

if there is leakage of CSF?

National EMS Education Competencies

Trauma

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

Head, Facial, Neck, and Spine Trauma

Recognition and management of

› Life threats (pp 993–995)
› Spine trauma (pp 991–1001, 1003–1018)

Pathophysiology, assessment, and management of

› Penetrating neck trauma (Chapter 27, *Face and Neck Injuries*)
› Laryngotracheal injuries (Chapter 27, *Face and Neck Injuries*)
› Spine trauma (pp 991–1001, 1003–1018)
› Facial fractures (Chapter 27, *Face and Neck Injuries*)
› Skull fractures (pp 986–988, 992–1002)
› Foreign bodies in the eyes (Chapter 27, *Face and Neck Injuries*)
› Dental trauma (Chapter 27, *Face and Neck Injuries*)

Nervous System Trauma

Pathophysiology, assessment, and management of

› Traumatic brain injury (pp 988–989, 992–1002)
› Spinal cord injury (pp 991–1001, 1003–1018)

Knowledge Objectives

1. Describe the anatomy and physiology of the nervous system, including its divisions into the central nervous system (CNS) and peripheral nervous system (PNS) and the structures and functions of each. (pp 981–984)
2. Explain the functions of the somatic and autonomic nervous systems. (p 984)
3. List the major bones of the skull and spinal column and their related structures; include their functions as they relate to the nervous system. (pp 984–986)
4. Explain the different types of head injuries, their potential mechanism of injury (MOI), and general signs and symptoms of a head injury that EMTs should consider when performing a patient assessment. (pp 986–991)
5. Define traumatic brain injury (TBI). (p 988)
6. Explain the difference between a primary (direct) injury and a secondary (indirect) injury; include examples of possible MOIs that may cause each one. (p 988)
7. Describe the different types of brain injuries and their corresponding signs and symptoms, including increased intracranial pressure (ICP), concussion, contusion, and injuries caused by medical conditions. (pp 988–991)
8. Describe the different types of injuries that may damage the cervical, thoracic, or lumbar spine; include examples of possible MOIs that may cause each one. (p 991)
9. Explain the steps in the patient assessment process for a person who has a suspected head or spine injury; include specific variations that may be required as related to the type of injury. (pp 991–1001)
10. List the mechanisms of injury that cause a high index of suspicion for the possibility of a head or spinal injury. (p 992)
11. Explain emergency medical care of a patient with a head injury; include the three general principles designed to protect and maintain the critical functions of the CNS and ways to determine if the patient has a traumatic brain injury. ((pp 1001–1003)
12. Explain emergency medical care of a patient with a spinal injury; include the implications of not properly caring for patients with injuries of this nature, the steps for performing manual in-line stabilization, implications for sizing and using a cervical spine immobilization device, and key symptoms that contraindicate in-line stabilization. (pp 1003–1007)
13. Explain the process of preparing patients who have suspected head or spinal injuries for transport; include the use and functions of a long backboard, vacuum mattress, short backboard, and other short spinal extrication devices to immobilize the patient’s cervical and thoracic spine. (pp 1007–1018)
14. Explain the different circumstances in which a helmet should be left on or taken off a patient with a possible head or spinal injury. (p 1018)
15. List the steps EMTs must follow to remove a helmet, including the alternate method for removing a football helmet. (pp 1018–1022)
16. Discuss age-related variations that are required when providing emergency care to a pediatric patient who has a suspected head or spine injury. (p 1021)

Skills Objectives

1. Demonstrate how to perform a jaw-thrust maneuver on a patient with a suspected spinal injury. (p 1003)
2. Demonstrate how to perform manual in-line stabilization on a patient with a suspected spinal injury. (pp 1003–1004, Skill Drill 28-1)
3. Demonstrate how to apply a cervical collar to a patient with a suspected spinal injury. (pp 1005–1006, Skill Drill 28-2)
4. Demonstrate how to secure a patient with a suspected spinal injury to a long backboard. (pp 1007–1009, Skill Drill 28-3)
5. Demonstrate how to secure a patient with a suspected spinal injury using a vacuum mattress. (pp 1008, 1010–1013, Skill Drill 28-4
6. Demonstrate how to secure a patient with a suspected spinal injury who was found in a sitting position. (pp 1013–1016, Skill Drill 28-5)
7. Demonstrate how to remove a helmet from a patient with a suspected head or spinal injury. (pp 1019–1020, Skill Dril 28-6)
8. Demonstrate the alternate method for removal of a football helmet from a patient with a suspected head or spinal injury. (pp 1021–1022)

Introduction

The nervous system is a complex network of nerve cells that enables all parts of the body to function. It includes the brain, the spinal cord, and several billion nerve fibers that carry information to and from all parts of the body. Because the nervous system is so vital, it is well protected. The brain lies within the skull, and the spinal cord is inside the bony spinal canal.

Despite this protection, serious injuries can damage the nervous system.

This chapter briefly reviews the anatomy and function of the central and peripheral nervous systems and of the skeletal system. Discussion of specific head, brain, and spinal injuries follows, including signs, symptoms, assessment, and treatment. Extrication of patients with possible spinal injuries and removal of helmets are also described.

Anatomy and Physiology

Nervous System

The nervous system is divided into two anatomic parts: the central nervous system and the peripheral nervous system **Figure 28-1**. The central nervous system (CNS) includes the brain and the spinal cord, including the nuclei and cell bodies of most nerve cells. Long nerve fibers link these cells to the body's various organs through openings in the spinal column. These cables of nerve fibers make up the peripheral nervous system.

Central Nervous System

The CNS is composed of the brain and spinal cord. The brain is the organ that controls the body; it is also the center of consciousness. It is divided into three major areas: the cerebrum, the cerebellum, and the brainstem **Figure 28-2**.

The cerebrum, which contains about 75% of the brain's total volume, controls a wide variety of activities, including most voluntary motor function and conscious thought. It is the main part of the brain and is divided into two hemispheres with four lobes. Underneath the cerebrum lies the cerebellum, which coordinates balance and body movements. The most primitive part of the CNS, the brainstem, controls virtually all the functions that are necessary for life, including the cardiac and respiratory systems and nerve function transmissions. Deep within the cranium, the brainstem is the best-protected part of the CNS.

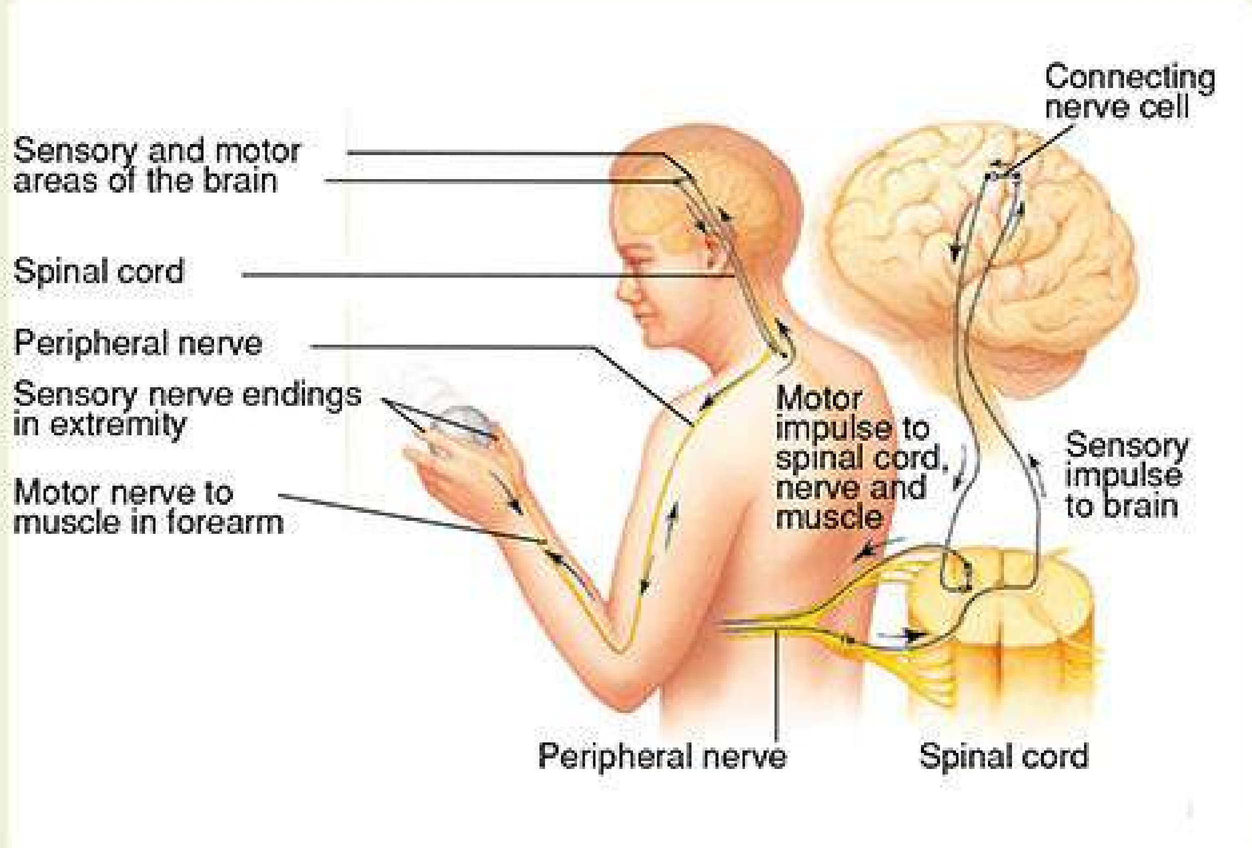

Figure 28-1 The nervous system has two anatomic components: the central nervous system and the peripheral nervous system. The central nervous system is composed of the brain and the spinal cord. The peripheral nervous system conducts sensory and motor impulses from the skin and other organs to the spinal cord.

The spinal cord, the other major portion of the CNS, is mostly made up of fibers that extend from the brain's nerve cells. The spinal cord carries messages between the brain and the body via the gray and white matter of the spinal cord. Gray matter is composed of neural cell bodies and synapses, which are connections between nerve cells. White matter consists of fiber pathways.

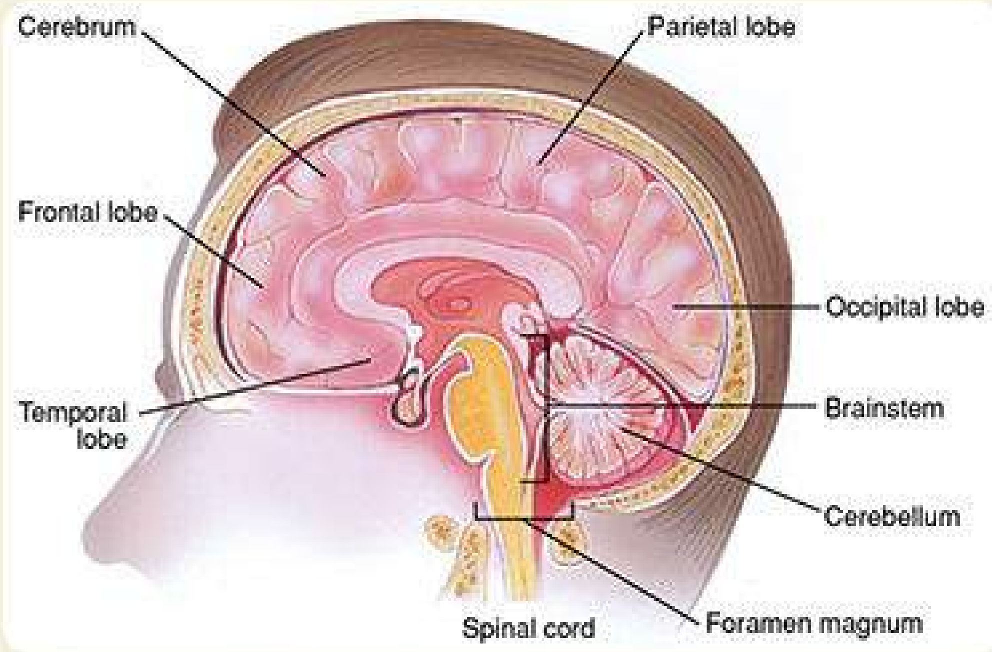

Figure 28-2 The brain is part of the central nervous system and is the organ that controls the body. It is divided into three major areas: the cerebrum, the cerebellum, and the brainstem.

Protective Coverings. The cells of the brain and spinal cord are soft and easily injured. Once damaged, they cannot be regenerated or reproduced. Therefore, the entire CNS is contained within a protective framework.

The thick, bony structures of the skull and spinal canal withstand injury very well. The skull is covered by layers of muscle, superficial fascia, and thick skin, which usually bears hair. Superficial fascia connects the muscle to the skin and contains white blood cells that are used to destroy pathogens when there is an open wound. The spinal canal is also surrounded by a thick layer of skin and muscles.

The CNS is further protected by the **meninges**, three distinct layers of tissue that suspend the brain and the spinal cord within the skull and the spinal canal **Figure 28-3**. The outer layer, the dura mater, is a tough, fibrous layer that closely resembles leather.

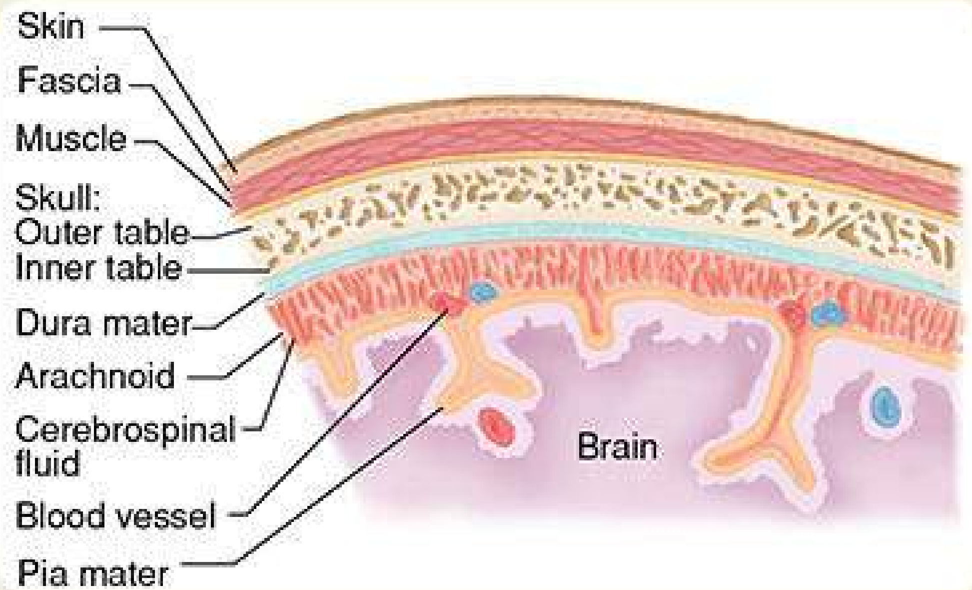

Figure 28-3 The central nervous system has several layers of protective coverings: the skin, muscles and their fascia, bone, and the meninges. The three layers of the meninges are the dura mater, the arachnoid, and the pia mater.

YOU are the Provider — PART 1

At 0220 hours, you receive a call for a man who was allegedly assaulted outside a nightclub. Law enforcement personnel are present and have secured the scene. While you are en route, one of the police officers radios you and informs you the patient was struck in the side of the head with a baseball bat and is unconscious. Your response time to the scene is less than 5 minutes.

1. Why is the structure of the cranium considered to be a mixed blessing in terms of blood flow, oxygen levels, and swelling?
2. What is the difference between a primary and a secondary brain injury?

This layer forms a sac to contain the CNS, with small openings through which the peripheral nerves exit.

The inner two layers of the meninges, called the arachnoid and the pia mater, are much thinner than the dura mater. They contain the blood vessels that nourish the brain and spinal cord. Cerebral spinal fluid (CSF) is produced in a chamber inside the brain, called the third ventricle. CSF is located in the subarachnoid space below the arachnoid, which is a web-like structure. There is approximately 125 to 150 mL of CSF in the brain at any one time. CSF primarily acts as a shock absorber. The brain and spinal cord essentially float in this fluid, buffered from injury. The brain depends on a rich supply of oxygenated blood to function properly. When this supply is interrupted, even for short periods of time, serious damage to the brain tissue may occur.

When an injury does penetrate all of these protective layers, clear, watery CSF may leak from the nose, the ears, or an open skull fracture. Therefore, if a patient with a head injury has what looks like a runny nose or reports a salty taste at the back of the throat, you should assume that the fluid is CSF.

Ironically, the closed bony structure of the skull (which is similar to a vault) and the meninges, the very layers of tissue that isolate and protect the CNS, may lead to serious problems in closed head injuries. Severe injury may cause bleeding within the skull, referred to as intracranial hemorrhage. Such bleeding causes increased pressure inside the skull and compresses softer brain tissue. In many cases, only prompt surgery can prevent permanent brain damage.

Peripheral Nervous System

The peripheral nervous system has two anatomic parts: 31 pairs of spinal nerves and 12 pairs of cranial nerves **Figure 28-4**.

The 31 pairs of spinal nerves conduct sensory impulses from the skin and other organs to the spinal cord. They also conduct motor impulses from the spinal cord to the muscles. Because the arms and legs have so many muscles, the spinal nerves serving the extremities are arranged in complex networks. The brachial plexus controls the arms, and the lumbosacral plexus controls the legs.

Cranial nerves are the 12 pairs of nerves that emerge from the brainstem and transmit information directly to or from the brain. For the most part, they perform special functions in the head and face, including sight, smell, taste, hearing, and facial expressions.

There are two major types of peripheral nerves. The sensory nerves, with endings that perceive only one type of information, carry that information from the body to the brain via the spinal cord. The motor nerves, one for each muscle, carry information from the CNS to the muscles. The connecting nerves, found only in the brain and spinal cord, connect the sensory and motor nerves with short fibers, which allow the cells on either end to exchange simple messages.

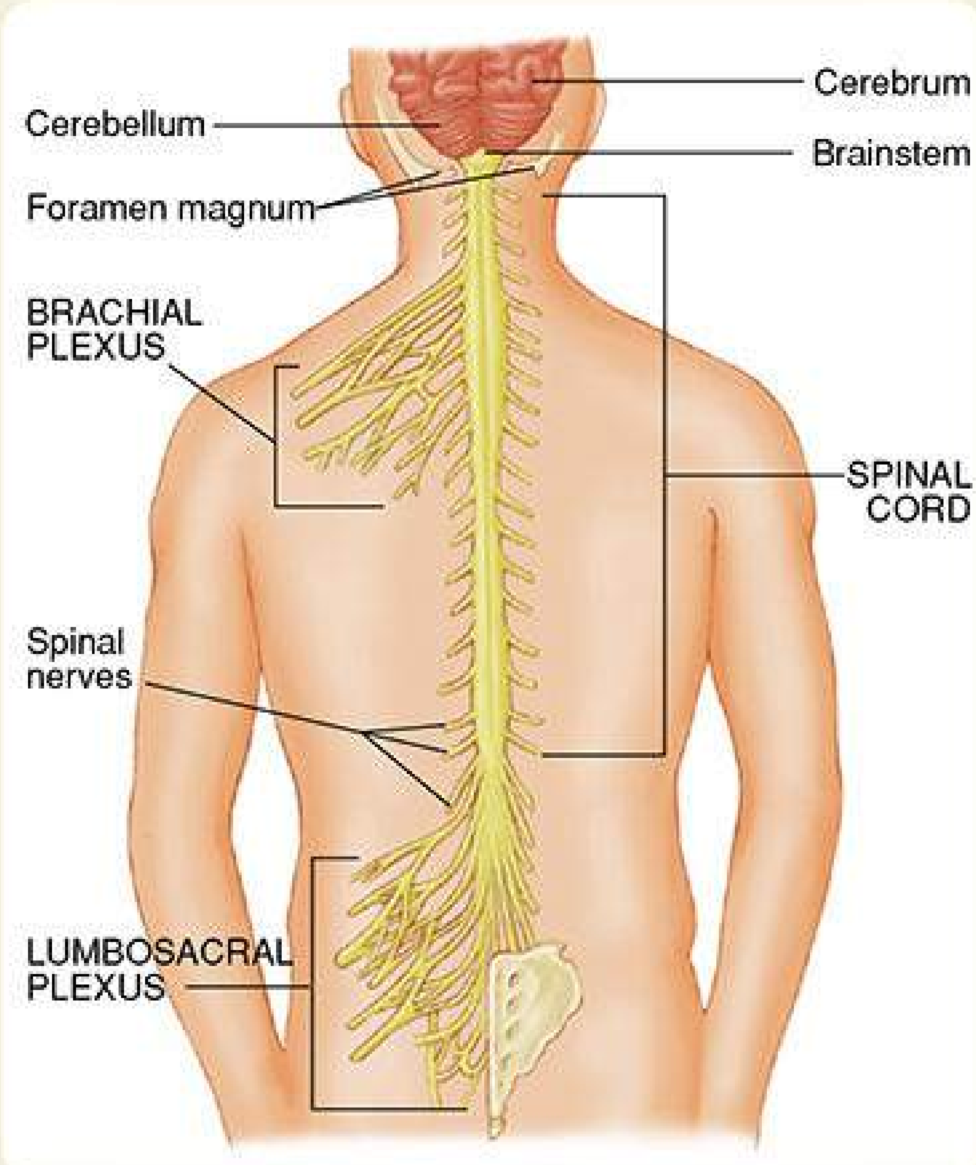

Figure 28-4 The peripheral nervous system is a complex network of motor and sensory nerves. The brachial plexus controls the arms, and the lumbosacral plexus controls the legs.

How the Nervous System Works

The nervous system controls virtually all of the body's activities, including reflex, voluntary, and involuntary activities.

In connecting the sensory and motor nerves of the limbs, the connecting nerves in the spinal cord form a reflex arc. If a sensory nerve in this arc detects an irritating stimulus, such as heat, it will bypass the brain and send a message directly to a motor nerve, causing a response such as pulling away from the heat **Figure 28-5**.

Voluntary activities are the actions that we consciously perform, in which sensory input determines the specific muscular activity—for example, reaching across the table for a salt shaker or to pass a dish. **Involuntary activities** are the actions that are not under our conscious control, such as breathing; in most instances, we inhale and exhale without consciously thinking about it. Many of our body's functions occur independently of thought, or involuntarily.

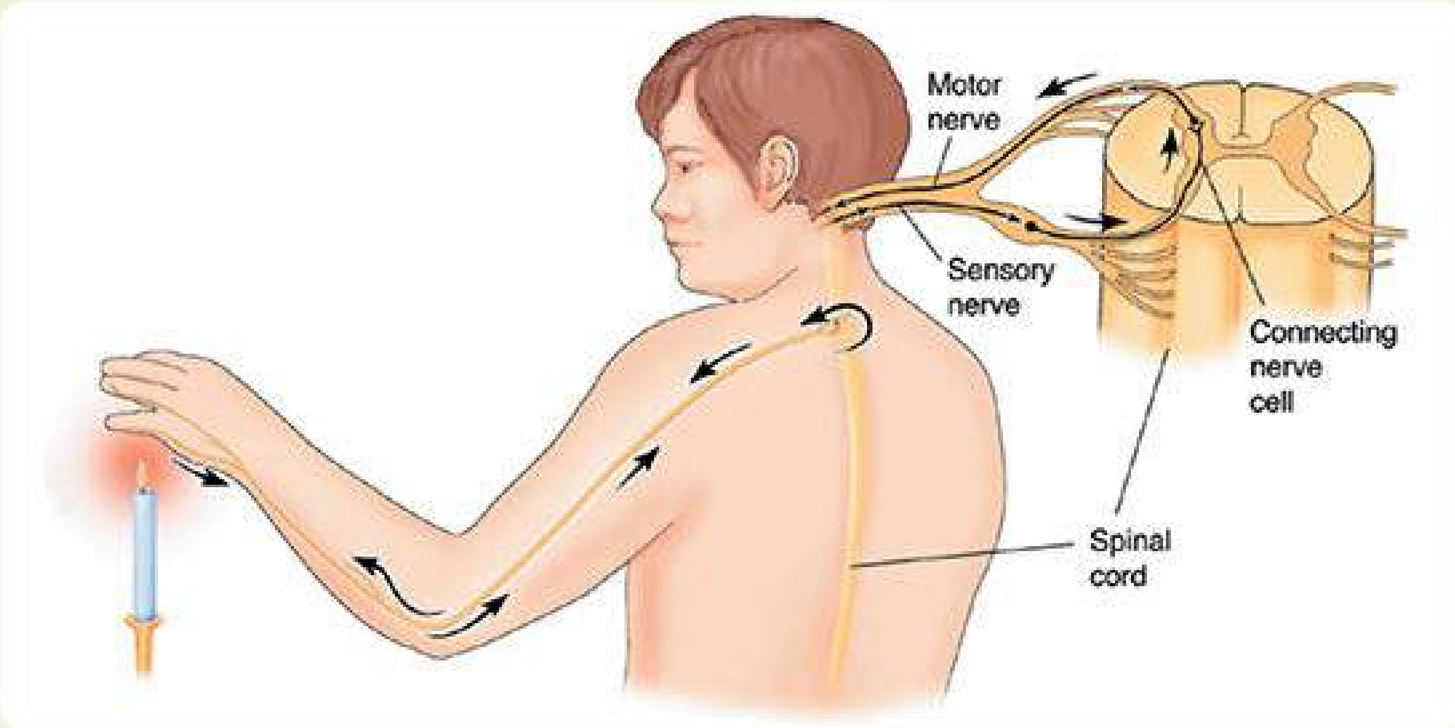

Figure 28-5 The connecting nerves in the spinal cord form a reflex arc. If a sensory nerve in this arc detects an irritating stimulus, it will bypass the brain and send a direct message to a motor nerve.

Words of Wisdom

Central nervous system structures, whose bony enclosures protect them quite well, are also very fragile. Protecting them from further damage is vital to the patient's future ability to live a normal life. Lean toward caution and overprotection in assessing and treating possible brain and spinal cord injuries.

The part of the nervous system that regulates or controls our voluntary activities, including almost all coordinated muscular activities, is called the somatic (voluntary) nervous system. The mechanism of the somatic nervous system is simple. The brain interprets the sensory information that it receives from the peripheral and cranial nerves and responds by sending signals to the voluntary muscles.

The body functions that occur without conscious effort are regulated by the much more primitive autonomic (involuntary) nervous system. The autonomic nervous system controls the functions of many of the body's vital organs, over which the brain has no voluntary control.

The autonomic nervous system is divided into two sections: the sympathetic nervous system and the parasympathetic nervous system. When confronted with a threatening situation, the sympathetic nervous system reacts to the stress with the fight-or-flight response. This response causes the pupils to dilate, smooth muscle in the lungs to dilate, heart rate to increase, and blood pressure to rise. This response also causes the body to shunt blood to vital organs and to skeletal muscle. During this time of stress, a hormone called epinephrine (also known as adrenaline) is released, which is responsible for much of these activities inside the body. The parasympathetic nervous system has the opposite effect on the body, causing blood vessels to dilate, slowing the heart rate, and relaxing the muscle sphincters. When this portion of the autonomic nervous system is activated, the body shunts blood to the organs of digestion. As the body attempts to maintain homeostasis (balance), these two divisions of the autonomic nervous system tend to balance each other so that basic body functions remain stable and effective.

Skeletal System

Skull

The skull is composed of two groups of bones: the cranium, which protects the brain, and the facial bones **Figure 28-6**. The cranium is composed of a number of thick bones that fuse together to form a shell above the eyes and ears that holds and protects the brain. It is occupied by 80% brain tissue, 10% blood supply, and 10% CSF. The brain connects to the spinal cord through a large opening at the base of the skull called the foramen magnum.

> **Special Populations**
>
> The spinal canal is closed by birth and must grow and expand as the child grows. Neural tube deformities are common and can result in serious birth defects. The most discussed neural tube deformity is spina bifida, in which the lower portion of the spine does not close prior to birth. As an EMT, you may be called on to treat or transport a child with one of these birth defects. Chapter 36, *Patients With Special Challenges,* covers spina bifida in detail.

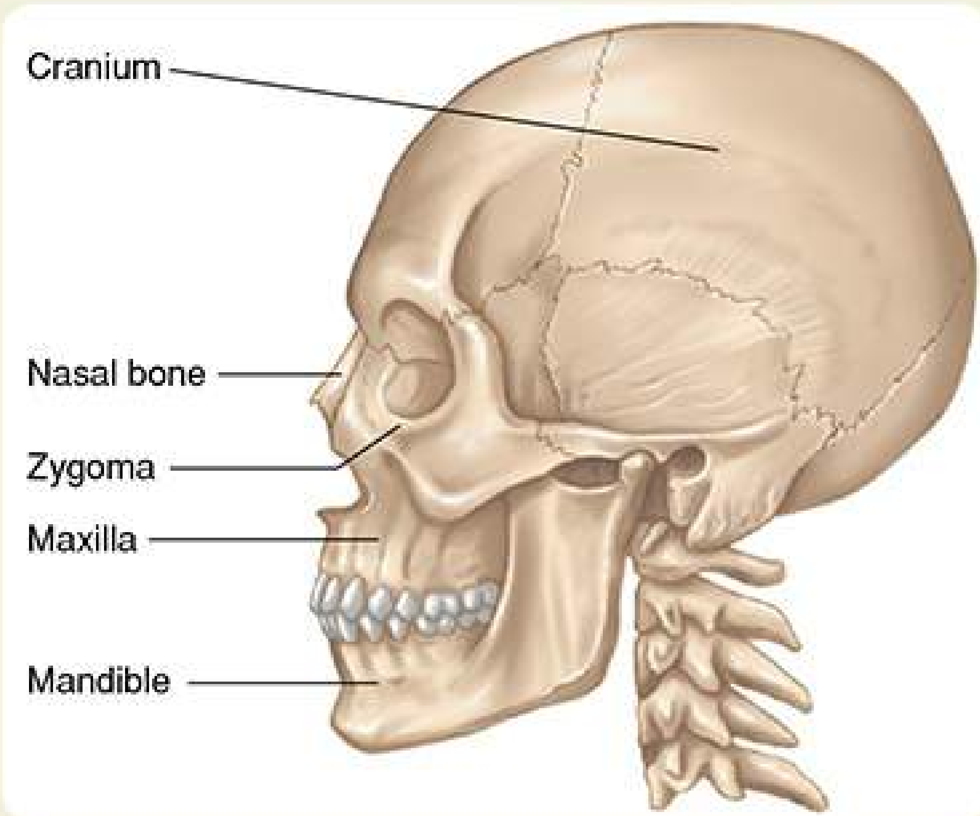

Figure 28-6 The skull includes two large structures: the cranium and the face.

Four major bones make up the cranium. The most posterior portion of the cranium is called the occiput. On each side of the cranium, the lateral portions are called the temples or temporal regions. Between the temporal regions and the occiput lie the parietal regions. The forehead is called the frontal region.

The face is composed of 14 bones. The upper, non-moveable jawbones are called the maxillae, the cheek bones are called the zygomas, and the mandible is the lower, moveable portion of the jaw.

The orbit (eye socket) is made up of two facial bones: the maxilla and the zygoma. The orbit also includes the frontal bone of the cranium. Together, these bones form a solid bony rim that protrudes around the eye to protect it. The nose mostly consists of flexible cartilage; in fact, only the proximal one-third of the nose is formed by bone with very short bones forming the bridge of the nose.

Spinal Column

The spinal column is the body's central supporting structure. It has 33 bones, called vertebrae, and is divided into five sections: cervical, thoracic, lumbar, sacral, and coccygeal **Figure 28-7**. Injury to the vertebrae, depending on the level at which the injury occurs, may result in paralysis if the underlying spinal cord or nervous structures are also damaged.

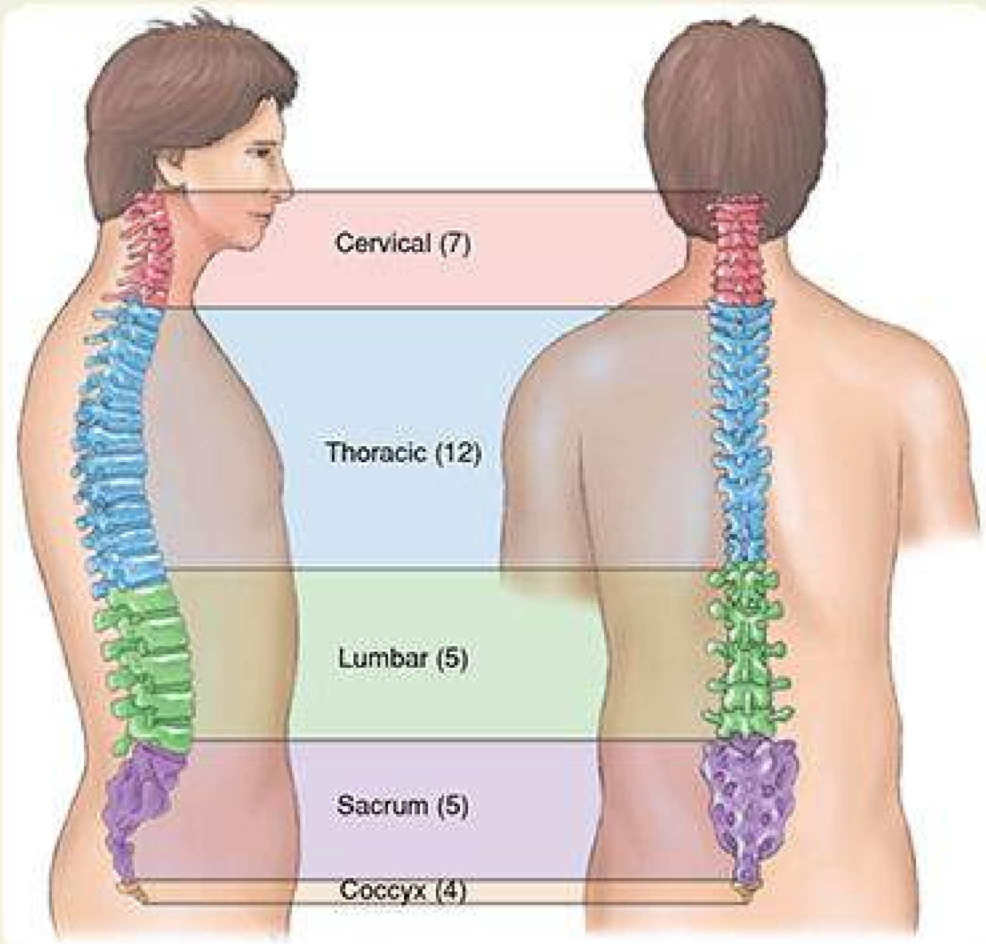

Figure 28-7 The spinal column is the body's central supporting system and consists of 33 bones divided into five sections. Injury to the vertebrae may cause paralysis.

The front part of each vertebra consists of a round, solid block of bone called the vertebral body; the back part forms a bony arch. From one vertebra to the next, the series of arches form a tunnel running the length of the spinal column. This tunnel is the spinal canal, which encases and protects the spinal cord **Figure 28-8**.

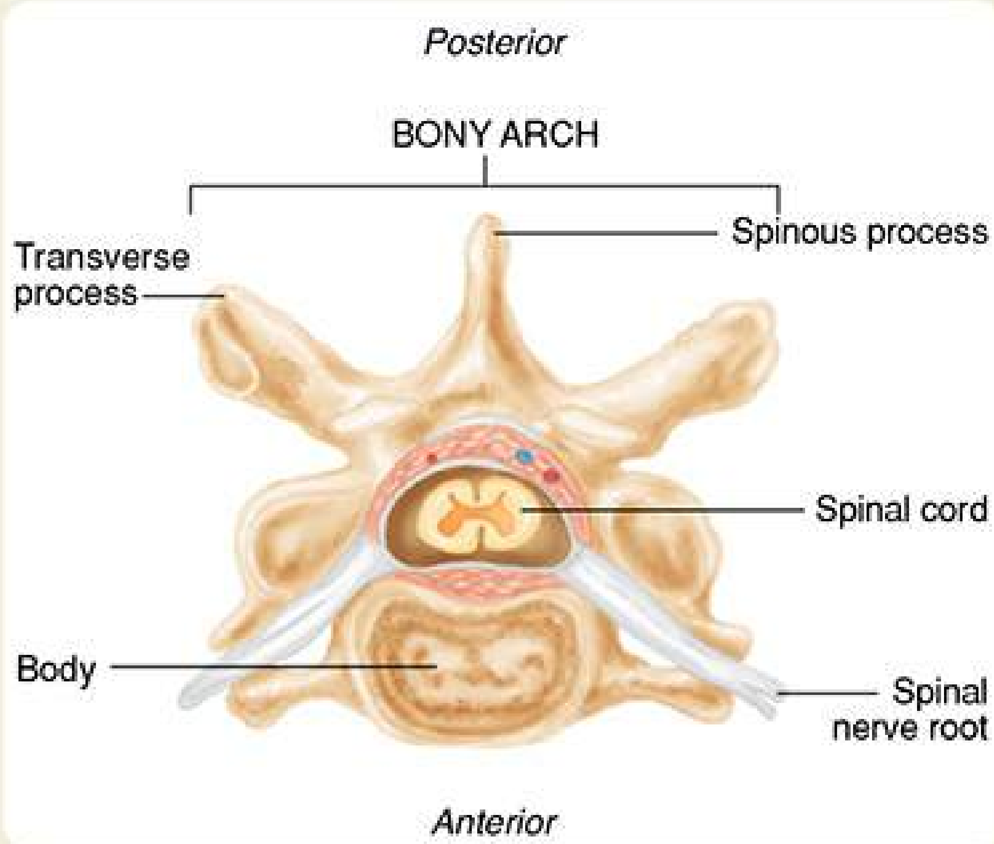

Figure 28-8 The spinal canal is formed by the vertebral body in the front (or anteriorly) and the bony arch in the back (or posteriorly).

The vertebrae are connected by ligaments and separated by cushions, called **intervertebral disks**. These ligaments and disks allow the trunk to bend forward and back, but they also limit motion so that the spinal cord is not injured. When the spine is injured or fractured, the spinal cord and its nerves are left unprotected. Therefore, until the spine is immobilized, you must keep it aligned as best you can to prevent further injury to the spinal cord.

The spinal column itself is almost entirely surrounded by muscles. However, you can usually palpate the posterior spinous process of each vertebra, which lies just under the skin in the midline of the back. The most prominent and most easily palpable spinous process is at the seventh cervical vertebra at the base of the neck.

Head Injuries

A head injury is a traumatic insult to the head that may result in injury to soft tissue, bony structures, or the brain. Approximately 4 million people experience head injuries of varying severity in the United States each year. According to the Brain Trauma Foundation, 52,000 deaths occur annually as the result of severe head injury. More than 50% of all traumatic deaths result from a head injury. When head injuries are fatal, the cause is invariably associated injury to the brain. In addition to the head injury, and dependent on the mechanism of injury (MOI), you should be alert to the fact that the patient may have sustained additional trauma such as cervical spine injuries, pelvic injuries, and chest injuries.

There are two general types of head injuries. **Closed head injuries** are those in which the brain has been injured but there is no opening into the brain. For example, a severe blow that fractures the skull but does not create an open wound would be considered a closed head injury. An **open head injury** is one in which an opening from the brain to the outside world exists. Obvious skull deformity with a break in the skin is a sign of an open head injury, which is often caused by penetrating trauma. There may be bleeding and exposed brain tissue.

Motor vehicle crashes are the most common MOI, with more than two-thirds of people involved in motor vehicle crashes experiencing a head injury. Head injuries also occur commonly in victims of assault, when older adults fall, during sports-related incidents, and in a variety of incidents involving children.

Any head injury is potentially serious. If not properly treated, those that at first seem minor may end up becoming a life-threatening brain injury **Table 28-1**. Conversely, severe lacerations of the scalp or fractures of the skull may occur with little or no brain injury and may lead to minimal or no long-term consequences.

Table 28-1 General Signs and Symptoms of a Head Injury

Following a head injury, any patient who exhibits one or more of these signs or symptoms has potentially sustained a very serious underlying brain injury:

- Lacerations, contusions, or hematomas to the scalp
- Soft area or skull depression on palpation
- Visible fractures or deformities of the skull
- Decreased mentation, confusion
- Irregular breathing pattern
- Widening pulse pressure
- Slow heart rate
- Ecchymosis about the eyes or behind the ear over the mastoid process
- Clear or pink CSF leakage from a scalp wound, the nose, or the ear
- Failure of the pupils to react to light
- Unequal pupil size
- Loss of sensation and/or motor function
- A period of unconsciousness
- Amnesia
- Seizures
- Numbness or tingling in the extremities
- Irregular respirations
- Dizziness
- Visual complaints
- Combative or other abnormal behavior
- Nausea or vomiting
- Posturing (decorticate or decerebrate)

Scalp Lacerations

Scalp lacerations can be minor or very serious. Because both the face and the scalp have unusually rich blood supplies, even small lacerations can quickly lead to significant blood loss **Figure 28-9**. Occasionally, this blood loss may be severe enough to cause hypovolemic shock, particularly in children. In any patient with multiple injuries, bleeding from scalp or facial lacerations may contribute to hypovolemia. In addition, because scalp lacerations are usually the result of direct blows to the head, they are often an indicator of deeper, more serious injuries.

Skull Fracture

Significant force applied to the head may cause a skull fracture. As with any fracture, a skull fracture may be open or closed, depending on whether there is an overlying laceration of the scalp. Injuries from bullets or other penetrating weapons frequently result in fracture of the skull. The diagnosis of a skull fracture is usually made in the hospital with a computed tomography (CT) scan, but maintain a high index of suspicion that a fracture is present if the patient's head appears deformed or if there is a visible crack in the skull within a scalp laceration. Additional signs of skull fracture that you may see include ecchymosis (bruising) that develops under the eyes (**raccoon eyes**) **Figure 28-10A** or behind one ear over the mastoid process (**Battle sign**) **Figure 28-10B**.

Figure 28-9 The scalp has an unusually rich blood supply; therefore, even small lacerations can result in significant blood loss.

Linear Skull Fractures

Linear skull fractures (nondisplaced skull fractures) account for approximately 80% of all fractures to the skull **Figure 28-11A**. Radiographs are required to diagnose a linear skull fracture because there are often no physical signs such as deformity. If the brain is uninjured and there are no scalp lacerations, then linear fractures are not life threatening. However, if there is a scalp laceration with the linear fracture—making it an open fracture—there is a risk of infection and bleeding inside the brain.

Depressed Skull Fractures

Depressed skull fractures result from high-energy direct trauma to the head with a blunt object (such as a baseball bat to the head) **Figure 28-11B**. The frontal and parietal bones of the skull are most susceptible to these types of fractures because the bones in these areas are relatively thin. As a consequence, bony fragments may be driven into the brain, resulting in injury. The scalp may or may not be lacerated. Patients with depressed skull fractures often present with neurologic signs (such as loss of consciousness).

Figure 28-10

Signs of skull fracture include **A.** ecchymosis under the eyes (raccoon eyes) or **B.** behind one ear over the mastoid process (Battle sign).

Basilar Skull Fractures

Basilar skull fractures are also associated with high-energy trauma, but they usually occur following diffuse impact to the head (eg, falls, motor vehicle crashes). These injuries generally result from extension of a linear fracture to the base of the skull and are usually diagnosed with a CT scan of the head **Figure 28-11C**.

Signs of a basilar skull fracture include CSF drainage from the ears, which indicates rupture of the tympanic membrane in the ear, and freely flowing CSF through the ear. Patients with leaking CSF are at risk for bacterial meningitis.

Other signs of a basilar skull fracture include raccoon eyes or Battle sign. Depending on the extent of the damage, raccoon eyes and Battle sign may appear relatively quickly, but in many patients, they may not appear until up to 24 hours following the injury, so their absence in the field does not rule out a basilar skull fracture.

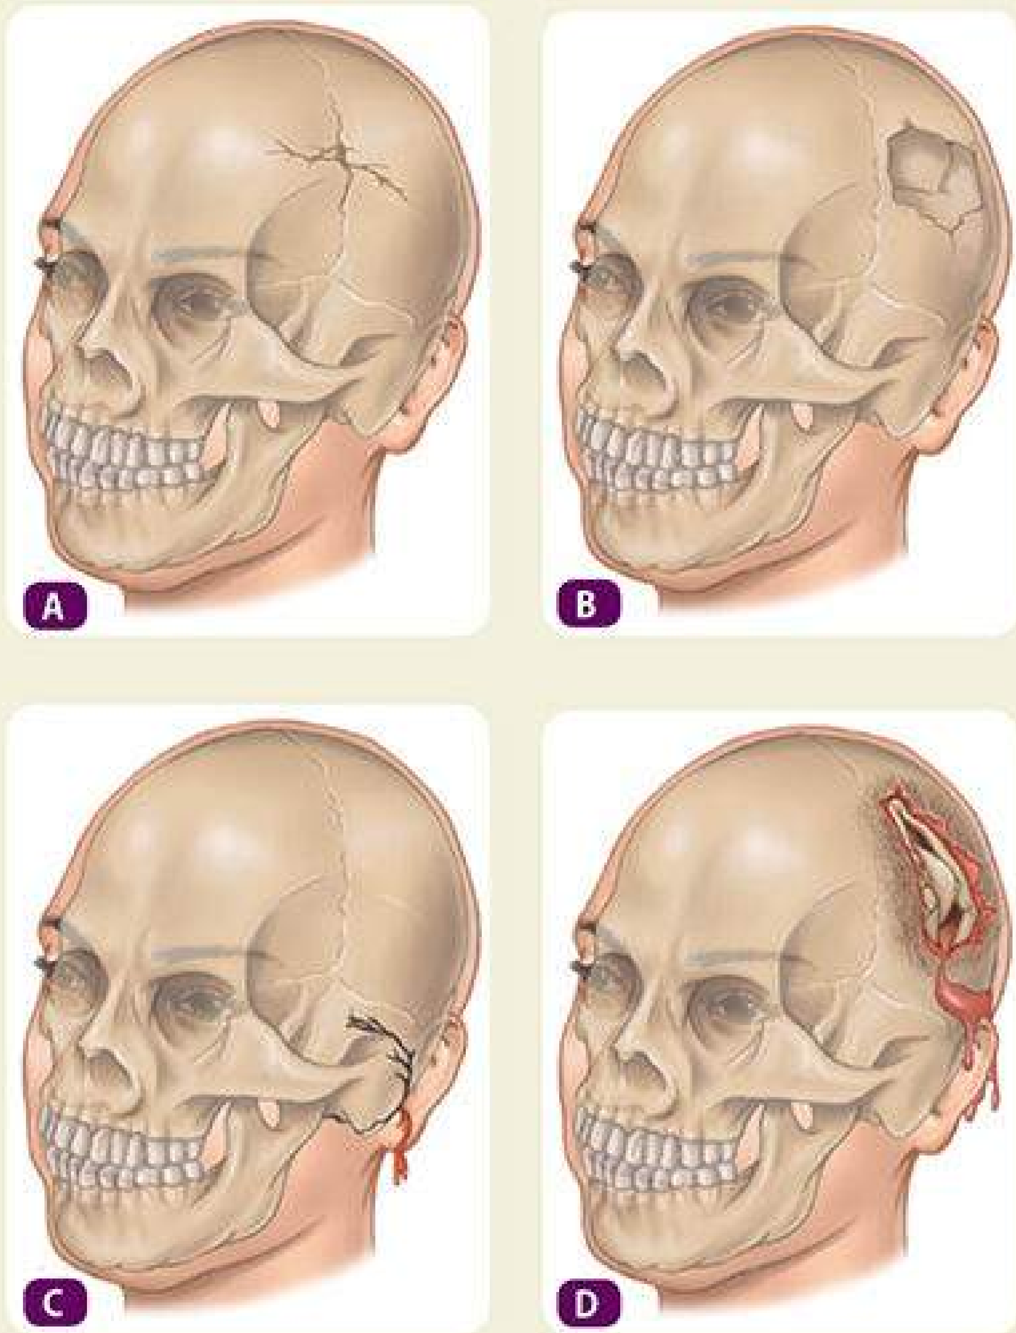

Figure 28-11 Types of skull fractures. **A.** Linear. **B.** Depressed. **C.** Basilar. **D.** Open.

Open Skull Fractures

Open fractures of the cranial vault result when severe forces are applied to the head and are often associated with trauma to multiple body systems Figure 28-11D. Brain tissue may be exposed to the environment, which significantly increases the risk of a bacterial infection (such as bacterial meningitis). Open cranial vault fractures have a high mortality rate.

Traumatic Brain Injuries

The National Head Injury Foundation defines a **traumatic brain injury (TBI)** as "a traumatic insult to the brain capable of producing physical, intellectual, emotional, social, and vocational changes." Traumatic brain injuries are the most serious of all head injuries. Traumatic brain injuries are classified into two broad categories: **primary (direct) injury** and **secondary (indirect) injury**. Primary brain injury is injury to the brain and its associated structures that results instantaneously from impact to the head. Secondary brain injury refers to a multitude of processes that increase the severity of a primary brain injury and, therefore, negatively impact the outcome. Secondary injuries may be caused by cerebral edema, intracranial hemorrhage, increased intracranial pressure, cerebral ischemia, and infection; however, hypoxia and hypotension are the two most common causes. According to the Brain Trauma Foundation, hypoxia or hypotension will increase death and disability significantly in a patient with a head injury. It is important to monitor and address hypoxia and hypotension when identified. Secondary brain injury may occur anywhere from a few minutes to several days following the initial head injury.

The brain can be injured directly by a penetrating object, such as a bullet, knife, or other sharp object. More commonly, brain injuries occur indirectly, as a result of external forces exerted on the skull. Consider the most common cause of brain injury, the motor vehicle crash. When the passenger's head hits the windshield on impact with a fixed object, the brain continues to move forward until it comes to an abrupt stop by striking the inside of the skull. This rapid deceleration results in compression injury (or bruising) to the anterior portion of the brain along with stretching or tearing of the posterior portion of the brain Figure 28-12. As the brain strikes the front of the skull, the body begins its path of moving backward. The head falls back against the headrest and/or seat, and the brain slams into the rear of the skull. This type of front-and-rear injury is known as a **coup-contrecoup injury**. The same type of injury may occur on opposite sides of the brain in a lateral collision.

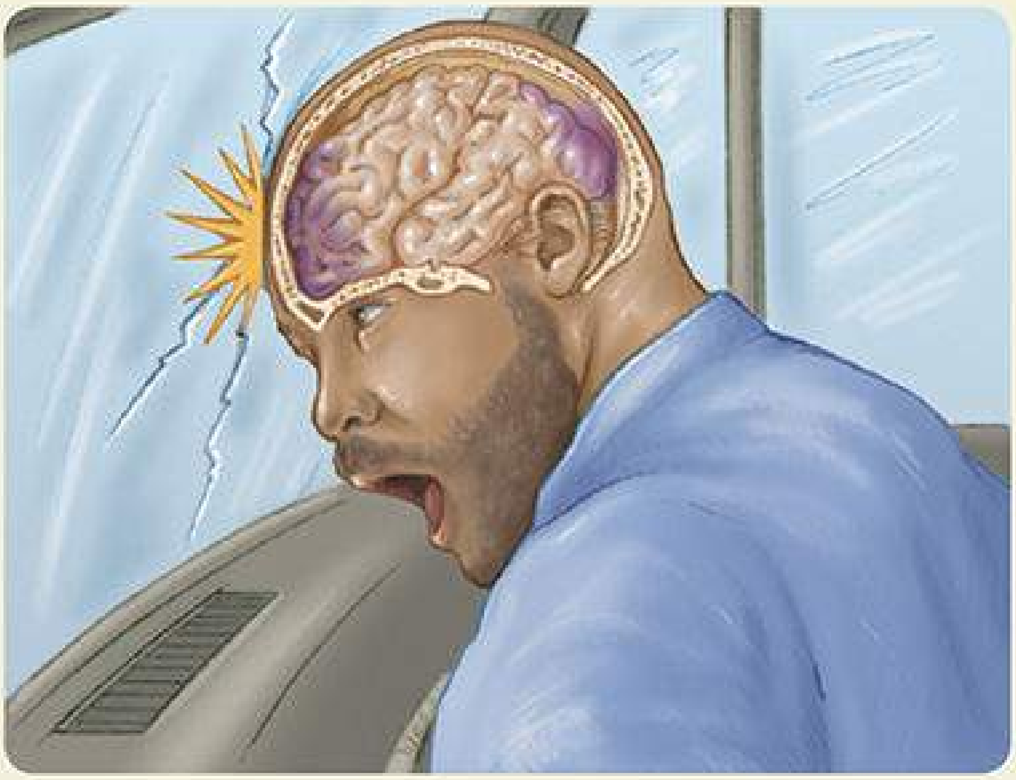

Figure 28-12 For the unrestrained driver or passenger in a motor vehicle crash, the brain continues its forward motion and strikes the inside of the skull, resulting in compression injury to the anterior portion of the brain and stretching of the posterior portion.

The injured brain starts to swell, initially because of cerebral vasodilation. An increase in cerebral water (cerebral edema) then contributes to further brain swelling. **Cerebral edema** (swelling of the brain) may not develop until several hours following the initial injury, however.

Low oxygen levels in the blood aggravate cerebral edema. Therefore, cerebral edema can be minimized by maintaining high oxygen saturations. In fact, the brain consumes more oxygen than any other organ in the body. For this reason, you must make sure that the airway is open and that adequate ventilations and high-flow oxygen (if indicated) are given to any patient with a head injury. This is especially true if the patient is unconscious. Do not wait for cyanosis or other obvious signs of hypoxia to develop.

It is not uncommon for the patient with a head injury to have a convulsion, or seizure. This is the result of excessive excitability of the brain, caused by direct injury or the accumulation of fluid within the brain (edema). Be prepared to manage seizures in all patients who have had a head injury because the brain may have sustained an injury as well.

Intracranial Pressure

For adults, the skull is a rigid, unyielding globe that allows little, if any, expansion of the intracranial contents. It also provides a hard and somewhat irregular surface against which brain tissue and its blood vessels can be injured when the head sustains trauma.

Accumulations of blood within the skull or swelling of the brain can rapidly lead to an increase in **intracranial pressure (ICP)**, the pressure within the cranial vault. Increased ICP squeezes the brain against bony prominences within the cranium. Cheyne-Stokes respirations (respirations that are fast and then become slow, with intervening periods of apnea) or ataxic (Biot) respirations (characterized by irregular rate, pattern, and volume of breathing with intermittent periods of apnea) are signs of increased intracranial pressure. Other signs and symptoms include decreased pulse rate, headache, nausea, vomiting, decreased alertness, bradycardia, sluggish or nonreactive pupils, decerebrate posturing, and increased or widened blood pressure. Signs and symptoms will increase and become more severe as the level of pressure increases.

The triad of increased systolic blood pressure, decreased pulse rate, and irregular respirations is called Cushing reflex, and signifies increased ICP.

Intracranial Hemorrhage

The closed compartment of the skull has no extra room for an accumulation of blood, so bleeding inside the skull also increases the ICP. Bleeding can occur between the skull and dura mater, beneath the dura mater but outside the brain, or within the tissue of the brain itself.

Epidural Hematoma

An **epidural hematoma** is an accumulation of blood between the skull and dura mater **Figure 28-13**. An epidural hematoma is nearly always the result of a blow to the head that produces a linear fracture of the thin temporal bone. The middle meningeal artery runs along a groove in that bone; therefore, it is vulnerable when the temporal bone is fractured. Arterial bleeding into the epidural space will result in rapidly progressing symptoms.

Often, the patient has an immediate loss of consciousness following the injury; this is often followed by a brief period of consciousness (lucid interval), after which the patient lapses back into unconsciousness. Meanwhile, as the ICP increases, the pupil on the side of the hematoma becomes fixed and dilated. Death will follow very rapidly without surgery to evacuate the hematoma.

Subdural Hematoma

A **subdural hematoma** is an accumulation of blood beneath the dura mater but outside the brain **Figure 28-14**. It usually occurs after falls or injuries involving strong deceleration forces. Subdural hematomas are more common than epidural hematomas and may or may not be associated with a skull fracture. Bleeding within the subdural space typically results from rupture of the veins that bridge the cerebral cortex and dura.

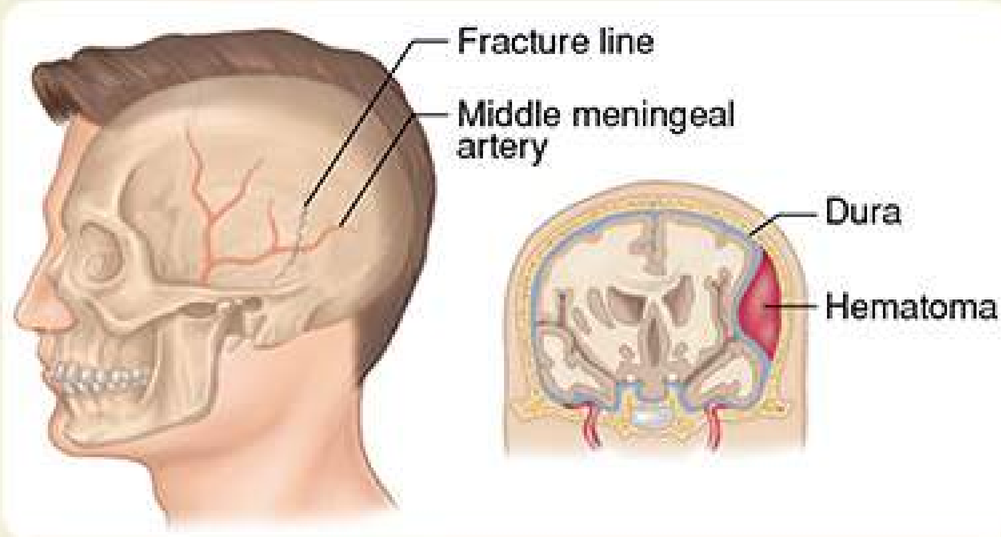

Figure 28-13 An epidural hematoma is usually the result of a blow to the head that produces a linear fracture of the temporal bone and damages the middle meningeal artery. Blood accumulates between the dura mater and the skull.

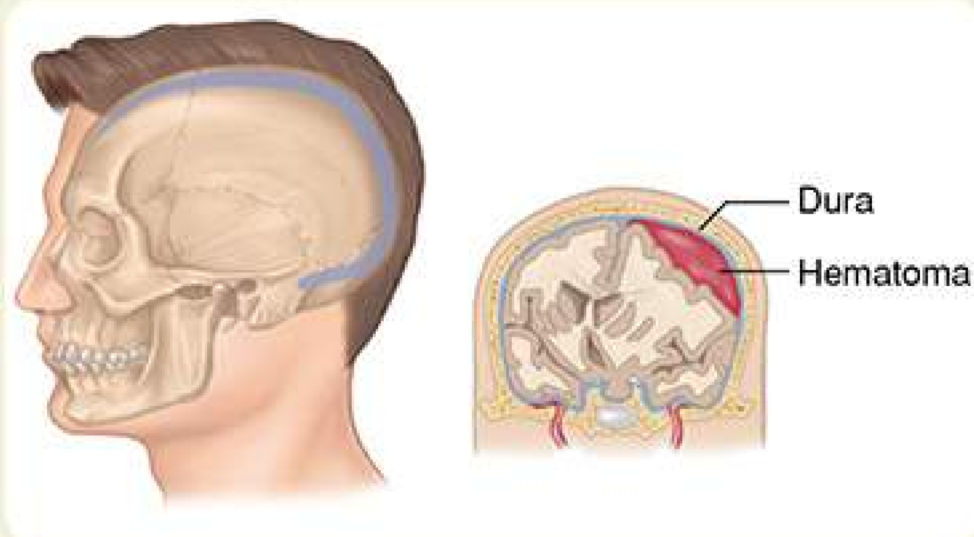

Figure 28-14 In a subdural hematoma, venous bleeding occurs beneath the dura mater but outside the brain.

Special Populations

Older people, people taking blood thinning medications, and those with a history of alcohol use are at higher risk for a subdural hematoma developing. This is caused by atrophy of the brain tissue that increases stretching of the bridging veins. Signs and symptoms of the condition may not occur for several hours, days, or weeks. Be sure to get a thorough history of any previous trauma.

A subdural hematoma is associated with venous bleeding, so this type of hematoma and the signs of increased ICP typically develop more gradually than with an epidural hematoma. The patient with a subdural hematoma often experiences a fluctuating level of consciousness or slurred speech. Any patient who you suspect has a subdural hematoma needs to be evaluated by a physician.

Intracerebral Hematoma

An **intracerebral hematoma** involves bleeding within the brain tissue itself **Figure 28-15**. This type of injury may occur following a penetrating injury to the head or because of rapid deceleration forces.

Many small, deep intracerebral hemorrhages are associated with other brain injuries. The progression of increased ICP depends on several factors, including the presence of other brain injuries, the region of the brain involved (frontal and temporal lobes are the most common locations), and the size of the hemorrhage. Once symptoms appear, the patient's condition often deteriorates quickly. Intracerebral hematomas have a high mortality rate, even if the hematoma is surgically evacuated.

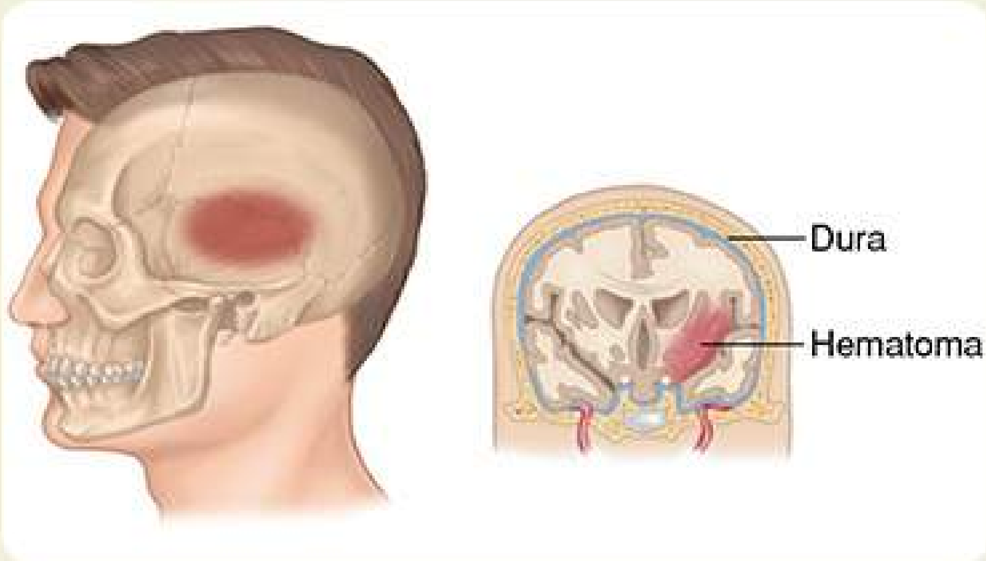

Figure 28-15 An intracerebral hematoma involves bleeding within the brain tissue itself.

Subarachnoid Hemorrhage

In a **subarachnoid hemorrhage**, bleeding occurs into the subarachnoid space, where the CSF circulates. It results in bloody CSF and signs of meningeal irritation (such as neck rigidity, headache). Common causes of a subarachnoid hemorrhage include trauma or rupture of an aneurysm.

The patient with a subarachnoid hemorrhage reports a sudden, severe headache. As bleeding into the subarachnoid space increases, the patient experiences the signs and symptoms of increased ICP: decreased level of consciousness, changes in the pupils, vomiting, and seizures.

A sudden, severe subarachnoid hemorrhage usually results in death. People who survive often have permanent neurologic impairment.

Concussion

A blow to the head or face may cause **concussion** of the brain. Concussions are also known as mild traumatic brain injuries. There is no universal agreement on the exact definition of a concussion, but in general, it is a closed injury with a temporary loss or alteration of part or all of the brain's abilities to function without demonstrable physical damage to the brain. For example, a person who "sees stars" after being struck in the head has sustained a concussion that affects the occipital portion of the brain. A concussion may result in unconsciousness and even the inability to breathe for short periods of time; however, approximately 90% of patients who sustain a concussion do not experience a loss of consciousness.

A patient with a concussion may be confused or have amnesia (loss of memory). Occasionally, the patient can remember everything but the events leading up to the injury; this is called **retrograde amnesia**. Inability to remember events after the injury is called **anterograde (posttraumatic) amnesia**.

Usually, a concussion lasts only a short time. In fact, it has often resolved by the time you arrive. Nevertheless, you should ask about symptoms of concussion in any patient who has sustained an injury to the head; these symptoms include dizziness, weakness, or visual changes. Additional signs and symptoms you may encounter with a patient who has sustained a concussion may include nausea or vomiting, and the patient may report ringing in the ears. Slurred speech and the inability to focus may also be present. Dependent on the severity of the concussion, you may also notice that the patient has a lack of coordination, a delay of motor functions, or displays inappropriate emotional responses. Patients may also report a temporary headache and may appear to be disoriented at times.

Patients with symptoms consistent with concussion may also have more serious underlying brain injury. A CT scan is necessary to differentiate between these conditions. Always assume that a patient with signs or symptoms of concussion has a more serious injury until proven otherwise. All patients with signs or symptoms of a concussion should be evaluated by a physician or other qualified healthcare provider.

Words of Wisdom

Be aware that all athletes who sustain a concussion should be evaluated by a qualified healthcare provider prior to being allowed to return to play. Some of the tools these healthcare providers use are specific, commercially-available computerized tests to assess concussion and recovery from it. Often the results of the test are compared to baseline evaluations conducted prior to injury. EMTs are not qualified to conduct these types of assessments.

Contusion

Like any other soft tissue in the body, the brain can sustain a contusion, or bruise, when the skull is struck. A contusion is far more serious than a concussion because it involves physical injury to the brain tissue, which may sustain long-lasting and even permanent damage. As with contusions that occur elsewhere in the body, there is associated bleeding and swelling from injured blood vessels. Injury of brain tissue or bleeding inside the skull causes an increase of pressure within the skull. A patient who has sustained a brain contusion may exhibit any or all of the signs of brain injury.

Other Brain Injuries

Brain injuries are not always a result of trauma. Certain medical conditions, such as blood clots or hemorrhages, can also cause brain injuries that produce significant bleeding or swelling. Problems with the blood vessels themselves, high blood pressure, or any number of other problems may cause spontaneous bleeding into the brain, affecting the patient's level of consciousness. This is known as altered mental status. The signs and symptoms of nontraumatic injuries are often the same as those of traumatic brain injuries, except that there is no obvious history of MOI or any external evidence of trauma. Altered mental status is discussed in Chapter 17, *Neurologic Emergencies*.

Spine Injuries

The cervical, thoracic, and lumbar portions of the spine can be injured in a variety of ways. Compression injuries can occur as a result of a fall, regardless of whether the patient landed on his or her feet or experienced a direct blow to the crown of the skull, coccyx, or top of the head. The forces that compress the patient's vertebral body can cause the herniation of disks, subsequent compression on the spinal cord and nerve roots, and fragmentation into the spinal canal. Motor vehicle crashes or other types of trauma can overextend or hyperflex the cervical spine and damage the ligaments and joints. Rotation-flexion injuries of the spine result from rapid acceleration forces. This is more likely to happen at C1 and C2. Injuries to this area of the spine are considered to be unstable due to the location on the spine and the lack of bony and soft-tissue support. Any one of these unnatural motions, as well as excessive lateral bending, can result in fractures or neurologic deficit.

When the spine is pulled along its length (hyperextension), it can cause fractures in the spine as well as ligament and muscle injuries. For example, hangings often result in fracture of the vertebrae in the upper portion of the cervical spine.

When the bones of the spine are altered from traumatic forces, they can fracture or move out of place. When these injuries pinch, pull, or penetrate the spinal cord, permanent damage may occur. Common findings include pain and tenderness on palpation of the region. Less commonly you may feel or observe a deformity of the spine, sometimes referred to as a "step-off" where the spinous process may be palpable on physical examination. If you suspect these types of injuries, take extra precautions when immobilizing the spine, both manually and with adjuncts.

Words of Wisdom

When assessing the spine, be aware of the possibility of open wounds from the associated trauma. These open wounds can be penetrating injuries or lacerations. If you follow the mnemonic DCAP-BTLS, you will discover any open wounds prior to securing the patient to a backboard.

Patient Assessment

You should suspect a possible head or spinal injury any time you encounter one of the following mechanisms of injury:

- Motor vehicle crashes (including motorcycles, snowmobiles, and all-terrain vehicles)

- Pedestrian–motor vehicle crashes
- Fall >20 feet (adult)
- Fall >10 feet (pediatric)
- Blunt trauma
- Penetrating trauma to the head, neck, back, or torso
- Rapid deceleration injuries
- Hangings
- **Axial loading injuries** (injuries where load is applied along the vertical or longitudinal axis of the spine; for example, falling from a height and landing on the feet in an upright position)
- Diving accidents

Motor vehicle crashes, direct blows, falls from heights, assault, and sports injuries are common causes of head and spinal injury. A deformed wind-shield or dented helmet may indicate a major blow to the head, which is likely to have caused traumatic brain injury **Figure 28-16**. It is especially important to evaluate and monitor the level of consciousness in patients with suspected head injuries, paying particular attention to any changes that may occur.

Figure 28-16 The classic "star" on the windshield after an automobile crash is a significant indicator of head injury. Be alert for the signs and symptoms of head injury.

YOU are the Provider — PART 2

When you arrive at the scene you find a 22-year-old man lying supine on the ground; he is motionless and his head is lying in a large pool of blood. Your partner manually stabilizes his head in a neutral position and opens his airway with the jaw-thrust maneuver as you perform a primary assessment.

Recording Time: 0 Minutes	
Appearance	Motionless; large pool of blood under his head

Level of consciousness	Responsive only to deep painful stimuli
Airway	Open; clear of secretions or foreign bodies
Breathing	Slow and irregular
Circulation	Radial pulses; slow and bounding; skin, warm and dry; bleeding from a large laceration to the right side of his head

3. What are your most immediate treatment priorities for this patient?
4. Where should you focus your secondary assessment of this patient?

Scene Size-up

Evaluate every scene for hazards to your health and the health of your team or bystanders. Motor vehicle crashes are a common cause of head and spinal injuries. These situations have the potential to cause injury to rescuers and bystanders as well. Be prepared with appropriate standard precautions before you approach the patient. You will be spending a great deal of time at the head of the patient. Gloves, a mask, and eye protection should be the minimum standard precautions that you use. Because these patients can have very complicated injuries, call for ALS as soon as possible when a serious MOI or complicated presentation is evident. Law enforcement may be needed to control traffic or unruly people.

Words of Wisdom

Many mechanisms of injury that cause head and spine injuries may also pose a risk to EMTs. Before you approach the patient, get the "big picture" of scene safety and take any actions necessary to ensure your own well-being. Do not rely entirely on assistance from fire or police personnel; maintain your own awareness of the scene.

Words of Wisdom

Proper care of a patient with a possible spinal injury requires assessment of motor and sensory functions both before and after stabilizing the patient. Likewise, careful observation of level of consciousness at different stages of your care for a head-injured patient can provide crucial information. Document your detailed findings of these repeated neurologic examinations to make the information available to hospital personnel and to help establish that your care has been thorough and appropriate.

As you observe the scene, look for indicators of the MOI. This helps you develop an early index of suspicion for underlying injuries in the patient who has sustained a significant MOI. As you put together information from dispatch and your observations of the scene, consider how the MOI produced the injuries expected. For example, if you respond to a baseball field for a patient who was knocked unconscious by a foul ball, you may begin to suspect that the patient may have a depressed skull fracture and perform a neurologic assessment during the physical examination. Continue to consider the MOI while assessing a patient.

Primary Assessment

The primary assessment should focus on identifying and managing life-threatening concerns. Threats to circulation, airway, or breathing are considered life threatening and must be treated immediately to prevent mortality. Life-threatening external hemorrhage must be addressed before airway and breathing concerns.

Most head injuries are considered mild and result in no or limited permanent disability. A smaller percentage of head injuries are considered moderate, and the patient is left with some permanent disabilities. A still smaller percentage of head injuries are considered severe, and many patients with a severe head injury die before ever reaching the hospital or are left in a comatose state despite hospital intervention. There will be a number of patients with head or spine injuries that will not require much intervention other than a thorough assessment and continued observation while being transported to the hospital. In these patients you may choose to take some time at the scene to provide careful spine immobilization before transport. In patients who have problems with ABCs or have other conditions for which you decide a rapid transport to the closest appropriate hospital is needed, rapid immobilization of the spine and quick loading into the ambulance may be indicated. Reduction of on-scene time and recognition of a critical patient increase the patient's chances for survival or a reduction in the amount of irreversible damage.

Spinal Immobilization Considerations

When assessing a patient with suspected head and/or spine injuries, be aware that any unnecessary movement of the patient can cause additional injury. Assess the patient in the position found. After determining and correcting any life-threatening injuries, determine whether or not a cervical collar needs to be applied. Begin by assessing the scene to determine the risk of injury, then form a general impression of your patient based on his or her level of consciousness and the chief complaint.

Mechanism of injury alone is not a reason to place a person in full spinal immobilization. If the patient is absolutely clear in his or her thinking and does not have any neurologic deficits, spinal pain or tenderness, evidence of intoxication, or other illnesses or injuries that may mask a spinal injury, you may consider not placing the patient in spinal immobilization, if this is allowed per your local protocols.

Physicians have been considered to be the appropriate people to assess and clear patients with potential spinal injuries (c-spine clearance refers to assessing and determining whether or not a spinal injury is actually present). Many jurisdictions allow their EMTs to screen patients and to refrain from providing spinal immobilization on the basis of specific criteria.

The backboard is rigid and often places the patient in an anatomically incorrect position for a long period of time. During that time the back is pressed against the board, causing circulation to areas of skin to become compromised. The patient may report pain, there may be ischemia to the skin, and if left long enough, necrosis, which leads to decubitus ulcers. Some patients, especially patients who are obese, could experience respiratory compromise while lying flat. Consider placing padding under the patient to help minimize the risk of injury, and try to minimize the amount of time a patient is on a long backboard. Always follow your local protocols.

Apply a cervical collar as soon as you have assessed the airway and breathing and provided necessary treatments. A cervical collar may help maintain spinal immobilization as you treat the airway and breathing. The best time to apply the cervical collar depends on the patient's injuries and the seriousness of his or her condition. For some patients, you may have to apply the collar early on, while managing the ABCs. In other patients, manual stabilization may be adequate until you complete your assessment and determine if you need to place the patient on a backboard or other spinal immobilization device. The key to managing spinal injuries and airway and breathing problems is to move the patient as little as possible and as carefully as possible, maintaining spinal alignment throughout. Place an appropriately sized cervical collar on the patient when indicated. Once the cervical collar is on, do not remove it unless it causes a problem with maintaining the airway. If you must remove the cervical collar, you will have to maintain manual stabilization of the cervical spine until it can be replaced and the patient has been once again secured to the cervical collar.

Assessing for Signs and Symptoms of a Head or Spine Injury

Patients with head injuries frequently have spinal injuries and vice versa. When assessing a patient for possible head or spinal injury, begin by asking the responsive patient the following questions to determine his or her chief complaint:

- What happened?
- Where does it hurt?
- Does your neck or back hurt?
- Can you move your hands and feet?
- Did you hit your head?

Confused or slurred speech, repetitive questioning, or amnesia in responsive patients is an indication of a head injury. Whereas other problems may cause similar symptoms, in the setting of trauma, assume your patient has a head injury until your assessment proves otherwise. A decreased blood glucose level can mimic these same symptoms.

If the patient is found unresponsive, emergency responders, family members, or bystanders may have helpful information, including when the patient lost consciousness or what was his or her previous level of consciousness. Unresponsive patients with any trauma should be assumed to have a spinal injury. Patients with a decreased level of responsiveness on the AVPU scale (responds to verbal stimulus or responds to painful stimulus) should also be considered to have a spinal injury based on their chief complaint.

Airway, Breathing, and Circulation Considerations

In patients with head and spinal injuries, airway and breathing problems are common and may result in death if not recognized and treated immediately. When a spinal injury is suspected, how you open and assess the airway is important. Begin by manually holding the patient's head still while you assess the airway. Use a jaw-thrust maneuver to open the airway. When performed correctly, this will prevent movement of the cervical spine. If, however, you are unable to provide a patent and open airway using the jaw-thrust maneuver, it is acceptable to use the head tilt–chin lift maneuver. The patient cannot survive if the airway is not functioning, and even though this maneuver may cause further injury to the spine, it is considered the last resort to provide an airway for your patient. An oropharyngeal or nasopharyngeal airway may assist in maintaining an airway; proper BLS maneuvers have been shown to adequately protect the patient's airway. When it becomes difficult to maintain the airway with BLS techniques, advanced airway techniques, usually used by AEMTs and paramedics, can be used. The decision to use an oropharyngeal or nasopharyngeal airway is based on the patient's ability to maintain his or her own airway, the presence of a gag reflex, and the extent of facial injuries. Review the indications and contraindications for these airway adjuncts in Chapter 10*, Airway Management*, and the use of advanced airway techniques in Chapter 41*, A Team Approach to Health Care*.

Vomiting may occur in the patient with a head injury. With large amounts of emesis, the patient may need to be log rolled to the side and the mouth swept of secretions. When it is necessary to log roll the patient to clear the airway, roll the patient keeping the body in as straight a line as possible to minimize spinal injuries. Suctioning should be performed immediately to remove smaller amounts of secretions.

Irregular breathing, such as Cheyne-Stokes respirations, may result from increased pressure on the brain because of bleeding or swelling in the cranium. If the ICP increases, there will be more periods of apnea. In either situation, determine whether breathing is present and adequate and continue to monitor the patient's respiratory rate and depth. Prehospital administration of high-flow oxygen is indicated for patients with head and spinal injuries. A single episode of hypoxia in a patient with a head injury significantly increases the risk of death or permanent disability. Pulse oximeter values should not fall below 90% and, ideally, should be 95% or higher. Positive-pressure ventilations are not always necessary; however, if the patient's breathing rate is too slow or too fast and shallow, provide positive-pressure ventilations using a bag-valve mask (BVM) or a manually triggered ventilation device (see Chapter 10, *Airway Management*). The rate of ventilations should be based on the age of the patient and established BLS guidelines.

Do not panic and hyperventilate the patient because his or her condition appears severe. Hyperventilation (ventilating too fast or with too much force) should be reserved for specific conditions and performed under specific guidelines. Hyperventilation is controversial because it can increase the severity of head injuries; therefore, it should be avoided except in cases where signs of brainstem herniation have been identified. Even when used, hyperventilation should be used with caution and only when capnography is available to ensure an end-tidal carbon dioxide ($ETCO_2$) level between 30 and 35 mm Hg. Be sure to know your local protocols on this subject.

When approaching a patient who is unconscious, the obvious question is, "Is this person alive?" Whereas checking immediately to determine whether a pulse is present is tempting, it is more important for you to remember the ABCs. Always assess airway and breathing prior to moving on to assessment of circulation. Patients who are responsive and moving obviously have a pulse; however, you should still check to see if the pulse is weak or strong and if it is generally too fast or too slow. A pulse that is too slow in the setting of a head injury can indicate a serious condition in your patient. If the pulse is present and adequate, continue your evaluation of the patient.

A single episode of hypoperfusion in a patient with a head injury can lead to significant brain damage and even death. Assess for signs and symptoms of shock and treat appropriately. Neurogenic (spinal) shock is discussed in Chapter 12, *Shock*.

Bleeding may also be present from the same injury that caused the spine and/or head injury. That injury may involve blunt or penetrating forces. Consider again the MOI and the effects it has had on your patient. Control bleeding as previously discussed. When bandaging the head, be careful that you do not move the neck if spinal injuries are suspected and do not apply pressure if a skull fracture is suspected. Remember that head and spine injuries often occur together.

Manner of Transport

Several transport considerations should be kept in mind for patients with head trauma. Patients with impaired airways, open head wounds, abnormal vital signs, or those patients who do not respond to painful stimuli may need to be rapidly extracted from a motor vehicle and transported. During transport, providing the patient with a patent airway and high-flow oxygen is paramount. Because of the potential for increasing ICP, there is an increased risk of vomiting and seizures, so suction should be readily available. A patient with head trauma may deteriorate rapidly, thus requiring aeromedical transport depending on your local protocols. In supine patients, the head should be elevated 30 degrees, if possible, to help reduce ICP. Remember to maintain immobilization of the spine.

Words of Wisdom

A blanket or one or two towels placed under the long backboard will elevate the head.

Studies have shown that the use of lights and siren for transportation of patients does not significantly reduce transport time. In fact, the use of lights and siren may increase the patient's level of distress. Patients who are conscious and aware of the inability to move their limbs need to be offered emotional support. Remember that it can be very traumatizing for a patient to realize that he or she may now have a debilitating and life-altering injury; therefore, you need to be careful in your choice of words. A patient may ask you difficult questions, "Will I be able to walk?" It is best to tell the patient that you are providing immediate care and you cannot predict the outcome.

History Taking

After the life threats have been managed during the primary assessment, investigate the chief complaint. Obtain a medical history and be alert for injury-specific signs and symptoms as well as any pertinent negatives such as no pain or no loss of sensation.

Using OPQRST may provide some background on isolated extremity injuries. Does the patient have any recall of the incident? Inability to recall events is an important finding in patients with head injuries. You have the opportunity to interview the patient well in advance of the emergency physician. Any information you receive will be very valuable if the patient has a loss of consciousness.

If the patient is not responsive, attempt to obtain the history from other sources, such as friends or family members. Medical identification jewelry and cards in wallets may also provide information about the patient's medical history (follow local protocols regarding the removal of items from a patient's wallet.). Does the patient have a recent or previous history of unresponsiveness? These key indicators may lead you to suspect a developing traumatic brain injury.

Make every attempt to obtain a SAMPLE history from your patient. History may be difficult to obtain when a person is confused from a head injury or frightened from a spinal injury. Whereas the prehospital environment is an excellent place to obtain important history, do not delay rapid transport for patients who need hospital intervention. Gather as much SAMPLE history as you can while preparing for transport. In less urgent situations, you should have enough time to gather a complete SAMPLE history without compromising patient care.

Secondary Assessment

Remember that the ability to walk, move the extremities, or feel sensation does not necessarily rule out a spinal cord injury. Similarly, the absence of pain does not always indicate that a spinal injury has not occurred. Do not ask patients with possible spinal injuries to move their necks as a test for pain. Instead, instruct the patient to keep still and not to move the head or neck.

The physical examination may be a systematic full-body scan or a systematic assessment that focuses on a certain area or region of the body, often determined through the chief complaint.

Patients with moderate or severe head injuries associated with a significant MOI should receive life-saving medical or surgical intervention at the closest appropriate trauma hospital without delay. If time allows, perform a secondary assessment to identify and treat injuries that may have been missed during the primary assessment en route to the emergency department (ED). Extremities can be stabilized using the backboard and splinted individually while in the back of the ambulance as time and conditions permit.

Obtaining a complete set of baseline vital signs is essential in patients with head and spine injuries. Significant head injuries may cause the pulse to slow and the blood pressure to rise. With neurogenic shock, the blood pressure may drop and the heart rate may increase to compensate. Respirations will become erratic with complications from both head and spine injuries. Hypotension may be present with cervical or high thoracic spine injuries. The heart rate may become slow or fail to increase in response to hypotension.

In addition to hands-on assessment, you should use monitoring devices to quantify your patient's oxygenation and circulatory status. Pulse oximetry and $ETCO_2$ monitoring should be utilized, if available, on all patients suspected of having a head injury to ensure the patient is not hypoventilating or hyperventilating. Maintain $ETCO_2$ between 35 and 40 mm Hg. You may also use noninvasive methods to monitor the blood pressure. It is recommended that you always assess the patient's first blood pressure manually with a sphygmomanometer (blood pressure cuff) and stethoscope.

Physical Examination Considerations

Examine the entire body using DCAP-BTLS and examine the head, chest, abdomen, extremities, and back. Check perfusion, motor function, and sensation in all extremities prior to moving the patient. Make sure that you do not move any body parts excessively. Determine whether the strength in each extremity is equal by asking the patient to squeeze your hands and to gently push each foot against your hands **Figure 28-17**.

A decreased or altered level of consciousness is the most reliable sign of a head injury. Monitor the patient for changes in level of consciousness, including signs of confusion, disorientation, or deteriorating mental status. Is the patient unresponsive or repeating questions? Experiencing seizures? Nauseous or vomiting?

Figure 28-17 **A.** Assess the equality of strength in each extremity by asking the patient to squeeze your hands. **B.** Next, ask the patient to gently push each foot against your hands.

Determine whether there is decreased movement and/or numbness and tingling in the extremities. Is there any spinal cord posturing? Is the patient able to perform motor function such as squeezing your hands appropriately and equally? Can the patient smile? An inability to smile is a sign that the cervical vertebrae may be injured. Part the patient's hair and inspect the scalp for bruising. Look for blood or CSF leaking from the ears, nose, or mouth and for bruising around the eyes and behind the ears.

Assess pupil size and reaction to light. Unequal pupil size after a head injury in an unconscious patient often signals a serious problem. The brain controls the diameter of pupils and how quickly they react. If an injury has occurred on one side of the brain, just one pupil will dilate. Developing blood clots may be compressing the brain, causing one pupil to dilate and indicating that the brain is at extreme risk of sustaining catastrophic damage **Figure 28-18**. The pupils are windows to the brain and should be assessed as soon as possible to establish a baseline from which to monitor changes.

Figure 28-18 Assess pupil size and reaction to light in all patients at least once.

As soon as you have assessed the patient's level of consciousness, determine the reaction of each pupil to light. Sketch the size of both pupils on the ambulance report to indicate any difference between the two eyes. Continue to monitor the pupils. Any change in their reactions over time may indicate progressive brain injury.

Do not probe open scalp lacerations with your gloved finger because this may push bone fragments into the brain. Do not remove an impaled object from an open head injury.

Neurologic Examination

For a patient with a head injury, perform a neurologic examination. Perform a baseline assessment using the Glasgow Coma Scale (GCS) and record the time **Table 28-2**. The GCS helps you to identify the patient's speech and ability to follow commands. Always use simple, easily understood terms when reporting the level of consciousness, such as "does not remember events immediately before the injury" or "confused about date and time." Terms such as "obtunded" or "dazed" have different meanings to different people and should not be used in either written or verbal reports.

If your jurisdiction uses the Revised Trauma Score (RTS), then the findings from the GCS will be used to determine the RTS value. See Chapter 24, *Trauma Overview*, for a discussion of this scoring system.

Frequently, the level of consciousness will fluctuate—improving, deteriorating, and improving again over time. On other occasions, there may be a gradual, progressive deterioration in the patient's response to stimuli; this usually indicates serious brain injury that may need aggressive medical and/or surgical treatment. The physicians who treat the patient will need to know when a loss of consciousness occurred.

Table 28-2 Glasgow Coma Scale

Eye Opening		Best Verbal Response		Best Motor Response	
Spontaneous	4	Oriented conversation	5	Obeys commands	6
In response to speech	3	Confused conversation	4	Localizes pain	5
In response to pain	2	Inappropriate words	3	Withdraws to pain	4
None	1	Incomprehensible sounds	2	Abnormal flexion	3
		None	1	Abnormal extension	2
				None	1
Score: 13–15 may indicate mild dysfunction, although 15 is the score a person with no neurologic disabilities would receive.					
Score: 9–12 may indicate moderate dysfunction.					
Score: 8 or less is indicative of severe dysfunction.					

YOU are the Provider PART 3

Your secondary assessment reveals an area of depression to the right side of the patient's head over the temporal bone and dilated and sluggishly reactive pupils. The rest of his body is unremarkable for gross injury. He opens his eyes in response to pain, is making unrecognizable sounds, and his arms are flexed and drawn in toward his body. An engine company arrives at the scene to provide assistance. You ask them to prepare the backboard and straps while you quickly assess the patient's vital signs.

Recording Time: 5 Minutes	
Respirations	6 breaths/min and irregular (baseline); ventilations are being assisted
Pulse	60 beats/min; regular and bounding
Skin	Pink, warm, and dry
Blood pressure	190/104 mm Hg
Oxygen saturation (Spo_2)	94% (on oxygen)

There are numerous bystanders present; however, no one knows the patient. During your physical assessment, you did not find any medical alert bracelets or any other evidence of a past medical history.

5. What is this patient's Glasgow Coma Scale score?
6. What is the likely explanation for the patient's vital signs?

Special Populations

A modified Glasgow Coma Scale (GCS) for pediatric and nonverbal patients assesses eye opening, verbal response, and motor response. The scoring indicators are the same as the GCS but the modified scale takes into consideration responses of coos and babbling, scoring these responses as oriented and appropriate.

Words of Wisdom

A change in the level of consciousness is the single most important observation that you can make in assessing the severity of brain injury. Level of consciousness usually corresponds to the extent of loss of brain function.

They will want to compare their neurologic evaluation with the one you performed in the field.

As you proceed with your assessment, ask yourself these questions: Is the patient's speech clear and appropriate? Does the patient answer in a logical manner, and is the patient able to make decisions? Is the patient aware of his or her current location? Is the patient alert to person, place, time, and why you are at the scene? Can the patient recall the events leading up to the incident, or is there a period of memory lapse? Can the patient recall major current events?

Any person with a head injury that has resulted in a change in level of consciousness, progressive development of signs or symptoms of a concussion, or other causes of concern should be evaluated. This evaluation should occur soon after injury and must be conducted by a qualified healthcare provider. EMTs are not qualified to conduct these evaluations in the field.

Spine Examination

If there is a potential spine injury, examine the spine. To start, inspect for DCAP-BTLS and check the extremities for circulation, motor, or sensory problems. If there is impairment, note the level. You do not need to know the exact nerve impairment because this will not change your treatment.

Pain or tenderness when you palpate the spinal area is certainly a warning sign that a spinal injury may exist. Patients with spinal injuries may report constant or intermittent pain along the spinal column or in the extremities. A spinal cord injury may also produce pain independent of movement or palpation.

Other signs and symptoms of spinal injury include an obvious deformity as you gently palpate the spine; numbness, weakness, or tingling in the extremities; and soft-tissue injuries in the spinal region. Patients with severe spinal injury may lose sensation or experience paralysis below the suspected level of injury or be incontinent (loss of urinary or bowel control) **Figure 28-19**. Obvious injury to the head and neck may indicate injury to the cervical spine.

Injuries to the cervical area may limit the ability of the diaphragm to function fully and minimize the ability of the chest wall to fully expand. Another sign of spinal injury is abdominal excursion—when the patient is unable to breathe without the assistance of the abdomen.

Additional signs of spinal cord trauma are an inability to maintain body temperature, priapism (a persistent erection lasting more than 4 hours), and a loss of bowel or bladder control.

Reassessment

Repeat the primary assessment. Reassess vital signs and the chief complaint. Is the airway, breathing, and circulation still adequate? Recheck patient interventions. Are the treatments you provided for problems with the ABCs still effective? This is particularly important in patients with head or spinal injuries because these injuries can suddenly affect the respiratory, circulatory, and nervous systems. The patient's condition should be reassessed at least every 5 minutes.

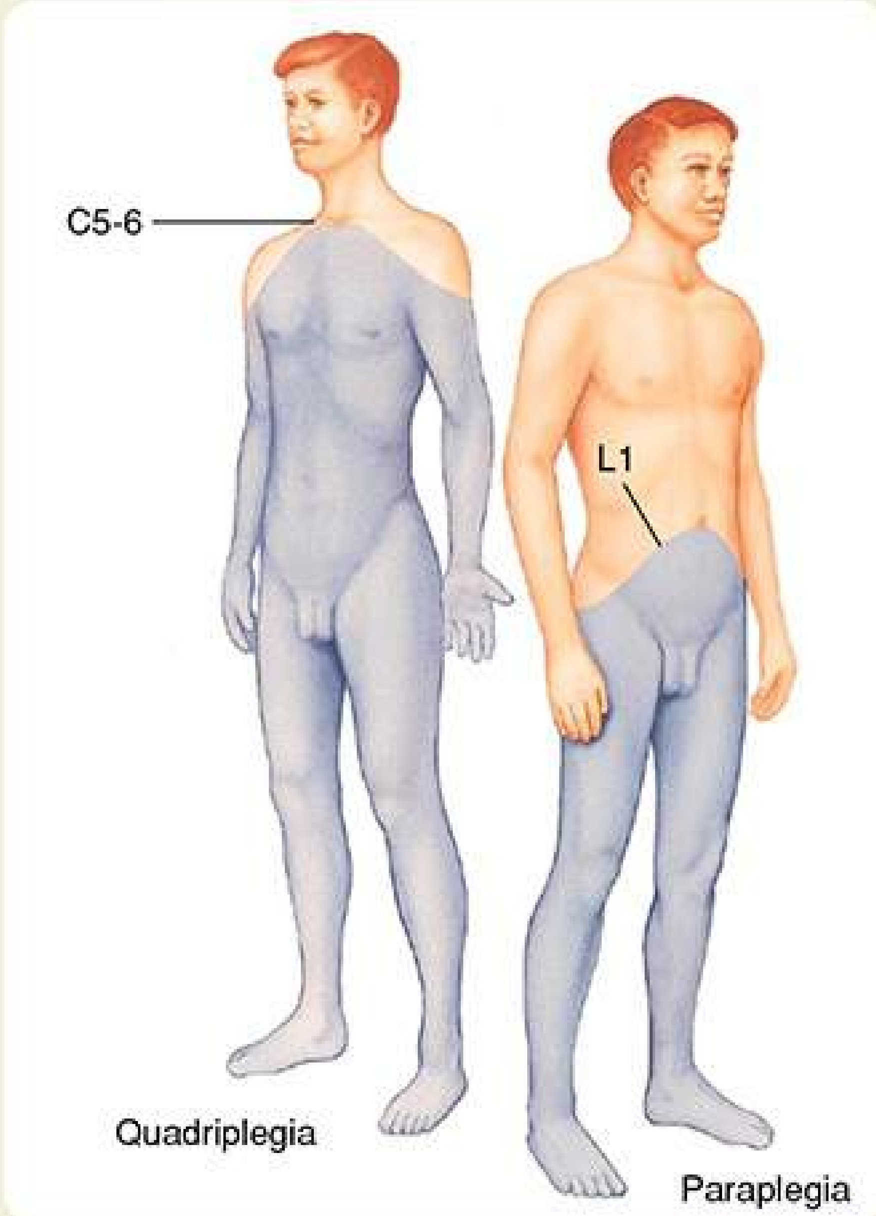

Figure 28-19 With severe spinal injuries, patients may lose sensation or experience paralysis below the suspected level of Injury.

Multiple interventions may be necessary in patients with head and spinal injuries. The effectiveness of positive-pressure ventilations, spinal immobilization, and treatments for shock may be determined only with both immediate and continuous observation after providing the intervention. If something is not working, try something else.

You have already established baseline vital signs as part of your assessment. Now is the time to compare those baseline vital signs with repeated vital signs. These changes will often tell you if treatments have been effective. For example, a dilated pupil may constrict with effective positive-pressure ventilations in an apneic head injury patient. Watch carefully for changes in the pulse, blood pressure, and respirations. If the ICP increases, the pulse may slow, blood pressure may rise, and respirations may become irregular. Document changes in the level of consciousness.

Rapid deterioration of neurologic signs following a head injury is a sign of an expanding intracranial hematoma or rapidly progressing brain swelling. You will notice a deterioration in a conscious patient's awareness of time, place, and person (self), in that order. You must act quickly to evaluate and treat these patients. The trauma patient with signs and symptoms of head injury who also displays signs of shock may have blood loss in another body cavity if hemorrhage is not seen externally. Neurogenic shock due to spinal cord injury without hemorrhage may also cause hypotension.

As discussed earlier, the appearance of clear or pink watery CSF from the nose, the ear, or an open scalp wound indicates that the dura and the skull have both been penetrated. You should make no attempt to pack the wound, ear, or nose in this situation. Cover the scalp wound, if there is one, with sterile gauze to prevent further contamination, but do not bandage it tightly.

Your local protocol for treatment of a suspected head injury should include the administration of high-flow oxygen and the application of a cervical collar, if indicated, as part of spinal immobilization. Reassessment should take place as the patient is transported to an appropriate trauma facility. Monitor the patient's condition and vital signs and relay this information to the receiving facility, especially if there is a significant or noteworthy change.

Special Populations

Infants, children, and adults may all have enough blood loss due to scalp lacerations to produce shock; however, this is more common in infants than in older children and adults. Provide oxygen, monitor the airway, treat for shock, and provide immediate transport.

A common response to head injuries, even among children with only very slight head injuries, is vomiting. This is sometimes the result of increased intracranial pressure. In managing such vomiting, pay particular attention to protecting the patient's airway.

When providing care for patients with suspected head and spinal injuries, it is essential to maintain good communication with other providers and give complete and detailed information to the destination facility. Key observations you relay help in the assessment and eventual treatment of your patient. Hospitals may better prepare for seriously injured patients with more advanced warning and a description of the most serious problems found during your assessment, and additional resources can be made available when you arrive. For example, a helicopter may be standing by for transport from a smaller hospital to a Level I trauma center. Larger hospitals may have trauma specialists or neurosurgeons available to meet you on arrival.

Your documentation should include the history you were able to obtain at the scene, your findings during your assessment, treatments you provided, and how the patient responded to them. How frequently you document repeat vital signs depends on the condition of your patient. More seriously injured patients should have documented vital signs every 5 minutes, whereas more stable patients should have documented vital signs every 15 minutes. Always follow local protocols. Take time after your verbal report to hospital staff to sit and make a complete and accurate record of the situation. This will be your only accepted legal memory of the call.

Many events that cause spinal or head injuries may eventually result in some type of litigation. As with all responses, proper documentation of what you observed and the treatment provided will be beneficial as time passes. You may be requested to testify as a witness at incidents years later, and proper and complete documentation recorded at the time of the incident will lay the framework for answering any questions that may be asked of you.

Emergency Medical Care of Head Injuries

Treat the patient with a head injury according to three general principles that are designed to protect and maintain the critical functions of the central nervous system:

1. Establish an adequate airway. If necessary, begin and maintain ventilation and provide supplemental oxygen.
2. Control bleeding, and provide adequate circulation to maintain cerebral perfusion. Begin cardiopulmonary resuscitation (CPR), if necessary. Be sure to follow standard precautions.
3. Assess the patient's baseline level of consciousness, and continuously monitor it.

As you continue to treat the patient, do not apply pressure to an open or compressed skull injury. In addition, you must assess and treat other injuries, dress and bandage open wounds as indicated in the treatment of soft-tissue injuries, splint fractures, anticipate and manage vomiting to prevent aspiration, be prepared for convulsions and changes in the patient's condition, and transport the patient promptly and with extreme care.

Managing the Airway

The most important step in the treatment of patients with head injury, regardless of the severity, is to establish an adequate airway. If the patient has an airway obstruction, perform the jaw-thrust maneuver to open the airway. Once the airway is open, maintain the head and cervical spine in a neutral, in-line position until you have placed a cervical collar and have secured the patient on a backboard **Figure 28-20**. Remove any foreign bodies, secretions, or vomitus from the airway. Make sure a suctioning unit is available, because you will often need to clear blood, saliva, or vomitus from the airway.

Once you have cleared the airway, check ventilation. If the respiratory control center of the brain has been injured, the rate and/or depth of breathing may be ineffective. Ventilation may also be limited by chest injuries or, if the spinal cord is injured, by paralysis of some or all of the muscles of respiration. Give supplemental oxygen to any patient with suspected head injury, particularly anyone who is having trouble breathing. This reduces hypoxia and possible cerebral edema. An injured brain is even less tolerant of hypoxia than a healthy brain, and studies have shown that supplemental oxygen can reduce brain damage; to be effective, however, it must be started as soon as possible. Do not wait until the patient becomes cyanotic. Continue to assist ventilations and administer supplemental oxygen until the patient reaches the hospital.

Figure 28-20 **A.** Maintain the head and cervical spine in a neutral in-line position. **B.** Apply a cervical collar as you finish the primary assessment.

▶ Circulation

If the heart is not beating, providing airway maintenance, ventilation, and oxygen accomplishes nothing. You must also begin CPR if the patient is in cardiac arrest.

Active blood loss aggravates hypoxia by reducing the available number of oxygen-carrying red blood cells. Although scalp lacerations rarely cause shock except in infants and children, they often cause the loss of large volumes of blood, which must be controlled. Bleeding inside the skull may cause the ICP to rise to life-threatening levels, even though the actual volume of blood loss inside the skull is relatively small.

You can almost always control bleeding from a scalp laceration by applying direct pressure over the wound. Remember to follow standard precautions. Use a dry, sterile dressing, folding any torn skin flaps back down onto the skin bed before applying pressure **Figure 28-21A**. In some instances, you will have to apply firm compression for several minutes to control bleeding **Figure 28-21B**. If you suspect a skull fracture, do not apply excessive pressure to the open wound. Otherwise, you may increase the ICP or push bone fragments into the brain. Bandages should not cover the mastoid process so that any apparent or developing sign of a basilar skull fracture still can be seen. If the bandage covers the patient's ears, remember that communication may become difficult because the patient's ability to hear will be decreased. To avoid limiting access to the patient's airway, do not cover the patient's mouth, nose, or jaw.

If the dressing becomes soaked, do not remove it. Instead, place a second dressing over the first. Continue applying manual pressure until the bleeding has been controlled, then secure the dressing in place with a soft, self-adhering roller bandage **Figure 28-21C**.

Shock that develops in a patient with a head injury is usually the result of hypovolemia caused by bleeding from other injuries. As with other trauma patients, shock in these cases indicates that the situation is critical. Such patients must be transported immediately to a trauma center. Maintain the airway while you protect the patient's cervical spine, ensure adequate ventilation, administer 100% oxygen, control obvious sites of bleeding with direct pressure, place the patient supine on a backboard, keep the patient warm, and provide immediate transport.

If the patient becomes nauseated or begins to vomit, elevate one side of the backboard to prevent aspiration. Be sure to maintain the head in the in-line neutral position, with the cervical collar in place. You should also have a suctioning unit available.

Cushing Triad

If the patient's head injuries are significant enough to cause a traumatic brain injury, the patient may begin to exhibit the signs of Cushing triad: increased blood pressure (hypertension), decreased heart rate (bradycardia), and irregular respirations such as Cheyne-Stokes respiration and Biot respiration. Cushing triad is also referred to as a herniation syndrome where the intracranial pressure is so great that it forces the brain stem and the midbrain through the foramen magnum, the hole at the base of the skull. If this process is allowed to continue, it is a fatal injury. If the patient exhibits these signs, it is commonly acceptable to perform controlled hyperventilation of your patient via positive-pressure ventilations at a rate of 20 breaths/min for adults. If capnography monitoring is in place, assisted ventilations can be delivered to target a goal $ETCO_2$ level of 30 to 35 mm Hg. Follow local protocols and your medical direction in regard to hyperventilation in the presence of herniation.

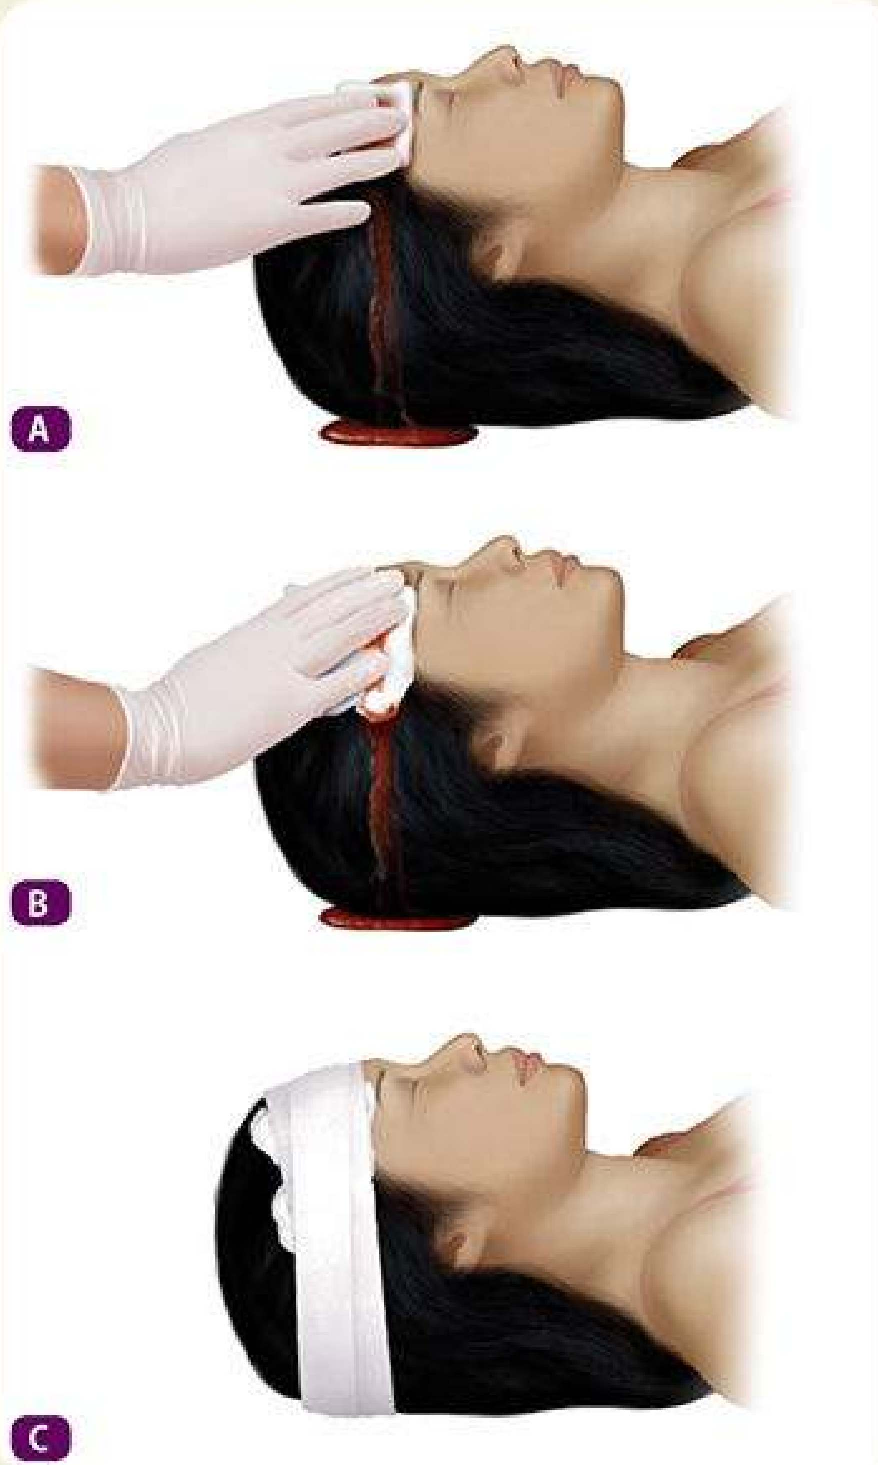

Figure 28-21

A. Use a dry sterile dressing to fold torn skin flaps back down onto the skin bed before applying pressure. **B.** If you do not suspect an open brain injury or skull fracture, apply firm compression for several minutes to control the bleeding. **C.** Secure the compression dressing in place with a soft, self-adhering roller bandage.

Words of Wisdom

Hypoxemia is one of the key indicators along with hypotension of a poor outcome in patients with traumatic brain injuries.

Emergency Medical Care of Spinal Injuries

Emergency medical care of a patient with a possible spinal injury begins, as does all patient care, with your protection; therefore, you must remember to follow standard precautions. Next, you must maintain the patient's airway while manually keeping the spine in the proper position, assess respirations, and give supplemental oxygen.

Managing the Airway

Knowing that improper handling of a spinal injury can leave a patient permanently paralyzed must not prevent you from properly addressing an airway obstruction. Remember, all patients without an airway will die. If a patient with a spinal injury has an airway obstruction, perform the jaw-thrust maneuver to open the airway **Figure 28-22**. Do not use the head tilt–chin lift maneuver because it extends the neck and may further damage the cervical spine. If the patient is unconscious, you can lift or pull the tongue forward so that you do not have to move the neck. Once the airway is open, hold the head still in a neutral, in-line position until it can be fully immobilized.

After you open the airway, consider inserting an oropharyngeal airway. If your patient accepts an oropharyngeal airway, be sure to monitor the airway closely. Have a suctioning unit available because you will often need to clear away blood, saliva, or vomitus. Provide supplemental oxygen. Continuously monitor the patient's airway and be prepared for any changes in the patient's condition based on your treatment.

Immobilization of the Cervical Spine

Establishing and maintaining the airway is your first priority. You must immobilize the head and trunk so that bone fragments do not cause further damage. Even small movements cause significant injury to the spinal cord. Follow the steps in **Skill Drill 28-1**:

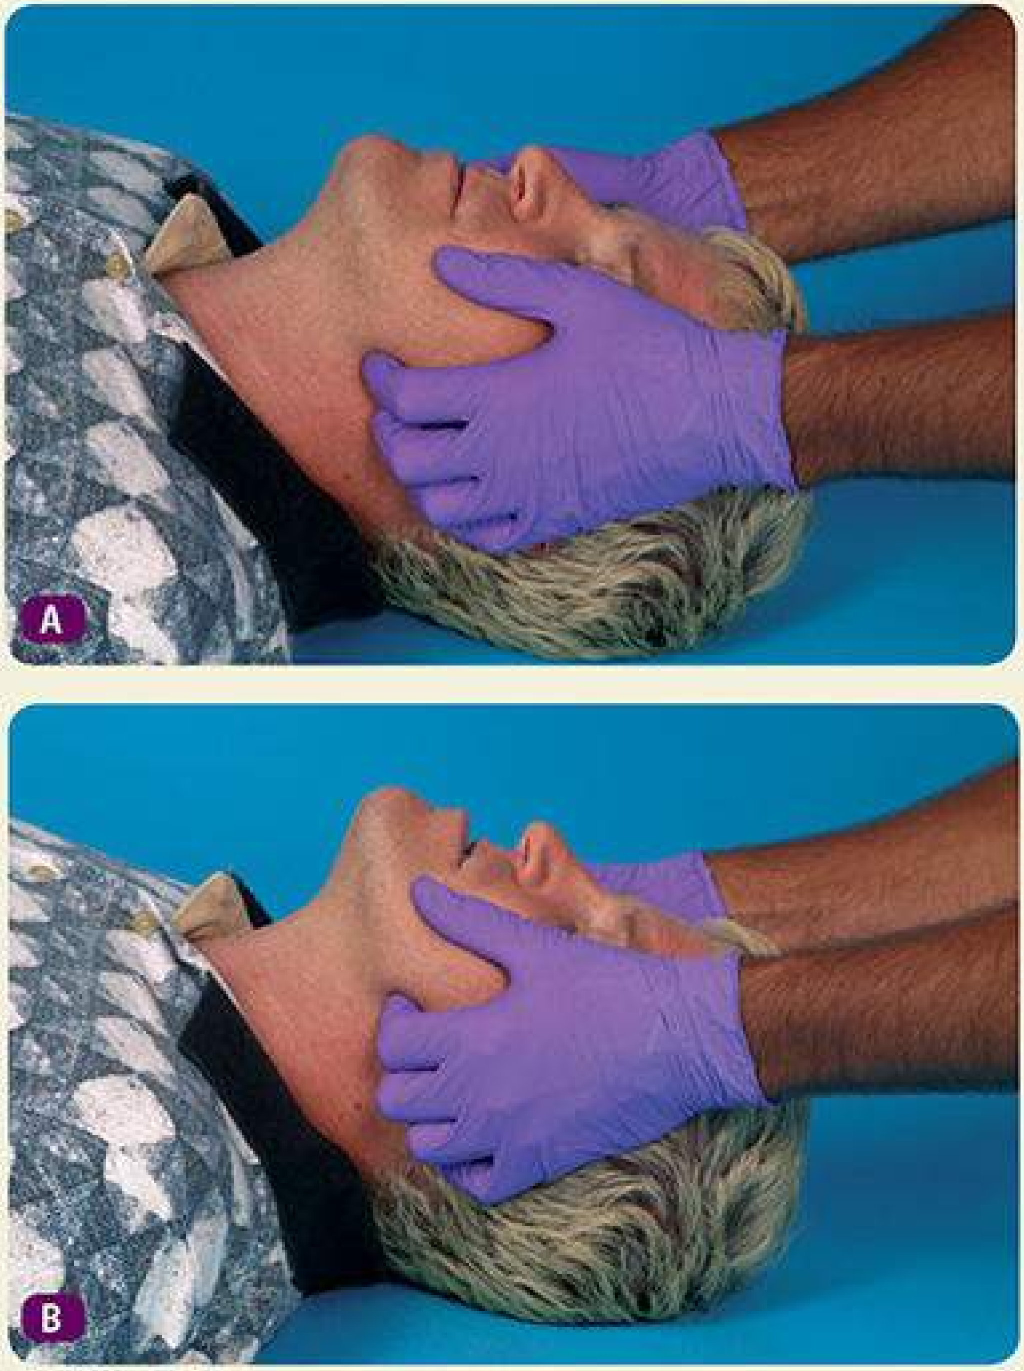

Figure 28-22 Jaw-thrust maneuver. **A.** Stabilize the neck in a neutral, in-line position. **B.** Push the angle of the lower jaw upward.

1. Take standard precautions. Begin manual in-line stabilization by holding or having someone firmly hold the head with both hands. Whenever possible, kneel at the head of the patient, and place your hands around the base of the skull on either side **Step 1**.
2. Support the lower jaw with your index and long fingers, while you are supporting the head with your palms. Then gently lift the head until the patient's eyes are looking straight ahead and the head and torso are in line. This neutral **eyes forward position** makes immobilization easier. Align the nose with the navel. Never twist, flex, or extend the head or neck excessively **Step 2**.

Skill Drill 28-1 Performing Manual In-Line Stabilization

Step 1

Take standard precautions. Kneel behind the patient and firmly place your hands around the base of the skull on either side.

Step 2

Support the lower jaw with your index and long fingers, and the head with your palms. Gently lift the head into a neutral, eyes forward position, aligned with the torso. Do not move the head or neck excessively, forcefully, or rapidly.

Step 3

Continue to manually support the head while your partner places a rigid cervical collar around the neck. Maintain manual support until you have completely secured the patient to a backboard.

3. Manually maintain this position as you continue to maintain the airway. Have your partner place a rigid cervical collar around the neck to provide more stability. Do not remove your hands from the patient's head until the patient's torso and head have been completely secured to a backboard. The patient must remain immobilized until he or she has been examined at the hospital **Step 3**.

You should never force the head into a neutral, in-line position. Do not move the head any farther if the patient reports any of the following symptoms:

- Muscle spasms in the neck
- Substantial increased pain
- Numbness, tingling, or weakness in the arms or legs
- Compromised airway or ventilations

In these situations, immobilize the patient in his or her current position.

Cervical Collars

Rigid cervical immobilization devices, or cervical collars, provide preliminary, partial support. A cervical collar should be applied to every patient who has a possible spinal injury based on the MOI, history, or signs and symptoms. Keep in mind, however, that cervical collars do not fully immobilize the cervical spine. Therefore, you must maintain manual support until the patient has been completely secured to a long or short backboard or vacuum mattress.

To be effective, a rigid cervical collar must be the correct size for the patient. The method for determining the correct size is provided by the manufacturer. Make sure you are familiar with the types of collars your service carries. The cervical collar should rest on the shoulder girdle and provide firm support under both sides of the mandible, without obstructing the airway or ventilation efforts in any way **Figure 28-23**. To apply a cervical collar, follow the steps in **Skill Drill 28-2**:

1. One EMT provides continuous manual in-line support of the head while the other EMT prepares the collar **Step 1**.
2. Measure the proper size collar according to the manufacturer's specifications. It is essential that the cervical collar fits properly. If you do not have the correct size collar, use a rolled towel around the patient's head; tape it to the backboard and provide supplemental continuous manual support **Figure 28-24** **Step 2**.
3. Begin by placing the chin support snugly underneath the chin **Step 3**.
4. Maintain head stabilization and neutral neck alignment, wrap the collar around the neck and secure the collar to the far side of the chin support **Step 4**.
5. Ensure that the collar fits properly and recheck that the patient is in a neutral, in-line position. Maintain in-line stabilization until the patient has been completely secured to the backboard **Step 5**.

Once the patient's head and neck have been manually stabilized, assess the pulse, motor, and sensory function in all extremities. Then assess the cervical spine area and neck. Keep in mind that the cervical collar is used to provide increased stability to the neck. It is used in addition to, not instead of, manual cervical stabilization. An improperly fitting collar will do more harm than good. In any case, maintain manual support until the patient has been fully secured to the backboard or vacuum mattress.

Figure 28-23 Proper fit is essential in applying a cervical collar. The collar should rest on the shoulder girdle and provide firm support under both sides of the mandible without obstructing the airway or any ventilation efforts.

Figure 28-24 If you do not have an appropriately sized cervical collar, you may use a rolled towel around the patient's head. Tape the towel to the backboard or mattress and provide continuous manual support.

Skill Drill 28-2 Application of a Cervical Collar

Step 1

Apply in-line stabilization.

Step 2

Measure the proper collar size.

Step 3

Place the chin support first.

Step 4

Wrap the collar around the neck and secure the collar.

Step 5

Ensure proper fit and maintain neutral, in-line stabilization until the patient is secured to a backboard.

Preparation for Transport

Supine Patients

A patient who is supine can be effectively immobilized by securing him or her to a long backboard or vacuum mattress. Another procedure for moving a patient from the ground to a backboard or vacuum mattress is the **four-person log roll**. In other cases, you may choose instead to slide the patient onto a backboard or vacuum mattress. The patient's condition, the scene, and the available resources will dictate the method you choose.

You should first take the necessary precautions and then direct the team from a kneeling position at the patient's head so that you can maintain manual in-line cervical immobilization. Your job is to ensure that the head, torso, and pelvis move as a unit, with your teammates controlling the movement of the body. If necessary, you may recruit bystanders to assist the team, but be sure to instruct them fully before moving the patient. To secure a patient to a backboard, follow the steps in **Skill Drill 28-3**:

1. Maintain in-line stabilization from a kneeling position at the patient's head. The EMT at the head will direct the log roll.
2. Assess pulse, motor, and sensory function in each extremity **Step 1**.
3. Apply an appropriately sized cervical collar **Step 2**.
4. The other team members should position the backboard and place their hands on the far side of the patient to increase their leverage. Instruct them to use their body weight and their shoulders and back muscles to ensure a smooth, coordinated pull, concentrating their pull on the heavier portions of the patient's body **Step 3**.
5. On command from the EMT at the head, the rescuers roll the patient toward themselves. One rescuer quickly examines the back while the patient is rolled on the side, and then slides the backboard behind and under the patient. The team rolls the patient back onto the backboard, avoiding independent rotation of the head, shoulders, or pelvis **Step 4**.
6. Ensure the patient is centered on the backboard **Step 5**.
7. Secure the upper torso to the backboard (without restricting the patient's breathing with the straps) once the patient is centered on the backboard **Step 6**. Consider padding voids between the patient and the backboard to make transport more comfortable and protect the patient.
8. Secure the pelvis and upper legs, using padding as needed. For the pelvis, use straps over the iliac crests and/or groin loops **Step 7**.
9. Begin to secure the head to the backboard by positioning a commercial immobilization device or towel rolls **Step 8**.
10. Secure the head by taping the towels across the forehead. To prevent airway problems and leave access to the airway, do not tape over the throat or chin. Avoid placing the sticky side of the tape on the patient's head. **Step 9**.
11. Check and readjust straps as needed to ensure that the entire body is snugly secured and will not slide during patient movement, but breathing is not restricted.
12. Reassess pulse, motor, and sensory function in each extremity, and continue to do so periodically **Step 10**.

> **Words of Wisdom**
>
> When utilizing a long backboard, ensure that the straps are tight enough to secure the patient but not so tight as to limit the movement of the patient's chest. Pulling the straps too tight may result in hypoventilation.

An alternative to the long backboard is to place the patient on a vacuum mattress. The vacuum mattress molds to the specific contours of the patient's body, reducing pressure point tenderness and therefore providing better comfort. The mattress also provides thermal insulation, potentially decreasing the risk of hypothermia, and is the standard equipment used to transport patients with spinal injuries in the United Kingdom. It is an excellent alternative to a backboard for older adults or patients with abnormal curvature of the spine. A drawback to the device is its thickness, requiring careful patient movement to maintain spinal stabilization during the application procedure. The vacuum mattress cannot be used for patients who weigh more than 350 pounds (159 kilograms).

Like a backboard, a vacuum mattress can be used on a supine, sitting, or standing patient.

A patient can be moved onto the vacuum mattress with a scoop stretcher or a log roll. For the scoop stretcher method, the mattress does not need to be partially rigid.

It is important to secure the patient sufficiently but without restricting the patient's breathing. If the patient is not secured sufficiently, this can cause excessive movement, increasing the risk of subsequent spinal cord injury.

Follow the steps in **Skill Drill 28-4** to immobilize a patient with a vacuum mattress:

1. Place the mattress on a flat surface near the patient. Make sure the head end of the mattress is at the patient's head **Step 1**.
2. Allow air to enter the mattress **Step 2**. The valve stem can remain open until the mattress is soft and pliable.
3. Smooth the mattress so that it is flat and level **Step 3**.
4. Remove any sharp or bulky items that may damage the vacuum mattress.
5. Connect the pump to the mattress **Step 4**.
6. Determine which method you will use to move the patient onto the mattress. If you will use the log roll method, evacuate the mattress until it is partially rigid **Step 5**. (This step is not needed if using the scoop stretcher method.) The surface should be smooth and the beads inside the mattress should be spread out as evenly as possible.

Skill Drill 28-3 Securing a Patient to a Long Backboard

Step 1

Apply and maintain manual cervical stabilization. Assess distal functions in all extremities.

Step 2

Apply a cervical collar.

Step 3

Rescuers kneel on one side of the patient and place hands on the far side of the patient.

Step 4

On command, rescuers roll the patient toward themselves, quickly examine the back, slide the backboard under the patient, and roll the patient onto the backboard.

Step 5

Center the patient on the backboard.

Step 6

Secure the upper torso first.

Step 7

Secure the pelvis and upper legs.

Step 8

Begin to secure the patient's head using a commercial immobilization device or rolled towels.

Step 9

Place tape across the patient's forehead to secure the immobilization device.

Step 10

Check all straps and readjust as needed. Reassess distal functions in all extremities.

7. Move the patient onto the vacuum mattress using one of the two methods: scoop stretcher or log roll **Step 6**. Throughout this procedure, maintain spinal alignment.
8. Scoop stretcher method (for this method, the mattress does not need to be partially rigid):
   a. Apply the scoop stretcher to the patient, then lift and transfer the patient onto the mattress.
   b. Position the patient so his or her head is in the head area of the mattress or very close to the mattress's top edge.
   c. Remove the scoop stretcher from around the patient and proceed with application of the vacuum mattress.
9. Log roll method (for this method, the mattress should be partially rigid):
   a. Place the mattress on a backboard or transfer device.
   b. Hold the mattress in place on the backboard, log roll the patient onto the backboard with the mattress on top of it. (The long backboard is used only for stabilization.)
   c. Position the patient so his or her head is very close to the top edge.
10. If the vacuum mattress is partially rigid, open the valve to allow air to enter **Step 7**. Keep the valve open until the mattress is pliable.
11. Conform the mattress to each side of the patient's head close to the shoulders, but not the top of the head **Step 8**. Continue to hold these "head blocks" that you have formed, and have a second person hold up the sides of the mattress to the patient's hips until the mattress is evacuated of air completely. Always form the mattress to meet the needs of the patient. Use additional rescuers if needed. Some patients may be more comfortable with their knees slightly bent.
12. Secure the patient's chest, hips, and legs in the mattress **Step 9**.

Skill Drill 28-4 Placing a Patient on a Full-Body Vacuum Mattress

Step 1

Place the mattress on a flat surface near the patient, with the head end of the mattress at the patient's head.

Step 2

Allow air to enter the mattress. Keep the valve stem open until the mattress is soft and pliable.

Step 3

Smooth the mattress. Remove any sharp or bulky items that may damage the mattress.

Step 4

Connect the pump to the mattress.

Step 5

Determine which method you will use to move the patient onto the mattress. If you will use the log roll method, evacuate the mattress until it is partially rigid (this step is not needed if using the scoop stretcher method). The surface should be smooth and the beads should be spread out as evenly as possible.

If using a scoop stretcher, you do not need to partially evacuate the mattress at this stage.

Step 6

Move the patient onto the vacuum mattress using the method you determined during the previous step. Maintain spinal alignment.

Step 7

If the vacuum mattress is partially rigid, open the valve to allow air to enter. Keep the valve open until the mattress is pliable.

Step 8

Conform the mattress to each side of the patient's head, close to the shoulders but not the top of the head. Continue to hold these "head blocks" that you have formed, and have a second person hold up the sides of the mattress to the patient's hips until the mattress is evacuated of air completely.

Step 9

Secure the patient's chest, hips, and legs.

Step 10

Secure the patient's head. Pad any voids at the top of the shoulders.

Step 11

Ensure the patient is as comfortable as possible, then evacuate the remaining air to achieve immobilization.

Step 12

Disconnect the vacuum pump and ensure that the valve is closed or secured.

Step 13

Reassess and adjust the straps around the chest, hips, and legs.

Step 14

Check the patient's neurovascular status and re-check all straps prior to lifting or moving the patient.

13. Secure the patient's head with medical tape **Step 10**. Pad any voids at the top of the shoulders.
14. If the patient is as comfortable as possible, evacuate the remaining air from the mattress to achieve rigid immobilization **Step 11**. (A portable suction unit can be used to evacuate some mattresses; see manufacturer recommendations.)
15. Disconnect the vacuum pump and ensure that the valve is closed or secured so the mattress is not accidentally deflated **Step 12**.
16. Reassess and adjust the straps around the chest, hips, and legs **Step 13**.
17. Check the patient's neurovascular status and re-check all straps prior to lifting or moving the patient **Step 14**.

Sitting Patients

Some patients with a possible spinal injury will be in a sitting position, such as after a vehicle crash. With these patients, you should use a short backboard or other short spinal extrication device to restrict movement of the cervical and thoracic spine. The short backboard is then secured to the long backboard.

The exceptions to this rule are situations in which you do not have time to first secure the patient to the short backboard, including the following situations:

- You or the patient is in danger.
- You need to gain immediate access to other patients.
- The patient's injuries justify urgent removal.

In these situations, your team should lower the patient directly onto a long backboard, using the rapid extrication technique as described in Chapter 8, *Lifting and Moving Patients*. Be sure that you provide manual stabilization of the cervical spine as you move the patient. Rapid extrication is indicated only in cases of life-threatening or limb-threatening injury. In all other cases, proceed with immobilization in a seated position. Follow the steps in **Skill Drill 28-5** to immobilize a sitting patient using a commercial immobilization device.

1. Take standard precautions. Take standard precautions. As with the supine patient, you must first stabilize the head and then maintain manual in-line stabilization until the patient has been secured to the long backboard or vacuum mattress.
2. Assess pulse, motor, and sensory function in each extremity.
3. Apply the cervical collar **Step 1**.

4. Insert an extrication device between the patient's upper back and the seat back **Step 2**.
5. Open the side flaps (if present), and position them around the patient's torso and snug to the armpits **Step 3**.
6. Once the extrication device has been properly positioned, secure the upper torso straps and then the mid-torso straps **Step 4**.
7. Position and fasten both groin (leg) straps. Check all torso straps to make sure they are secure. Make any adjustments necessary without excessive movement of the patient **Step 5**.
8. Pad any space between the patient's head and the extrication device as necessary.
9. Secure the forehead strap, and then fasten the lower head strap around the cervical collar **Step 6**.
10. Place the long backboard next to the patient's buttocks, perpendicular to the trunk **Step 7**.
11. Turn the patient parallel to the long backboard, and slowly lower him or her onto it.
12. Lift the patient (without rotating him or her), and slip the long backboard under the short board **Step 8**.
13. Secure the extrication device and long backboard together. Loosen or release the groin straps.
14. Reassess the pulse, motor, and sensory function in all four extremities. Document your findings, and prepare for immediate transport **Step 9**.

Standing Patients

You may arrive at a scene in which you find a patient standing or wandering around after a crash or injury. If the MOI and clinical indications suggest spinal injury, immobilize the patient to a long backboard before proceeding with assessment.

This process of immobilizing a patient found in the standing position requires three EMTs. Begin by establishing manual, in-line stabilization, and applying a cervical collar. Instruct the patient to remain still. Position the board upright directly behind the patient. The EMTs should be positioned with one on either side of the patient, and the third directly behind the patient, maintaining in-line stabilization. Next, the two EMTs at the patient's sides grasp the handholds at shoulder level or slightly above by reaching under the patient's arms. Carefully lower the patient as a unit under the direction of the EMT at the head. The EMT at the head must ensure that the patient's head stays against the board and must carefully rotate his or her hands as the patient is being lowered to maintain in-line stabilization. Remember that it is extremely uncommon for patients who are walking to have occult unstable cervical spine injuries that benefit from immobilization.

Skill Drill 28-5 Securing a Patient Found in a Sitting Position

Step 1

Take standard precautions. Stabilize the head and neck in a neutral, in-line position. Assess pulse, motor, and sensory function in each extremity. Apply a cervical collar.

Step 2

Insert an immobilization device between the patient's upper back and the seat.

Step 3

Open the side flaps, and position them around the patient's torso, snug around the armpits.

Step 4

Secure the upper torso flaps, then the mid-torso flaps.

Step 5

Secure the groin (leg) straps. Check and adjust the torso straps.

Step 6

Pad between the head and the device as needed. Secure the forehead strap and fasten the lower head strap around the cervical collar.

Step 7

Place a long backboard next to the patient's buttocks, perpendicular to the trunk.

Step 8

Turn and lower the patient onto the long backboard. Lift the patient, and slip the long backboard under the immobilization device.

Step 9

Secure the immobilization device and long backboard to each other. Loosen or release the groin straps. Reassess pulse, motor, and sensory function in each extremity.

▶Spinal Immobilization Devices

An injured spine is often very difficult to evaluate in a patient with a head injury. Sometimes, the patient has no neurologic loss. During assessment, pain in the spine may be missed because of shock or because the patient's attention is directed to more painful injuries. Evaluation is even more difficult if the patient is unconscious. Because any manipulation of the unstable cervical spine may cause permanent damage to the spinal cord, you must assume the presence of spinal injury in all patients who have sustained head injuries. Use manual in-line stabilization or a cervical collar and long backboard.

Short Backboards

There are several types of short backboards. The most common are the vest-type device **Figure 28-25** and the rigid short backboard. These devices are designed to immobilize and restrict movement of the head, neck, and torso. They are used to immobilize noncritical patients who are found in a sitting position and have possible spinal injuries.

Figure 28-25 A common short-board immobilization device is a vest-type device.

© Kendrick EMS

As described earlier in this chapter, the first step in securing a patient to a short backboard is to provide manual, in-line support of the cervical spine. Assess the pulse, motor function, and sensation in all extremities; next assess the cervical area; and then apply an appropriately sized cervical collar.

Position the device behind the patient, and secure it to the torso. Evaluate how well the torso and groin are secured, and make adjustments as necessary. Avoid excessive movement of the patient. Next, evaluate the position of the patient's head. Pad behind the head as needed to maintain neutral, in-line stabilization.

Now secure the patient's head to the device. Once the head is secured, you may release manual support of the head. Rotate or lift the patient to the long backboard. At this point, you must reassess the pulse, motor function, and sensation in all four extremities to determine whether the change in position has affected the patient's vital signs or neurologic status. Finally, you should secure the patient to the long backboard.

Long Backboards

There are several types of long backboards that provide full-body spinal immobilization **Figure 28-26**. These devices also provide motion restriction to the head, neck, torso, pelvis, and extremities. Long backboards are used to immobilize patients who are found in any position (standing, sitting, supine), sometimes in conjunction with short backboards.

Securing a patient to a long backboard was described in detail earlier in this chapter. Briefly, you should begin by providing manual, in-line support of the head. Assess pulse, motor function, and sensation in all extremities, and assess the cervical area. Then apply an appropriately sized cervical collar, and proceed as follows:

Figure 28-26 Long backboards provide full body spinal immobilization, including the head, neck, torso, pelvis, and extremities.

YOU are the Provider — PART 4

Full spinal immobilization is applied, assisted ventilations are continued, and the patient is loaded into the ambulance. An EMR from the engine company drives the ambulance so your partner can help you with the patient in the back. You begin transport to a local trauma center and reassess the patient's vital signs en route.

Recording Time: 11 Minutes	
Level of consciousness	Responsive only to deep painful stimuli
Respirations	6 breaths/min and irregular (baseline); ventilations are being assisted
Pulse	64 beats/min; regular and bounding

Skin	Pink, warm, and dry
Blood pressure	192/100 mm Hg
Spo_2	96% (on oxygen)

7. What further treatment is indicated for this patient?
8. What should you specifically monitor this patient for during transport?

1. Position the device.
2. Log roll the patient onto the device. You may also move the patient onto the device using a suitable lift or slide or by using a scoop stretcher. As you maintain in-line support, your partner should kneel by the patient's head and direct the other two EMTs as you roll the patient. Your partner's job is to make sure that the head, torso, and pelvis move as a unit. As the patient's back comes into view, quickly assess its condition if you did not do so during initial assessment. One EMT should position the device under the patient. Then, at your partner's command, roll the patient onto the backboard.
3. If there are spaces between the patient's head and torso and the backboard, fill them with padding.
4. Secure the torso to the device by applying straps across the chest, pelvis, and legs. Adjust these straps as needed. Then secure the patient's head to the board.
5. Reassess pulse, motor function, and sensation in all extremities.
6. When the patient has been properly secured, you can safely lift the backboard or turn it on its side, if necessary.

Helmet Removal

As you plan your care of a patient wearing a helmet, ask yourself the following questions:

- Is the patient's airway clear?
- Is the patient breathing adequately?
- Can you maintain the airway and assist ventilations if the helmet remains in place?
- Can the face guard be easily removed to allow access to the airway without removing the helmet?
- How well does the helmet fit?
- Can the patient move within the helmet?
- Can the spine be immobilized in a neutral position with the helmet on?

A helmet that fits well prevents the patient's head from moving and should be left on, provided (1) there are no impending airway or breathing problems, (2) it does not interfere with assessment and treatment of airway or ventilation problems, and (3) you can properly immobilize the spine. You should also leave on the helmet if there is any chance that removing it will further injure the patient.

Remove a helmet if (1) it is a full-face helmet **Figure 28-27**, (2) it makes assessing or managing airway problems difficult and removal of a face guard to improve airway access is not possible, (3) it prevents you from properly immobilizing the spine, or (4) it allows excessive head movement. Finally, always remove a helmet from a patient who is in cardiac arrest.

Sports helmets are typically open in the front and may or may not include an attached face mask. The mask can be removed without affecting helmet position or function by simply removing or cutting the straps that hold it to the helmet, thus allowing easy access to the airway **Figure 28-28**. A patient who is involved in full contact sports may be wearing bulky pads to protect various body regions, such as shoulder pads. Leaving a helmet in place whenever possible is preferred because it helps the body maintain an in-line neutral position. If the helmet is removed, be sure to provide padding to compensate for the shoulder pads and maintain in-line positioning of the body.

Preferred Method

Removing a helmet should always be at least a two-person job; however, the technique for helmet removal depends on the actual type of helmet worn by the patient. One EMT provides constant in-line support as the other EMT performs the various moves; you and your partner should not move at the same time. You should first consult with medical control, if possible, about your decision to remove a helmet. When you decide to do so, follow the steps in **Skill Drill 28-6**:

Figure 28-27 A full-face helmet, such as this motorcycle helmet, should be removed from the patient.

Figure 28-28 The mask on most sports helmets can be removed without affecting helmet position or function. **A.** Stabilize the patient's head and helmet. Remove the face mask in one of two ways: **B.** Use a trainer's tool designed for cutting retaining clips, or **C.** Unscrew the retaining clips from the face mask. **D.** After the face mask is removed, the helmet can be immobilized against the backboard and a BVM can be used effectively.

1. Begin by kneeling at the patient's head. Your partner should kneel on one side of the patient, at the shoulder area.
2. Open the face shield, if there is one, and assess the patient's airway and breathing. Remove eyeglasses if the patient is wearing them **Step 1**.
3. Stabilize the helmet by placing your hands on either side of it, with your fingers on the patient's lower jaw to prevent movement of the head. Once your hands are in position, your partner can loosen the face strap **Step 2**.
4. Once the strap has been loosened, your partner should place one hand on the patient's lower jaw at the angle of the jaw and the other behind the head at the occipital region. Once your partner's hands are in position, you may pull the sides of the helmet away from the patient's head **Step 3**.
5. Gently slip the helmet halfway off the patient's head, stopping when the helmet reaches the halfway point **Step 4**.
6. Your partner then slides his or her hand from the occiput to the back of the head. This will prevent the head from snapping back once the helmet has been completely removed **Step 5**.
7. With your partner's hand in place, remove the helmet, and stabilize the cervical spine.
8. Apply the cervical collar, and then secure the patient to the backboard.
9. With large helmets or small patients, you may need to pad under the shoulders to prevent flexion of the neck. If shoulder pads or heavy clothing are in place, you may need to pad behind the patient's head to prevent extension of the neck **Step 6**.

Skill Drill 28-6 Removing a Helmet

Step 1

Kneel at the patient's head with your partner at one side. Open the face shield to assess airway and breathing. Remove eyeglasses if present.

Step 2

Prevent head movement by placing your hands on either side of the helmet and fingers on the lower jaw. Have your partner loosen the strap.

Step 3

Have your partner place one hand at the angle of the lower jaw and the other at the occiput.

Step 4

Gently slip the helmet about halfway off, then stop.

Step 5

Have your partner slide the hand from the occiput to the back of the head to prevent the head from snapping back.

Step 6

Remove the helmet and stabilize the cervical spine. Apply a cervical collar and secure the patient to a long backboard. Pad as needed to prevent neck flexion or extension.

Alternate Method

An alternate method for removal of football helmets has also been used. The advantage of this method is that it allows the helmet to be removed with the application of less force, therefore reducing the likelihood of motion occurring at the neck. The disadvantage of this method is that it is slightly more time consuming. The first step involves removal of the chin strap. This can be cut or carefully unsnapped. Be careful during removal of the chin strap to avoid jarring the neck or head and causing excessive motion. Next, remove the face mask. The face mask is anchored to the helmet by plastic clips (loop straps) secured by screws. These can be removed with a screwdriver or cut with a knife. After the face mask has been removed, the jaw pads can be popped out of place. This can be accomplished with the use of a tongue depressor **Figure 28-29A**. You can then place your fingers inside the helmet, allowing greater control of the helmet during removal as the helmet is gently rocked back off the top of the head. The person at the side of the patient controls the head by holding the jaw with one hand and the occiput with the other **Figure 28-29B**. Padding is inserted behind the occiput to prevent neck extension. If the shoulder pads are in place, appropriate padding must be placed behind the head to prevent hyperextension. As with the previously described method, the person at the side of the patient's chest is responsible for making sure that the head and neck do not move during removal of the helmet.

Remember that small children may require additional padding to maintain the in-line neutral position. Children are not small adults. They have smaller airways and proportionally larger heads, so padding is important to maintain the airway. Pad under the shoulders to the toes, as needed, to avoid excessive neck flexion **Figure 28-30**. In addition, place blanket rolls between the child and the sides of an adult-sized backboard to prevent the child from slipping to one side or the other **Figure 28-31**. Appropriately sized backboards are available for children.

Special Populations

You are likely to find infants and children who have been in motor vehicle crashes and are still in their car seats. Follow your local protocols regarding spinal immobilization techniques. See Chapter 34, *Pediatric Emergencies*, for a complete discussion on removing pediatric patients from car seats and performing spinal stabilization maneuvers.

YOU are the Provider — PART 5

Your partner continues to assist the patient's ventilations while you reassess his condition and vital signs. His Glasgow Coma Scale score remains unchanged from the previous readings. You call the trauma center to give your radio report and advise the center of your estimated time of arrival.

Recording Time: 16 Minutes	
Level of consciousness	Responsive only to deep painful stimuli
Respirations	6 breaths/min and irregular (baseline); ventilations are being assisted
Pulse	70 beats/min; regular and bounding
Skin	Pink, warm, and dry
Blood pressure	188/98 mm Hg
Spo_2	98% (on oxygen)

You deliver the patient to the emergency department and give your verbal report to the attending physician. After further assessment and treatment in the emergency department, the patient is taken to radiology for a CT scan, which reveals an epidural hematoma.

9. What is an epidural hematoma?

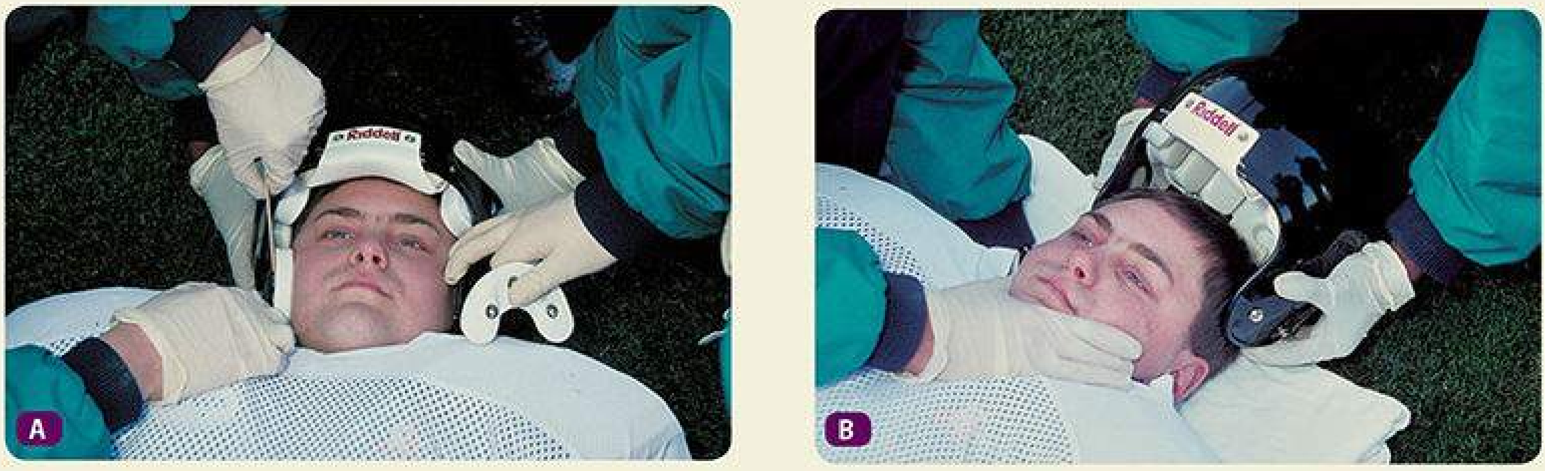

Figure 28-29 **A.** The jaw pads can be removed from the inside of a football helmet with the aid of a tongue depressor. **B.** Place the fingers inside the helmet and gently rock it out of place. The person at the side controls the lower jaw with one hand and the occiput with the other. Insert padding behind the occiput to prevent neck extension.

Figure 28-30 Children have proportionately larger heads than adults, so you may need to place padding under the shoulders to avoid excessive flexion of the head.

Figure 28-31 Place blanket rolls between the child and the sides of an adult-sized backboard to prevent the child from slipping to one side or the other.

YOU are the Provider — SUMMARY

1. Why is the structure of the cranium considered to be a mixed blessing in terms of blood flow, oxygen levels, and swelling?

The cranium does an excellent job of protecting the brain from direct trauma following minor injuries. The hard shell of the cranium provides protection for the brain from the bumps and blows that occur as a part of everyday life. However, the very fact that the cranium is a hard shell makes it a mixed blessing following a significant head injury. The cranium's rigid, unyielding structure allows little, if any, expansion of the brain. Furthermore, its hard and somewhat irregular internal surface can injure the brain and its blood vessels following significant head trauma.

2. What is the difference between a primary and a secondary brain injury?

A traumatic brain injury (TBI) can be classified into two categories: primary (direct) injury and secondary (indirect) injury.

Primary brain injury is injury to the brain and its associated structures that occurs immediately on impact to the head. It can occur following a penetrating injury, such as a stabbing, a gunshot wound, or if a bone fragment is driven into the brain following a skull fracture; however, it more commonly occurs following blunt force trauma.

Secondary brain injury refers to the after effects of the primary head injury. It includes abnormal processes such as cerebral edema, increased intracranial pressure (ICP), cerebral ischemia and hypoxia, and infection. Secondary brain injury can occur anywhere from a few minutes to several days following the initial head injury.

3. What are your most immediate treatment priorities for this patient?

As with any patient, your initial treatment must focus on what will kill him or her first. Your patient's breathing rate and quality—slow and irregular—is not adequate and requires immediate treatment. You should instruct your partner to stabilize the patient's head with his knees while he assists the patient's ventilations with a BVM and high-flow oxygen. If a law enforcement officer is available, ask him or her to stabilize the patient's head while your partner assists his ventilations.

Consider inserting a simple airway adjunct. If the patient does not have a gag reflex, insert an oropharyngeal (oral) airway. Use of a nasopharyngeal (nasal) airway should be avoided in patients with a head injury, especially if you observe fluid drainage from the nose. This sign could indicate a mid-face fracture, in which case a nasal airway could inadvertently penetrate the brain. If a simple airway adjunct is not an option, keep the airway open with the jaw-thrust maneuver and maintain the patient's head in a neutral position.

While your partner is managing the patient's airway, you should control the bleeding from the laceration to his head. Use just enough pressure to control the bleeding; if a skull fracture is present, too much pressure could drive fractured bone fragments into his brain. Quickly scan the rest of the patient's body for any other external bleeding and control it as well. Remember the objective of the primary assessment: find it, fix it, and move on.

4. Where should you focus your secondary assessment of this patient?

When the patient is unconscious or has experienced a significant mechanism of injury, the entire body should be assessed to look for life-threatening injuries that were not grossly apparent in the primary assessment. If immediate threats to the patient's life are found, they should be treated immediately.

Emphasis should be placed on the patient's head and face because this area appears to be where the patient experienced the most injury. Assess the integrity of the skull by gently palpating it and noting any areas of deformity, crepitus, or instability. Although you have already bandaged the laceration on the patient's head, you should reassess the bandage to ensure that the bleeding is controlled.

Look in the ears for fluid drainage and look behind the ears for Battle sign. Fluid or blood drainage from the ears may contain cerebrospinal fluid which would indicate a basilar skull fracture.

Assess the size, equality, and reactivity of the patient's pupils. The nerves that control the dilation and constriction of the pupils are very sensitive to ICP. Normally, both pupils should briskly constrict when a light is shone into either of the eyes. Pupils that are sluggish (slow) to react could indicate early increased ICP and/ or cerebral hypoxia. Unequal or bilaterally fixed and dilated (blown) pupils are later, more ominous signs of increased ICP and indicate pressure on one or both oculomotor nerves.

Palpate the facial bones for stability and note any deformities or crepitus.

Patients with a significant head injury should also be assumed to have a cervical spine injury until proven otherwise. Blunt force trauma that is significant enough to render the patient unconscious could easily fracture a cervical vertebra. Palpate the cervical spine for obvious deformities and then apply a cervical collar. Manually stabilize the patient's head until full spinal immobilization has been achieved (cervical collar, backboard, straps, head blocks).

Your secondary assessment of any critically injured patient should not take an exorbitant amount of time. Address only life-threatening injuries and remain focused on preparing the patient for immediate transport.

5. What is this patient's Glasgow Coma Scale score?

Your patient opens his eyes in response to painful stimuli; therefore, you should assign a score of 2 for eye opening. He is making unrecognizable sounds; therefore, you should assign a score of 2 for verbal response. You noted that his arms were flexed and drawn in toward his body (decorticate posturing); therefore, you should assign a score of 3 for motor response. Based on these findings, the patient's present Glasgow Coma Scale (GCS) score is 7, which indicates a severe traumatic brain injury.

6. What is the likely explanation for the patient's vital signs?

Your patient's current vital signs represent a classic trio of findings in patients with a traumatic brain injury and increased ICP. Hypertension, bradycardia, and irregular respirations—called Cushing triad—indicate significant cerebral edema and increased ICP.

A predictable response of the injured brain is swelling; this causes cerebral edema and a decrease in cerebral perfusion pressure (CPP) because there is little room in the cranium for the brain to swell. In an attempt to maintain cerebral blood flow, and thus CPP, arterial blood pressure increases, which presents with hypertension, and the cerebral blood vessels dilate. Bradycardia occurs as a reflex response to the increase in the patient's blood pressure.

Pressure on the respiratory centers of the brainstem causes a variety of abnormal respiratory patterns. Irregular respirations—slow or fast—are the third component of Cushing triad. Cheyne-Stokes respirations are characterized by a pattern of rapid breathing (tachypnea), followed by slow breathing (bradypnea), and periods of apnea. Central neurogenic hyperventilation is characterized by deep, rapid breathing; this pattern is similar to Kussmaul respirations, but without an acetone breath odor. Biot respirations, also called ataxic respirations, are characterized by an irregular rate, pattern, and depth of breathing with intermittent periods of apnea.

7. What further treatment is indicated for this patient?

Continue to ensure adequate oxygenation and ventilation and take steps to decrease the ICP and maximize cerebral blood flow. Continue to assist the patient's ventilations; however, do not hyperventilate him. Hyperventilation with high-flow oxygen constricts the blood vessels in the brain, and while this may cause a slight decrease in the ICP, it also pushes oxygenated blood away from the brain, potentially causing a decrease in cerebral perfusion pressure and further brain injury.

Consider elevating the head of the backboard to a 30-degree angle to reduce the ICP. Elevating the backboard greater than 30 degrees however, may cause blood (and oxygen) to leave the brain by gravity, thus causing a decrease in cerebral perfusion, and should be avoided.

Notifying the receiving facility early is critical in the treatment of a patient with a traumatic brain injury. Report your findings, any treatment that you provided, the patient's response to your treatment, and your estimated time of arrival. This will allow the receiving facility adequate time to prepare to receive the patient.

8. What should you specifically monitor this patient for during transport?

The importance of reassessing the brain-injured patient cannot be overemphasized. Patients with increased ICP commonly vomit and experience seizures. Be prepared to turn the backboard to the side and suction the patient's airway if vomiting occurs. If the patient experiences a seizure, continue to assist his ventilations and do not attempt to restrain him.

Carefully and frequently monitor the patient's vital signs, specifically, the blood pressure and oxygen saturation. A single episode of hypotension (a systolic BP of less than 90 mm Hg) in the adult with a traumatic brain injury is associated with a significant increase in mortality because it causes a decrease in cerebral perfusion. A single drop in the patient's oxygen saturation to below 90% is also associated with a significant increase in mortality; ensure the continual delivery of high-flow oxygen and adequate ventilation!

Frequently reassess the patient's GCS score and pupils, and observe for signs of brain herniation. If directed by local protocol or online medical control, ventilate the patient at a rate of 20 breaths/min if signs of brain herniation are observed.

If possible, request an ALS ambulance at the scene, if it does not delay your scene time, or consider an ALS intercept during transport, provided that it does not cause a delay in transport. The most important intervention for the patient with a traumatic brain injury, however, is to rapidly transport him or her to a definitive care facility as soon as possible.

9. What is an epidural hematoma?

Your patient was diagnosed with an epidural hematoma, which is an accumulation of blood between the skull and dura mater. An epidural hematoma is almost always the result of a blow to the head that produces a fracture of the thin temporal bone (recall that the patient had a compressed area over the temporal region of his skull). The middle meningeal artery courses along the groove in the temporal bone, so it is prone to laceration or rupture when the temporal bone is fractured. When this occurs, brisk arterial bleeding will result in rapidly progressing symptoms. The patient with an epidural hematoma typically has an immediate loss of consciousness; this may be followed by a brief return of consciousness (lucid interval), after which the patient's level of consciousness rapidly declines and he or she manifests with signs and symptoms of increasing ICP. *This is consistent with how your patient presented*.

Narrative

Medic 11 dispatched to a nightclub for a male patient who was assaulted. En route, law enforcement personnel, who were present at the scene, advised that the patient was struck in the side of the head with a baseball bat and was unconscious. On arrival at the scene, found the patient, a 22-year-old male, lying supine on the ground; a large pool of blood was under his head. He was motionless and his breathing appeared slow and irregular. Manual c-spine stabilization was initiated immediately and the patient's airway was opened with the jaw-thrust maneuver. Primary assessment revealed that he was responsive only to deep painful stimuli. His airway was clear of secretions or foreign bodies, his breathing was slow and irregular, and he was bleeding from a large laceration to the temporal region of his skull. The patient's gag reflex was intact, so an oral airway was not inserted. A nasal airway was avoided because of the potential for occult skull fracture. Patient's ventilations were assisted with a BVM and high-flow oxygen, and bleeding from the scalp laceration was controlled with a light pressure dressing. Secondary assessment revealed no gross trauma to the rest of the body. Assessment of the head revealed a depression over the area of the laceration. Pupils were bilaterally dilated and sluggish to react to light. There was no evidence of Battle sign or fluid drainage from the ears or nose. Facial bones were stable. Initial GCS score of 7 was assigned (eye opening, 2; verbal response, 2; motor response, 3). Engine company 4 arrived to provide assistance; as they retrieved spinal immobilization equipment, initial vital signs were obtained. Applied full spinal immobilization, loaded patient into ambulance, and began transport. EMR from assisting engine company drove the ambulance because of patient care demands that required two EMTs. En route to the hospital, reassessed vital signs and elevated the head end of the backboard to a 30-degree angle. Continued to assist ventilations at a rate of 10 breaths/min and noted that ventilations consistently produced adequate chest rise. Oxygen saturation remained greater than 95%. Notified trauma center of the patient's condition and our estimated time of arrival. Reassessment revealed no change in patient's condition; he remained responsive only to deep painful stimuli and his GCS score remained at 7. Pupils remained bilaterally dilated and sluggish to react to light. Delivered patient to emergency department and gave verbal report to attending physician. Medic 11 cleared the hospital and returned to service at 0256.**End of report**

Prep Kit

Ready for Review

- The nervous system of the human is divided into two anatomic parts: the central nervous system and the peripheral nervous system.
- The central nervous system is composed of the brain and the spinal cord; the peripheral nervous system includes a network of nerve fibers, like cables, that transmit information to and from the body's organs to and from the brain.
- The central nervous system is well protected by bony structures; the brain is protected by the skull and the spinal cord is protected by the bones of the spinal column.
- The central nervous system is also covered and protected by three layers of tissue called the meninges. The layers are called the dura mater, the arachnoid, and the pia mater.
- A head injury is a traumatic injury to the head that may result in injury to soft tissue, bony structures, or the brain.
- A traumatic brain injury is a severe head injury that can be a life threat or leave the patient with life-altering injuries.
- The cervical, thoracic, and lumbar portions of the spinal column can be injured through compression such as in a fall, unnatural motions such as overextension from trauma, pulling forces such as from a hanging, or a combination of mechanisms. Each of these may also cause injury to the spinal cord encased in these regions of bone, causing permanent neurologic injury or death.
- Motor vehicle crashes, direct blows, falls from heights, assault, and sports injuries are common causes of spinal injury. A patient who has experienced any of these events may have also sustained a head injury.
- Treat the patient with a head injury according to three general principles that are designed to protect and maintain the critical functions of the central nervous system: establish an adequate airway, control bleeding, and reassess the patient's baseline level of consciousness.
- Treat the patient with a spinal injury by maintaining the airway while keeping the spine in proper alignment, assess respirations, and give supplemental oxygen.
- In those situations in which your patient has problems with the ABCs or has other conditions for which you decide a rapid transport to the hospital is needed, rapid immobilization of the spine and quick loading into the ambulance may be indicated. Reduction of on-scene time and recognition of a critical patient increases the patient's chances for survival or a reduction in the amount of irreversible damage.
- Infants and young children are more susceptible to shock. Provide oxygen, monitor the airway, treat for shock, and provide immediate transport.
- Older people are at higher risk for a subdural hematoma developing. Signs and symptoms of the condition may not occur for several hours,days, or weeks. Be sure to get a thorough history of any previous trauma.

Vital Vocabulary

anterograde (posttraumatic) amnesia Inability to remember events after an injury.

axial loading injuries Injuries in which load is applied along the vertical or longitudinal axis of the spine, which results in load being transmitted along the entire length of the vertebral column; for example, falling from a height and landing on the feet in an upright position.

basilar skull fractures Usually occur following diffuse impact to the head (such as falls, motor vehicle crashes); generally result from extension of a linear fracture to the base of the skull and can be difficult to diagnose with a radiograph.

Battle sign Bruising behind an ear over the mastoid process that may indicate a skull fracture.

cerebral edema Swelling of the brain.

closed head injury Injury in which the brain has been injured but the skin has not been broken and there is no obvious bleeding.

concussion A temporary loss or alteration of part or all of the brain's abilities to function without actual physical damage to the brain.

coup-contrecoup injury Dual impacting of the brain into the skull; coup injury occurs at the point of impact; contrecoup injury occurs on the opposite side of impact, as the brain rebounds.

epidural hematoma An accumulation of blood between the skull and the dura mater.

eyes forward position A head position in which the patient's eyes are looking straight ahead and the head and torso are in line.

four-person log roll The recommended procedure for moving a patient with a suspected spinal injury from the ground to a long backboard or other spinal immobilization device.

intervertebral disk The cushion that lies between two vertebrae.

intracerebral hematoma Bleeding within the brain tissue (parenchyma) itself; also referred to as an intraparenchymal hematoma.

intracranial pressure (ICP) The pressure within the cranial vault.

involuntary activities Actions of the body that are not under a person's conscious control.

linear skull fractures Account for 80% of skull fractures; also referred to as nondisplaced skull fractures; commonly occur in the temporal-parietal region of the skull; not associated with deformities to the skull.

meninges Three distinct layers of tissue that surround and protect the brain and the spinal cord within the skull and the spinal canal.

open head injury Injury to the head often caused by a penetrating object in which there may be bleeding and exposed brain tissue.

primary (direct) injury An injury to the brain and its associated structures that is a direct result of impact to the head.

raccoon eyes Bruising under the eyes that may indicate a skull fracture.

retrograde amnesia The inability to remember events leading up to a head injury.

secondary (indirect) injury The after effects of the primary injury; includes abnormal processes such as cerebral edema, increased intracranial pressure, cerebral ischemia and hypoxia, and infection; onset is often delayed following the primary brain injury.

subarachnoid hemorrhage Bleeding into the subarachnoid space, where the cerebrospinal fluid circulates.

subdural hematoma An accumulation of blood beneath the dura mater but outside the brain.

traumatic brain injury (TBI) A traumatic insult to the brain capable of producing physical, intellectual, emotional, social, and vocational changes.

voluntary activities Actions that we consciously perform, in which sensory input or conscious thought determines a specific muscular activity.

Assessment *in Action*

You are called to an automotive body shop for an assault patient. Law enforcement personnel have arrived and declared the scene safe. You and your partner find a 44-year-old man seated in an office holding the left side of his head. According to bystanders, the patient was struck on the side of his head with a tire iron during a dispute with another employee. He was unconscious for approximately 3 minutes.

1. While performing a secondary assessment of the patient you find a depressed area above the patient's left ear. This indicates that the patient could have:

   A. an intracerebral hemorrhage.
   B. a subdural hematoma.
   C. a subarachnoid hemorrhage.
   D. an epidural hematoma.

2. Your transport time to the appropriate hospital is going to be 30 minutes. What support should you call for, based on your assessment and findings?

   A. Additional drivers
   B. An ALS intercept
   C. A police escort
   D. Another transport unit

3. When you secure this patient to a backboard, what area of the body should you secure last?

   A. Head
   B. Upper torso
   C. Pelvis
   D. Lower legs

4. During transport, the patient has a loss of consciousness. The time between the two periods of unconsciousness is referred to as the:

A. lucid interval.
B. recognition period.
C. danger zone.
D. coherent stage.

5. Which of the following describes the initial signs of a head injury?

   A. Runny nose and watering eyes
   B. Decreased level of consciousness, confusion, nausea
   C. Dizziness and coughing
   D. Decrease in blood pressure, pulse, and respirations

6. During transport when you reassess the patient you find the left pupil dilated and fixed. What does this indicate?

   A. Decreased blood pressure
   B. Increased blood pressure
   C. Increased intracranial pressure
   D. Drug abuse

7. An epidural hematoma is nearly always the result of a blow to the head that produces a linear fracture in what region of the cranium?

   A. Frontal
   B. Parietal
   C. Occipital
   D. Temporal

8. Discuss the pathophysiology of an epidural hematoma and a subdural hematoma.
9. Explain the difference between a primary (direct) brain injury and a secondary (indirect) brain injury.
10. What actions should you take to help prevent secondary brain injuries?

CHAPTER 29

Chest Injuries

National EMS Education Standard Competencies

Trauma

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

Chest Trauma

Recognition and management of

› Blunt versus penetrating mechanisms (pp 1034–1036, 1041–1048)
› Open chest wound (pp 1034–1036)
› Impaled object (pp 1034–1036)

Pathophysiology, assessment, and management of

› Blunt versus penetrating mechanisms (pp 1034–1040)
› Hemothorax (pp 1036–1040, 1044)
› Pneumothorax (pp 1036–1042)
  • Open (pp 1036–1042)
  • Simple (pp 1036–1040, 1042–1043)
  • Tension (pp 1036–1040, 1043–1044)
› Cardiac tamponade (pp 1036–1040, 1045)
› Rib fractures (pp 1036–1040, 1045)
› Flail chest (pp 1036–1040, 1045–1046)
› Commotio cordis (pp 1036–1040, 1047–1048)

Knowledge Objectives

1. Explain the mechanics of ventilation in relation to chest injuries. (pp 1033–1034)
2. Describe the differences between an open and closed chest injury. (pp 1034–1035)

3. Recognize the signs of chest injury. (pp 1035–1036)
4. Describe the management of a patient with a suspected chest injury, including pneumothorax, hemothorax, cardiac tamponade, rib fractures, flail chest, pulmonary contusion, traumatic asphyxia, blunt myocardial injury, commotio cordis, and laceration of the great vessels. (pp 1041–1048)
5. Recognize the complications that can accompany chest injuries. (pp 1041–1048)
6. Explain the complications of a patient with an open pneumothorax (sucking chest wound). (pp 1041–1042)
7. Differentiate between a pneumothorax (open, simple, and tension) and hemothorax. (1041–1044)
8. Describe the complications of cardiac tamponade. (p 1045)
9. Describe the complications of rib fractures. (p 1045)
10. Describe the complications of a patient with a flail chest. (pp 1045–1046)

Skills Objectives

1. Describe the steps to take in the assessment of a patient with a suspected chest injury. (pp 1036–1039)
2. Demonstrate the management of a patient with a sucking chest wound. (pp 1041–1042)

Introduction

EMTs commonly encounter chest injuries. According to the Centers for Disease Control and Prevention (CDC), chest trauma causes more than 700,000 emergency department (ED) visits and more than 18,000 deaths in the United States annually. Given the location of the heart, lungs, and great blood vessels within the chest cavity, potentially serious injuries may occur. Chest injuries may be the result of blunt trauma, penetrating trauma, or both. Blunt trauma may occur from motor vehicle crashes or falls. Penetrating trauma may be due to shootings, stabbings, or other mechanisms, such as industrial or construction incidents.

Any injury that interferes with normal breathing must be treated without delay to minimize or prevent permanent damage to tissues that depend on a continuous supply of oxygen. Another major problem with chest injuries may be internal bleeding. Blood from lacerations of the thoracic organs or major blood vessels can collect in the chest cavity, compressing the lungs or heart. This may also occur when air collects in the chest and prevents the lungs from expanding. Your ability to act quickly to care for patients with these injuries can make the difference between a successful outcome and death.

This chapter begins with a review of the anatomy of the chest and the physiology of respiration. It then describes the common signs and symptoms of chest injuries and the proper emergency medical treatment for specific injuries.

Anatomy and Physiology

To understand and evaluate chest injuries in the prehospital setting, you must first understand the anatomy of the chest and the mechanism by which gases are exchanged during breathing. A quick review will help you understand the logic in the emergency treatment of chest injuries and the potential complications of that treatment.

A key point to remember is the difference between ventilation and oxygenation. Ventilation is the body's ability to move air in and out of the chest and lung tissue. This is described later in the section on mechanics of ventilation. Any injury that affects the patient's ability to move air in and out of the chest is serious and may be life threatening. Oxygenation is the process of delivering oxygen to the blood by diffusion from the alveoli following inhalation into the lungs. Oxygen must be delivered to the cells, and carbon dioxide (a waste product of cell function) must be removed from the body for proper organ system function.

The chest (thoracic cage) extends from the lower end of the neck to the diaphragm **Figure 29-1**. In a person who is lying down or who has just completed exhalation, the diaphragm may rise as high as the nipple line. Thus, a penetrating injury to the chest, such as a gunshot or stab wound, may also penetrate the lung and diaphragm and injure the liver or stomach.

The skin, muscle, and bones of the thoracic region have some unique features to allow for the ventilation process. Just under the normal three layers of skin, the epidermis, dermis, and subcutaneous layers, lies striated or skeletal muscle. This muscle extends between the ribs, forming the intercostal muscles. These muscles, innervated from the spinal nerves originating in the cervical region C6 and C7, allow the chest to expand on contraction and allow for the active portion of ventilation to occur. A patient who has sustained a spinal cord injury in that region may be unable to move the intercostal muscles and may breathe entirely with the diaphragm. Often called belly breathing, this is considered a clinical or positive diagnostic finding indicating cord damage at or above the level of C6 and C7. In very young children, the intercostal muscles are not yet developed. Children therefore have a tendency to breathe with their diaphragms. This is considered normal for this age group and does not typically indicate spinal cord injury.

YOU are the Provider — PART 1

At 1020 hours, you are dispatched to a construction site for a man with a chest injury. The caller, whose supervisor asked him to call 9-1-1, was unable to provide the dispatcher with the exact mechanism of injury. You respond to the scene, which is located about 5 miles away.

1. What major organs and structures lie within the chest cavity?
2. What injuries commonly result from blunt chest trauma? Penetrating chest trauma?

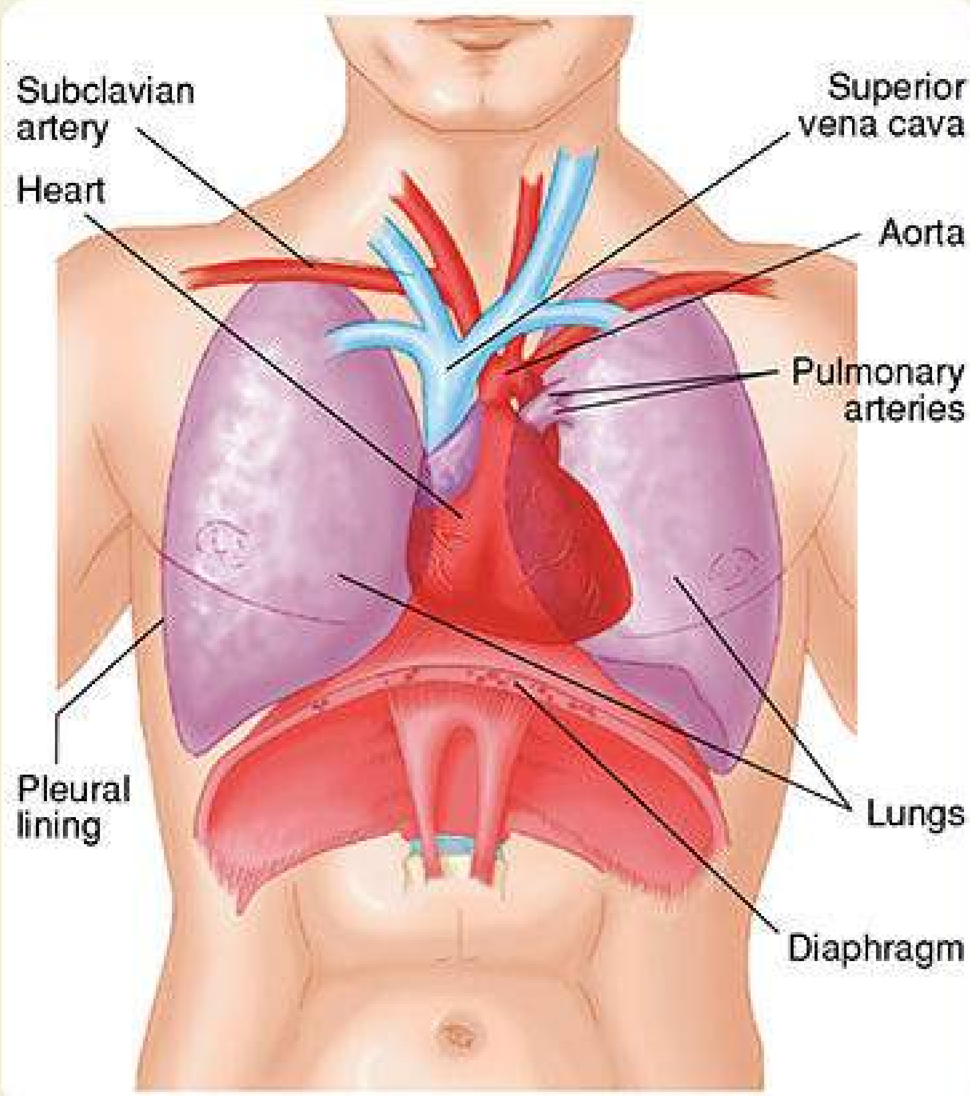

Figure 29-1 A view of the anterior aspect of the chest shows the major organs beneath the surface.

Lying close to each rib along the bottom (inferior) and slightly posterior to the lowest margin of each rib is the neurovascular bundle, composed of a network of nerves, arteries, and veins. Consider this structure when evaluating patients who have sustained rib fractures, because this may be a source of significant bleeding into the pleural space, creating a hemothorax. The ribs themselves create a protective and functional cage around the vital organs. Each side of the chest (hemithorax) contains lung tissue that is separated into lobes. The right lung has three lobes, and the left lung has two lobes. The left lobe formation allows space for the heart to reside; this is called the cardiac notch. A thin membrane called the pleura covers each of the lungs and the thoracic cavity. The inner chest wall has a lining called the parietal pleura, and a lining called the visceral pleura covers the lung. Between these two linings is a small amount of pleural fluid that allows the lungs to move freely against the inner chest wall as a person breathes. Pleural fluid also creates surface tension to allow the lungs to adhere to the rib cage, thus allowing the mechanics of ventilation to occur.

The contents of the chest are partially protected by the ribs, which are connected in the back to the vertebrae and in the front, through the costal cartilages, to the sternum **Figure 29-2**. The trachea, in the middle of the neck, divides into the left and right mainstem bronchi, which supply air to the lungs. The thoracic cage also contains the heart and the great vessels: the aorta, the right and left subclavian arteries and their branches, the pulmonary arteries, and the superior and inferior venae cavae. The esophagus runs through the back of the chest, connecting the pharynx above with the stomach and the abdomen below. The esophagus, trachea, and great vessels lie in the mediastinum, a cavity or space centrally located in the thorax. This location is where a thoracic aortic dissection can occur—a severing of the aorta that can occur when the body is exposed to traumatic forces. At the bottom of the chest, the diaphragm is a muscle that separates the thoracic cavity from the abdominal cavity.

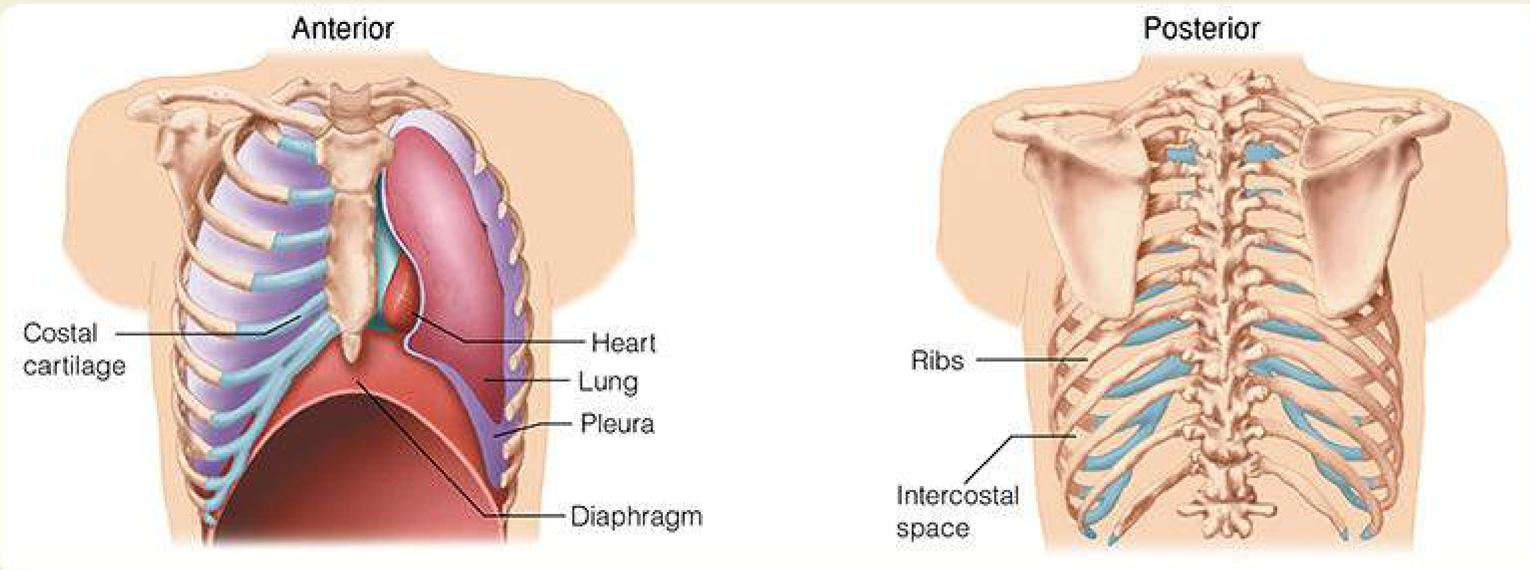

Figure 29-2 The organs within the chest are protected by the ribs, which are connected in back to the vertebrae and in front, through the costal cartilage, to the sternum.

Mechanics of Ventilation

When you inhale, the intercostal muscles between the ribs contract, elevating and expanding the rib cage. At the same time, the diaphragm contracts or flattens and pushes the contents of the abdomen down. The intrathoracic pressure inside the chest decreases, creating a negative pressure differential. Air then enters the lungs through the nose and mouth, which is the path of least resistance from the ambient air space to the upper and lower airway. When you exhale, the intercostal muscles and diaphragm relax, and the tissues move back to their normal positions, allowing air to be exhaled **Figure 29-3**. In a normal respiratory system, relaxation of the thoracic muscles and the diaphragm is a relatively passive function. Normal physiology dictates that the body should not have to work to breathe when in a resting state. When you are assessing the patient, you should be able to recognize when there is an increase in the work of breathing and equate that with respiratory distress and a life threat.

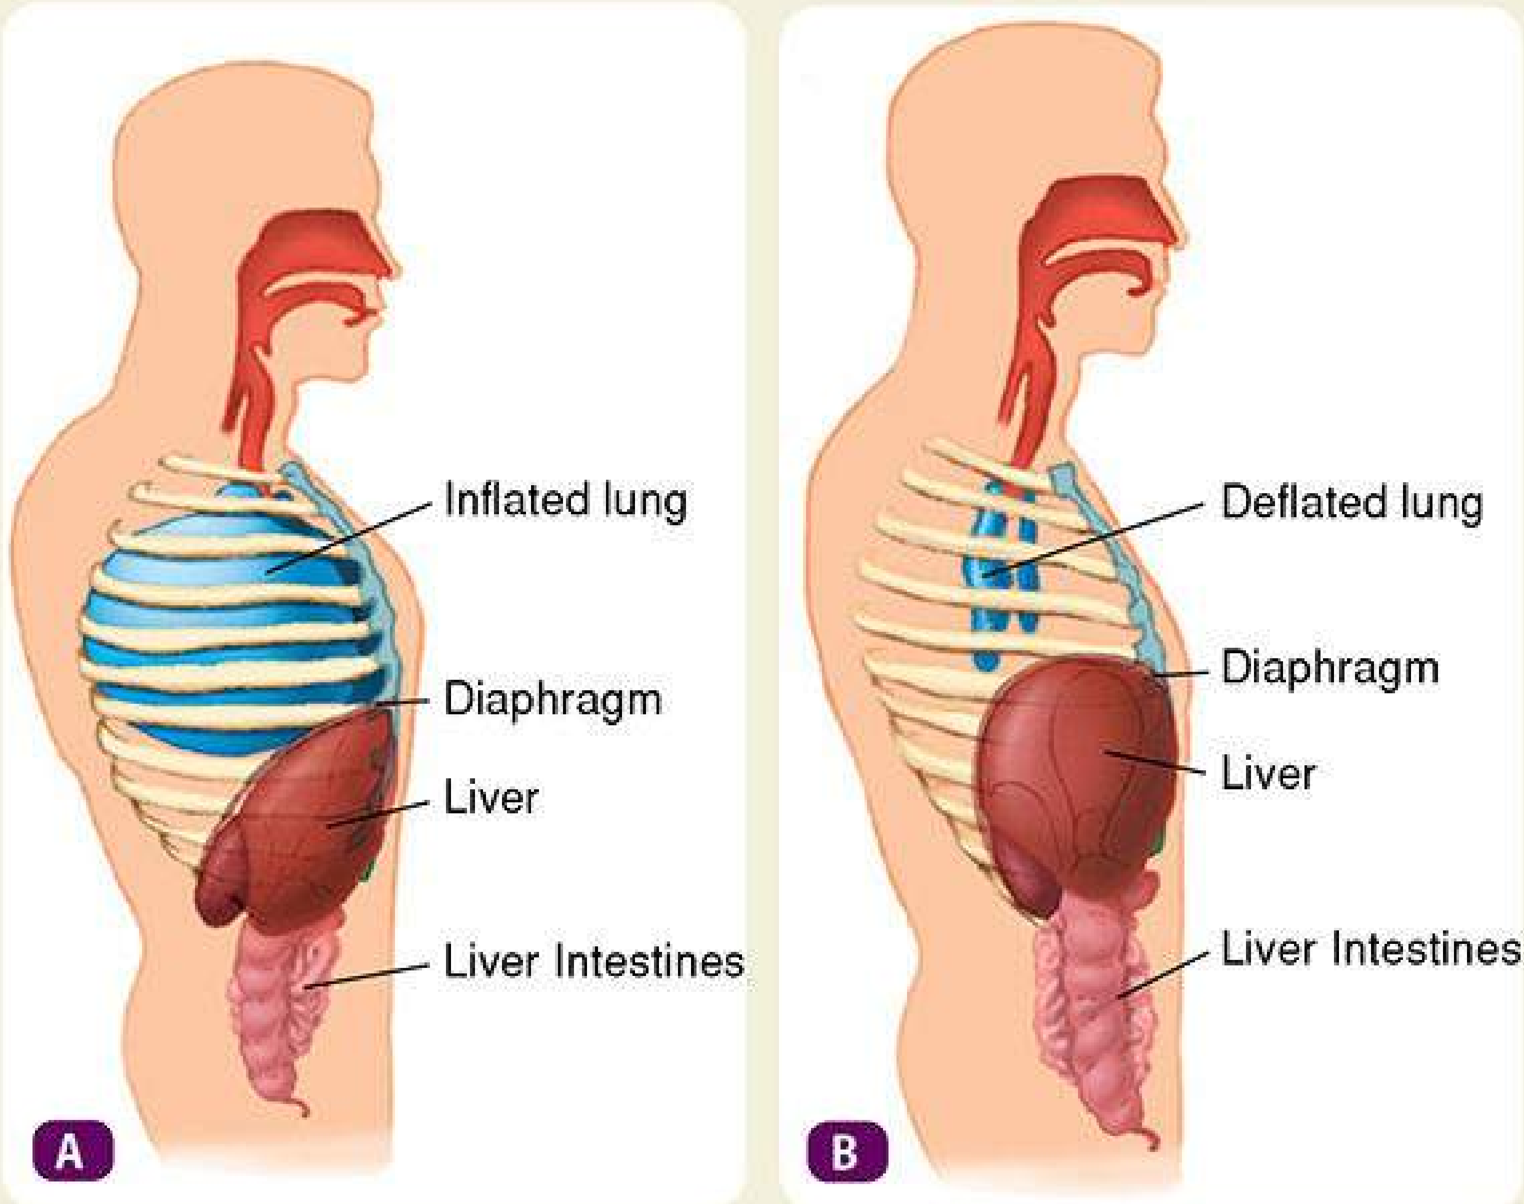

Figure 29-3 The anatomy of the thoracic cavity during inspiration **(A)** and expiration **(B)**.

A, B: © Jones & Bartlett Learning.

Note that the nerves supplying the diaphragm (the phrenic nerves) exit the spinal cord at C3, C4, and C5. Refer to Chapter 6, *The Human Body*, for a review of the spinal column. A patient whose spinal cord is injured below the C5 level may lose the power to move the intercostal muscles, but the diaphragm should still be able to contract. The patient will still be able to breathe because the phrenic nerves remain intact, but the injury may cause belly breathing. Patients with spinal cord injuries at C3 or above can lose their ability to breathe entirely **Figure 29-4**.

Figure 29-4 A patient who sustains a spinal cord injury below the level of C5 and is paralyzed can still breathe spontaneously because the phrenic nerves, which cause the diaphragm to contract, originate at the C3, C4, and C5 levels.

As discussed in Chapter 10, *Airway Management*, tidal volume is the amount of air in milliliters (mL) that is moved into or out of the lungs during a single breath. The average tidal volume for a man is approximately 500 mL. If you multiply this amount of air by the number of breaths/min, the result is called the minute ventilation or minute volume (the amount of air moved through the lungs in 1 minute). If you change either of these numbers (increase or decrease the rate or volume), then you can affect the amount of air moving through the system. For example, if you move 600 mL at the normal rate of 12 breaths/ min, then the minute volume is 7,200 mL (7.2 L). If you increase the ventilation rate by four extra breaths a minute, then the minute volume increases to 9,600 mL (9.6 L). Conversely, if the amount of tidal volume decreases, then the minute volume will drop along with it.

This information is important because if the patient is only able to inhale small amounts of air (in the case of a chest injury or a reactive airway pathology), the patient will need to exceed the normal respiratory rate range of 12 to 20 breaths/min to make up the difference in the minute volume. Remember that the average bag-valve mask (BVM) consists of a self-inflating bag that contains 1,000 to 1,500 mL of air. This device can quickly overinflate the lungs, causing gastric distention, and impair the function of the lungs. Overventilation can also increase intrathoracic pressure (pressure inside the chest), reducing cardiac output and potentially worsening chest injuries such as pneumothorax. In addition, there is the risk of causing acid-base imbalance and blood gas imbalance by "blowing off" carbon dioxide faster than the body needs to get rid of it.

Injuries of the Chest

Recall the discussion of kinematics in Chapter 24, *Trauma Overview*. There are two basic types of chest injuries: open and closed. As the name implies, a **closed chest injury** is one in which the skin is not broken. This type of injury is generally caused by blunt trauma, such as when a person strikes a steering wheel or an air bag in a motor vehicle crash, is struck by a falling object, or is struck in the chest by some object during a fight or physical assault **Figure 29-5**. These types of injuries often cause significant contusions in both the cardiac muscle (cardiac contusion) and the lung tissue (pulmonary contusion), thus impairing the function of those organs.

If the heart is damaged in this manner, it may not be able to refill with blood or blood may not be pumped with enough force out of the heart, creating a form of inadequate tissue oxygenation called cardiogenic shock. Any bruising of the lung tissue can result in exponential loss of the surface area where oxygen and carbon dioxide exchange occurs. This impairment can cause a decrease in available oxygen (hypoxia) and an increase in carbon dioxide in the blood (hypercarbia), leading to alterations of consciousness and possible death if not recognized and treated. Rib fractures create sharp broken bone ends that can lacerate lung tissue and cause further vessel damage with every movement of the chest wall. This type of bleeding can be hidden from external view and rapidly lead to hypovolemic shock.

Figure 29-5 Closed chest injuries usually result from blunt trauma, such as when a patient strikes the steering wheel or an air bag in a motor vehicle crash or is struck by a falling object. A closed chest injury can occur even when a seat belt is worn.

Courtesy of ED, Royal North Shore Hospital/NSW Institute of Trauma & Injury.

Words of Wisdom

The ability to pump blood depends on having a functional pump (the heart), an adequate volume of blood to be pumped, and an appropriate amount of resistance to the pumping mechanism. Collectively, these properties help determine cardiac output. Cardiac output is the volume of blood delivered to the body in 1 minute. Any injury that limits the heart's pumping ability, the delivery of blood to the heart, the blood's ability to leave the heart, or the heart rate will affect cardiac output.

An **open chest injury** is generally caused by penetrating trauma. Some object, such as a knife, a bullet, a piece of metal, or the broken end of a fractured rib, penetrates the chest wall itself **Figure 29-6**. The damage occurring from this type of trauma typically is instant. However, the symptoms of these injuries may take time to develop as the damaged vessels continue to bleed or the lung collapses from a puncture. Occasionally, the object that penetrates and creates an open chest injury remains in place. This is referred to as an impaled object. When you have a patient with an impaled object, do not attempt to move or remove the object because it may be occluding the hole in the vessel that has been punctured. If you remove the object, the patient may bleed heavily. Another reason to not remove the impaled object from the chest is that the objects that cause tissue damage on entry will likely cause damage on removal, resulting in further injury. The removal is best left for the surgeon. Any alteration from this standard should come directly from online medical control.

Figure 29-6 Open chest injuries occur when an object or the broken end of a fractured rib penetrates the chest wall.

In blunt trauma, a blow to the chest may fracture the ribs, the sternum, or whole areas of the chest wall, bruise the lungs and the heart, and even damage the aorta. Almost one-third of people who are killed immediately in car crashes die as a result of traumatic rupture of the aorta. Although the skin and chest wall are not penetrated in a closed injury, broken ribs may lacerate the contents of the chest. Damage to the chest wall structures may result in decreased ability of patients to ventilate on their own. Also, vital organs can be torn from their attachment in the chest cavity without any break in the skin; this condition can cause serious and life-threatening bleeding that is unseen outside the body.

Signs and Symptoms of Chest Injury

Important signs and symptoms of chest injury include:

- Pain at the site of injury
- Pain localized at the site of injury that is aggravated by or increased with breathing
- Bruising to the chest wall

YOU are the Provider — PART 2

You arrive at the scene and ensure it is safe. You are directed to the patient by a coworker. The patient, a 19-year-old man, was struck in the left side of the chest by a two-by-four board that was thrown from a table saw when another coworker was cutting it. You find the patient sitting on the ground; he is conscious and alert but restless and is experiencing respiratory distress. He tells you that it hurts to breathe.

Recording Time: 0 Minutes	
Appearance	Restless; obvious respiratory distress
Level of consciousness	Conscious and alert, but restless
Airway	Open; clear of secretions and foreign bodies

Breathing	Increased rate; labored
Circulation	Radial pulses, strong and rapid; skin, pink and moist; no obvious external bleeding

Your partner applies high-flow oxygen via nonrebreathing mask as you perform a secondary assessment. The patient denies any other injuries, and coworkers confirm that he did not lose consciousness.

3. How should you proceed with your secondary assessment?

- **Crepitus** (the sensation felt when broken bone ends grind together) with palpation of the chest
- Any penetrating injury to the chest
- Dyspnea (difficulty breathing, shortness of breath)
- Hemoptysis (coughing up blood)
- Failure of one or both sides of the chest to expand normally with inspiration
- Rapid, weak pulse and low blood pressure
- Cyanosis around the lips or fingernails

After a chest injury, any change in normal breathing is a particularly important sign. A healthy, uninjured adult usually breathes at a rate ranging from 12 to 20 breaths/min without difficulty and without pain. The chest should rise and fall in a symmetric pattern with each breath. Respirations of fewer than 12 breaths/min or of more than 20 breaths/min may indicate inadequate breathing. Patients with chest injuries often have **tachypnea** (rapid respirations) and shallow respirations because it hurts to take a deep breath. Note that the patient may be making breathing attempts but may not actually be moving air. Chest wall trauma may interfere with the ability to actually move air. Check the respiratory rate and see if there is actual air movement from the mouth and/or nose. This is best accomplished through the use of auscultation of multiple locations on the chest wall for adequate breath sounds.

As with any other injury, pain and tenderness are common at the point of impact as a result of a bruise or fracture. The normal process of breathing usually aggravates pain. Irritation of or damage to the pleural surfaces causes a characteristic sharp or sticking pain with each breath when these normally smooth surfaces slide on one another. This sharp pain is called *pleuritic pain*, or *pleurisy.*

In an injured patient, dyspnea, or difficulty breathing, has many causes, including airway obstruction, damage to the chest wall, improper chest expansion because of the loss of normal control of breathing, or lung compression because of accumulated blood or air in the chest cavity. Dyspnea in an injured patient indicates potential compromise of lung function; prompt, vigorous support of oxygenation and ventilation with prompt transport are required.

Hemoptysis, the spitting or coughing up of blood, usually indicates that the lung itself or the air passages have been damaged. With a laceration of the lung tissue, blood can enter the bronchial passages and is coughed up as the patient tries to clear the airway.

A rapid, weak pulse and low blood pressure are the principal signs of hypovolemic shock, which can result from extensive bleeding from lacerated structures within the chest cavity, where the great vessels and heart are located. Shock following a chest injury may also result from insufficient oxygenation of the blood by the poorly functioning lungs, from an increase in intrathoracic pressure from air or blood in the chest, or from direct injury to the heart itself.

Cyanosis in a patient with a chest injury is a sign of inadequate respiration. The classic blue or ashen gray appearance around the lips and fingernails indicates that blood is not being oxygenated sufficiently. Patients with cyanosis are unable to provide a sufficient supply of oxygen to the blood through the lungs and require immediate ventilation and oxygenation.

Many of these signs and symptoms occur simultaneously. When any one of them develops as a result of a chest injury, the patient requires prompt hospital care. Remember that the principal reason for concern about a patient who has a chest injury is that his or her body has no means of storing oxygen; it is supplied and used continuously, even during sleep. Any interruption in this supply can be rapidly lethal and must be treated aggressively.

Patient Assessment

Scene Size-up

As you arrive on the scene, observe for hazards and threats to the safety of the crew, bystanders, and the patient. Consider the possibility that the area where the patient is located may be a crime scene; therefore, make every attempt to not disturb potential evidence. Ensure that the police are on scene at incidents involving violence, such as assaults or gunshot wounds. Begin the encounter with scene safety as the highest priority. If you determine that power company, fire department, or advanced life support (ALS) units are needed, call for them early.

Ensure that you and your crew take standard precautions, and put on a minimum of gloves and eye protection. Put several pairs of gloves in your pocket for easy access in case your gloves tear or there are multiple patients with bleeding. Because of the color of blood and the fact that it easily soaks through clothing, you can often identify patients with bleeding as you approach the scene. However, darker clothing may mask signs of bleeding, so you must remain vigilant when the mechanism of injury (MOI) suggests the patient may be bleeding.

As you observe the scene, look for indicators and significance of the MOI. This helps you develop an early index of suspicion for underlying injuries in a patient who has sustained a significant MOI. Chest injuries are common in motor vehicle crashes, falls, industrial incidents, and assaults. Determine the number of patients, and consider spinal stabilization.

Words of Wisdom

Air bags can hide signs, such as seat belt marks, that would suggest that a significant force or blow occurred to the chest. Maintain a high degree of suspicion for severe injuries when an air bag has deployed.

Primary Assessment

During your primary assessment, you must quickly identify and treat potential life threats and determine priority of patient care and transport. Life-threatening hemorrhage, when present, should be addressed immediately, even before airway concerns.

As you approach, note the patient's level of consciousness. Responsive patients may be able to tell you their chief complaint. Note not only what they say, but also how they say it. Difficulty speaking may indicate several problems, and chest injury is an important one. Perform a rapid physical examination of the patient. Look for obvious injuries, the appearance of blood, and difficulty breathing. Look for cyanosis, irregular breathing, and chest rise and fall on only one side. Observe the neck, looking for accessory muscle use while breathing; also look for extended or engorged external jugular veins. If no obvious problems are seen, begin looking for them by focusing on the ABCs. The initial general impression will help you develop an index of suspicion for serious injuries and determine your sense of urgency for medical intervention. A good question to ask yourself is, "How sick is this patient?" Patients with significant chest injuries will "look" sick and are often frightened or anxious. Keep in mind that you are rapidly searching for life threats and you will repeat the physical examination in a more detailed manner later in the assessment if time and patient condition allow.

Addressing life threats begins with the assessment of airway and breathing unless life-threatening uncontrolled bleeding is seen. Ensure that the patient has a clear and patent airway. Normal breathing should be effortless, and any deviation from this pattern should be cause for concern. How you assess and manage the airway depends a great deal on whether you suspect a spinal injury. A significant number of patients with traumatic chest injuries also have spinal injuries, and proper precautions should be taken when blunt trauma is present. Be suspicious, and protect the spine early in your care. While you are considering immobilization of the cervical spine, note whether the jugular veins are distended. If you note this finding, it can be the result of a tension pneumothorax (significant ongoing air accumulation in the pleural space) or injury to the heart that allows bleeding into the pericardium, creating a cardiac tamponade, otherwise referred to as a pericardial tamponade.

Once you have determined the patient has a patent airway, determine whether breathing is present and adequate. With chest injuries, begin by inspecting for DCAP-BTLS, and look for equal expansion of the chest wall. Listen with a stethoscope to each side of the chest. Absent or decreased breath sounds on one side usually indicate significant damage to a lung, preventing it from expanding properly. Be alert to the pattern of symmetric rise and fall of the patient's chest wall. If the chest wall does not expand on each side when the patient inhales, the chest muscles may have lost their ability to work appropriately. Loss of muscle function may be the result of a direct injury to the chest wall, or it may be related to an injury of the nerves that control those muscles. Check also for **paradoxical motion**, an abnormality associated with multiple fractured ribs, in which one segment (often referred to as a flail segment) of the chest wall moves opposite the remainder of the chest; that is, out with expiration and in with inspiration.

If you determine the patient has penetrating trauma, address this life threat at once. This condition may interfere with the normal mechanics of breathing and can cause the patient's condition to worsen quickly. For quick initial care, you can use your gloved hand to occlude an open chest wound. When further dressings can be applied, apply an **occlusive dressing** to all penetrating injuries to the chest. Depending on local protocol, the dressing may be taped on three sides to allow air to escape during exhalation. Apply oxygen with a nonrebreathing mask at 15 L/min. Provide positive-pressure ventilation with 100% oxygen if breathing is inadequate based on the patient's level of consciousness and breathing rate and quality. Positive-pressure ventilation may be particularly important for the patient with a flail chest that compromises ventilation. However, positive-pressure ventilation overcomes the normal physiologic functions, and, if your patient has a pneumothorax (collapsed lung), you can quickly worsen the injury. Be diligent with auscultation of breath sounds, and evaluate the effectiveness of your ventilatory support with signs of circulation to the skin. Be aware of decreasing oxygen saturation (Spo_2) values because they may indicate the development of hypoxia. Watch for signs of an impending tension pneumothorax, such as increasingly poor compliance during ventilation (difficulty delivering breaths to the patient).

Assess the patient's pulse. Determine whether it is present and adequate. If the pulse is too fast or too slow, or if the skin is pale, cool, or clammy, consider your patient to be in shock. You need to treat aggressively to reverse the cause of shock and support the patient's circulatory system. In the early stage of shock, the body compensates for blood loss by increasing the heart rate. Be alert for this change, especially if tachycardia is still present beyond a few minutes after the initial adrenaline rush from the incident or injury. External bleeding may or may not be significant, but if it is considered life threatening, address this threat immediately. Bleeding inside the chest can be significant and, as discussed earlier, can be a quick cause of death. Control external bleeding with direct pressure and a bulky trauma dressing.

Priority patients are considered patients who have a problem with their airway, breathing, and/or circulation. Sometimes the priority is obvious, and the decision to transport quickly is also easy. At other times, what is happening outside the body may not provide obvious clues to the seriousness of what is happening inside the body. Pay attention to subtle clues such as the appearance of the skin, level of consciousness, or a sense of impending doom in the patient. These symptoms are not as grand as a large gash across the chest or air being sucked into the chest; however, they can be equally important indicators of a life-threatening condition. When you find signs of poor perfusion or inadequate breathing, transport quickly and perform the remainder of the assessment en route to the emergency department. A delay on the scene to perform a lengthy assessment will reduce the chances of survival for your patient. With chest injuries, when in doubt, transport rapidly to a hospital. Table 29-1 lists the "deadly dozen" chest injuries.

Table 29-1 Deadly Dozen Chest Injuries

1. Airway obstruction
2. Bronchial disruption
3. Diaphragmatic tear
4. Esophageal injury
5. Open pneumothorax
6. Tension pneumothorax
7. Massive hemothorax
8. Flail chest
9. Cardiac tamponade
10. Thoracic aortic dissection (leakage from a traumatic aneurysm of the portion of the aorta that lies within the chest)
11. Myocardial contusion
12. Pulmonary contusion

History Taking

Once you have identified and treated life threats, you can move on to gathering a history from the patient. If you have not yet done so, determine and investigate the patient's chief complaint and further investigate the MOI. Identify any associated signs and symptoms and pertinent negatives. If the patient was assaulted with a blunt object such as a bat, further evaluate the spinal region for injury because the force may have been transferred through the body from the point of impact. If the patient fell from a great height and is reporting chest discomfort or dyspnea, this may distract the patient from recognizing that he or she has fractures or is bleeding from the extremities. Palpation of the chest will typically cause direct pain at the site of the fracture. When a patient reacts to the pain, be certain to verify where the pain was located in relationship to the area being touched.

YOU are the Provider — PART 3

Your secondary assessment reveals bruising and crepitus on the left side of the chest and diminished breath sounds over that same side; no paradoxical chest wall movement is noted. The trachea is midline, and the jugular veins are nondistended. Your partner takes the patient's vital signs and reports them to you.

Recording Time: 5 Minutes	
Respirations	24 breaths/min; labored
Pulses	110 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	138/88 mm Hg
Oxygen saturation (Spo_2)	95% (on oxygen)

4. On the basis of your assessment findings, what injury or injuries should you suspect?
5. How should you proceed with your treatment of this patient?

Pertinent negatives when examining the chest include no associated shortness of breath, no rapid breathing, no absent or abnormal breath sounds, and no areas of deformity or abnormal movement. In a patient with a suspected spinal cord injury, equal expansion of the chest and movement of the rib cage and the diaphragm can confirm that there is nerve conduction to that region of the body.

Obtaining a SAMPLE history from a patient with a chest injury may not seem very important. Regardless, a basic evaluation of signs and symptoms, allergies, medications, pertinent medical history, including respiratory or cardiovascular disease, and last oral intake should be completed when time allows. The events leading to the emergency should also be identified. Questions about the events surrounding the incident should focus on the MOI: the speed of the vehicle or height of the fall, the use of safety equipment such as a helmet, air bag, seat belt, or life jacket, the type of weapon used, the number of penetrating wounds, and so on. A SAMPLE history can be obtained quickly in most situations and can certainly be obtained while accomplishing other tasks. However, if the patient has a loss of consciousness, it will no longer be possible to obtain the information.

Secondary Assessment

In a patient who has an isolated injury to the chest with a limited MOI, such as in a stabbing, you should focus your assessment on the isolated injury, the patient's chief complaint, and the body region affected. Ensure that wounds are identified and the bleeding is controlled. Note the location and extent of the injury. Assess all underlying systems. Examine the anterior and posterior aspects of the chest wall, and be alert to changes in the patient's ability to maintain adequate respirations.

It is important in patients with a chest injury not to focus only on a chest wound. With significant trauma, you should quickly assess the entire patient from head to toe. If there is significant trauma (such as a blunt trauma or gunshot wound) likely affecting multiple systems, start with a rapid physical examination of the body, looking for DCAP-BTLS to determine the nature and extent of thoracic injury. This examination will help to determine all of the injuries and the extent of the injuries. Inspection or visualization of the region looking for deformities, such as asymmetry of the left and right sides of the chest or shoulder girdle, may reveal the presence of multiple rib fractures, crush injuries, or significant chest wall injury. Identification of discrete areas of contusion or abrasion may pinpoint a specific point of impact. The presence of puncture wounds or other penetrating injuries indicates a possible open chest injury that should be managed accordingly. Be alert for associated burns, which may alter respiratory mechanics. Palpate for tenderness to localize the injury and the presence of fractures. Look for lacerations and local swelling. Application of this systematic approach to patient assessment minimizes the chance of missing a significant injury.

Once you have stabilized airway, breathing, and circulation problems and have checked the patient from head to toe to identify injuries, obtain a baseline set of vital signs. This activity should include assessment of pulse, respirations, blood pressure, skin condition, and pupils. Each of these is considered a sign indicating how your patient is tolerating the injuries. Consider these signs as a window to the functioning of the vital organs. This baseline set of vital signs will be used to evaluate changes in the patient's condition. Because patients with chest injury have so much potential for rapid deterioration, they should be reevaluated every 5 minutes or less. This will allow you to quickly recognize changes in the vital sign numbers or trends.

Special Populations

In older patients with reduced bone density or more fragile bones, even minor trauma to the chest wall can cause significant injury to the underlying tissues and organs. Older patients may have also sustained a number of fractures to the rib cage. Be alert for these injuries and for signs and symptoms of respiratory compromise, even in lower energy mechanisms of injury. Older patients also have a decreased amount of physiologic reserve and are likely to decompensate quickly following an injury.

If you find an accelerated pulse rate or respiratory rate, the chest injury may be causing either a decrease in available oxygen (hypoxia) or blood loss that results in a decreased number of red blood cells that can carry oxygen (hypoxemia). The increased respiratory rate is often associated with an obvious increase in work of breathing. This can be identified by noting increased use of the accessory muscles in the face, neck, and chest to assist in the movement of air. In the later stages of injuries, the pulse rate can slow as the myocardium becomes starved for oxygen and the body is no longer able to keep up with the demands. The respiratory rate may drop as the brain becomes starved for oxygen and overloaded with carbon dioxide and other waste products. These are usually signs of impending cardiopulmonary arrest. In the case of increasing pressure on the heart from the pleural space or the pericardial space, the blood pressure may exhibit a narrowing pulse pressure as the systolic and diastolic pressures come closer together. This is a result of the inability of the heart to fill with an adequate volume of blood and contract normally.

Reassessment

The reassessment identifies how your patient's condition is changing. It should focus on repeating the primary assessment, reassessing the chief complaint, and reassessing interventions performed. Reevaluate the patient's airway, breathing, pulse, perfusion, and bleeding. Has breathing improved now that the wound is sealed, or has it become more difficult? If assisting ventilations with a BVM, is it becoming increasingly difficult to deliver breaths to the patient? Other interventions should also be assessed to determine if they are effective. For example, are pulse oximeter values rising now that the patient is receiving oxygen? Reassess vital signs and compare them to vital signs taken earlier. Vital signs are a snapshot in time. They must be reassessed frequently to be able to trend the patient's status and determine if they are compensating versus decompensating. Does a drop in blood pressure and tachycardia indicate increasing pressure in the chest? Many chest injuries will worsen during transport to the hospital because of the seriousness of the injuries. An astute reassessment will help identify worsening conditions in a timely manner so that they can be addressed.

Provide appropriate spinal immobilization of any patient who has blunt trauma with suspected spinal injuries. Maintain an open airway, be prepared to suction the patient, and consider an oropharyngeal or nasopharyngeal airway. Whenever you suspect significant bleeding, provide high-flow oxygen. If needed, provide assisted ventilation using a BVM with high-flow oxygen. If significant bleeding is visible, you must control the bleeding. If you find penetrating trauma to the chest wall, place an occlusive dressing over the wound. Use caution to avoid increasing the work of breathing and pain. Be prepared to provide positive-pressure ventilation if the patient's efforts are not effective. If the patient has signs of hypoperfusion, treat aggressively for shock and provide rapid transport to the appropriate hospital. Do not delay transport of a seriously injured trauma patient to complete nonlifesaving treatments such as splinting extremity fractures; instead, complete these types of treatments en route to the hospital.

Communicating with hospital staff early when your patient has a significant MOI to the chest can help them be prepared with appropriate equipment and personnel when you arrive. If a penetrating injury is present, describe it in your report, along with what you have done to care for it. Your documentation should be complete and thorough. Describe all injuries and the treatment given. Remember, your documentation is your legal record of what happened.

Special Populations

In young children, the rib cage is very flexible and does not provide the same level of protection that the adult rib cage provides. This flexibility can allow any significant injury or compression of the rib cage to be masked because the ribs give way to the pressure and do not fracture. However, it is important to remember that the organs that underlie the rib cage have been exposed to that force and are likely injured. This flexibility of the ribs may result in fractures that are hidden on examination, and the only indication you may have of compromise is increased work of breathing or alterations in vital signs. This age group is often injured in pedestrian or bicycle collisions that involve vehicles. In auto-pedestrian collisions, children often turn toward the vehicle instead of away as adults do, thus resulting in direct impact to the chest by the bumper or hood. Children also may not be cognizant of height or distances and, therefore, may be prone to falls from distances greater than twice their height, resulting in severe trauma.

Complications and Management of Chest Injuries

Pneumothorax

In any chest injury, damage to the heart, lungs, great vessels, and other organs in the chest can be complicated by the accumulation of air in the pleural space. This is a dangerous condition called a **pneumothorax** (commonly called a collapsed lung). In this condition, air enters through a hole in the chest wall or the surface of the lung as the patient attempts to breathe, causing the lung on that side to collapse **Figure 29-7**. As a result, any blood that passes through the collapsed portion of the lung is not oxygenated, and hypoxia can develop. If the lung is collapsed past 30% to 40% you may hear diminished breath sounds on that side of the chest. Absent breath sounds are a significant finding in chest trauma and may indicate the development of a tension pneumothorax, discussed later. Depending on the size of the hole and the rate at which air fills the cavity, the lung may collapse in a few seconds or a few hours. In the uncommon situation when the hole is in the chest wall, you can hear a sucking sound as the patient inhales and the sound of rushing air as he or she exhales. For this reason, an open or penetrating wound to the chest wall is often called an **open pneumothorax** or a **sucking chest wound** **Figure 29-8**.

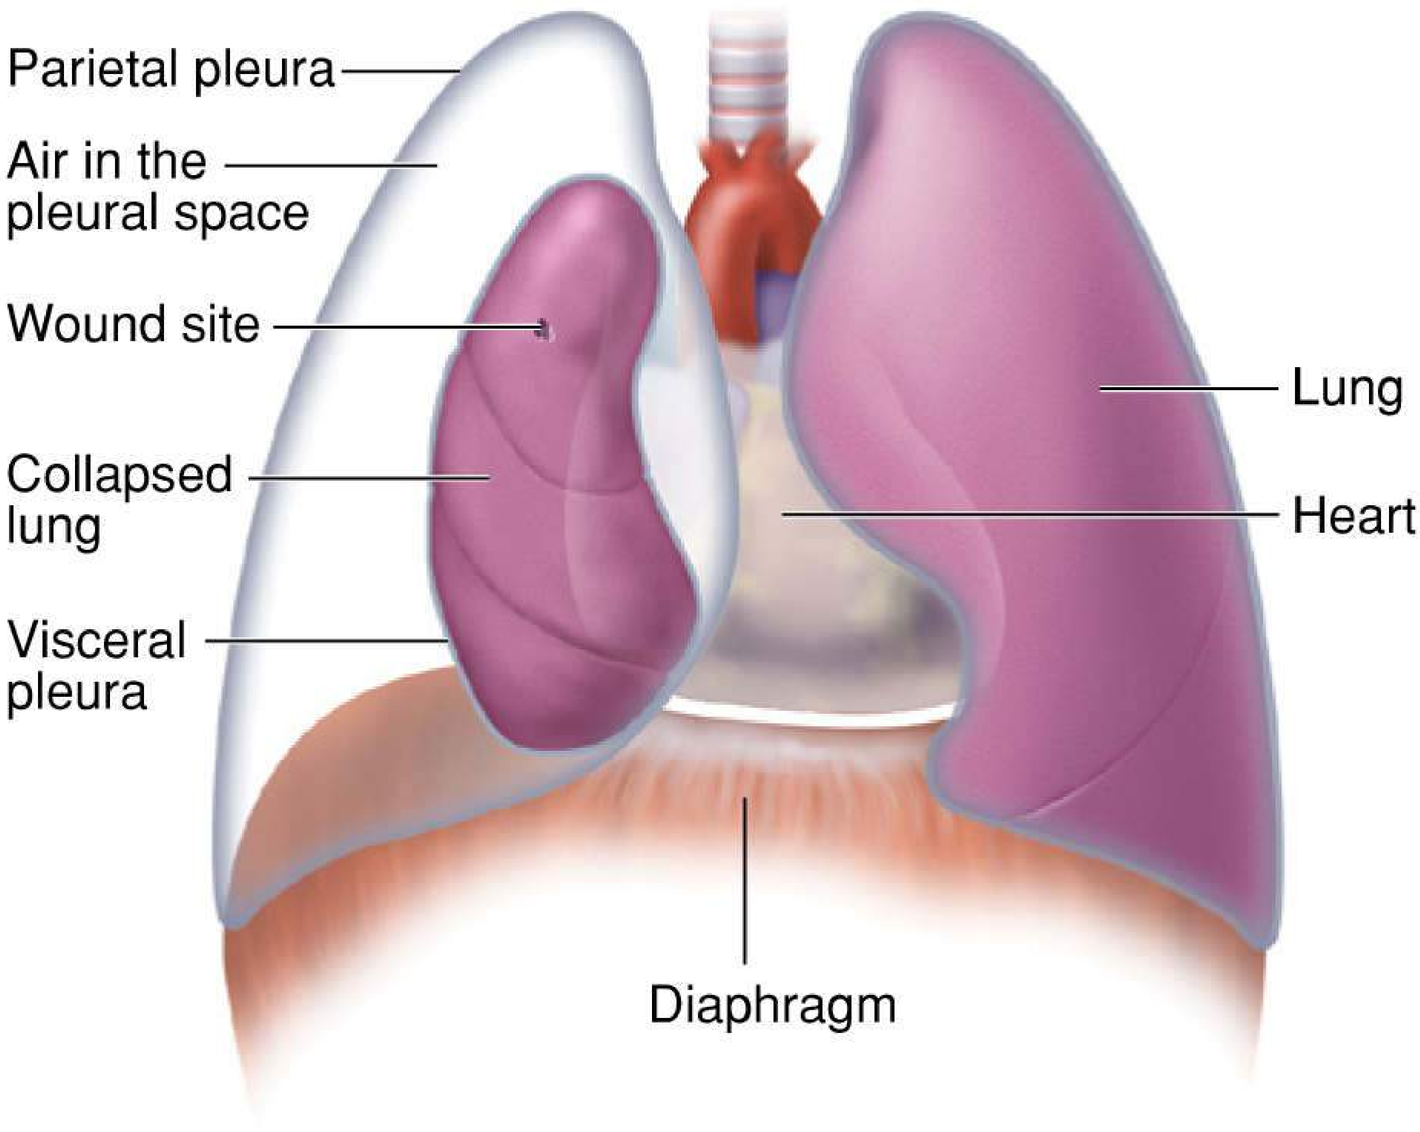

Figure 29-7 Pneumothorax occurs when air leaks into the space between the pleural surfaces from an opening in the chest wall or the surface of the lung. Air in the pleural space causes the lung to collapse.

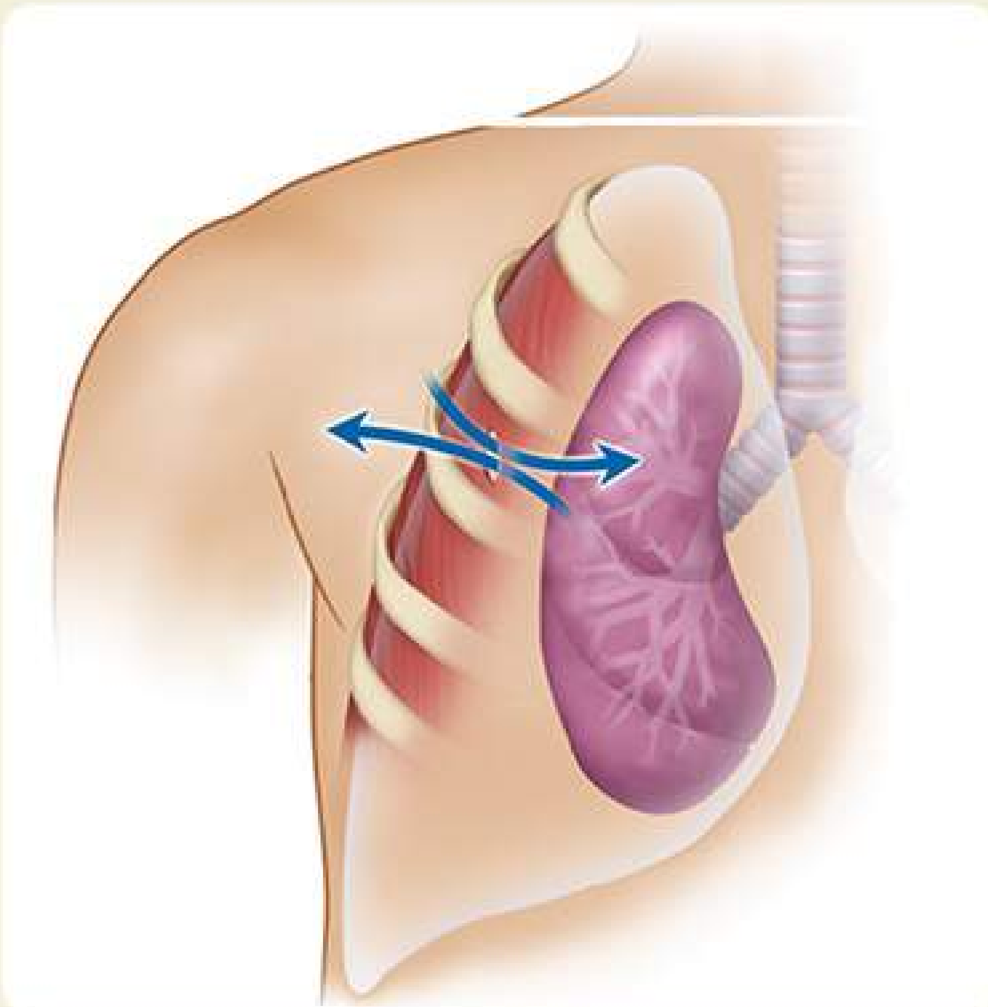

Figure 29-8 With a sucking chest wound, air passes from the outside into the pleural space and back out with each breath, creating a sucking sound.

This type of injury is a true emergency requiring immediate emergency medical care and transport. Initial emergency care, after clearing and maintaining the airway and then providing oxygen, is to rapidly seal the open wound with an occlusive dressing. The purpose of the dressing is to seal the wound and prevent air from being sucked into the chest through the wound. Two types of occlusive dressings are available: commercial vented occlusive dressings and improvised occlusive dressings that utilize petroleum jelly (Vaseline)-based gauze, aluminum foil, or plastic. Vented occlusive dressings contain a one-way valve, called a **flutter valve**, that allows air to leave the chest cavity but not return **Figure 29-9**. Follow local protocol and manufacturer's guidelines if you utilize such a dressing. An improvised occlusive dressing may be taped to the patient on only three sides of the dressing to simulate a flutter valve or taped on all four sides of the dressing, depending on your local protocol **Figure 29-10**. Regardless of which type of dressing you carry, use a dressing that is large enough so that it is not pulled or sucked into the chest cavity. Careful observation is required after the placement of an occlusive dressing. The occlusive seal or a clot in the injury may allow a tension pneumothorax to develop. If signs of a tension pneumothorax develop, it is suggested that the occlusive dressing be vented by opening it on one side to allow air to be released from the chest. Sometimes you may hear a sudden release of air pressure when you remove one side of the dressing. Adhere to standard precautions, and be aware that if there is clotting present, it may be expelled with the force of the buildup of pressure. This situation can develop even after a flutter valve has been applied.

Figure 29-9 A commercial occlusive dressing may be used to seal all four sides of a sucking chest wound. **A.** An Asherman Chest Seal, which is vented. **B.** A HALO Chest Seal, which is unvented.

Words of Wisdom

When you use an occlusive dressing to seal an open chest wound, record the type of material used, whether three or four sides were sealed, and any changes noted afterward: skin color, vital signs, breath sounds, and particularly the patient's level of anxiety.

Words of Wisdom

While pneumothorax is often discussed in the context of trauma, there are other potential causes, such as lung disease, **spontaneous pneumothorax**, or scuba diving injuries.

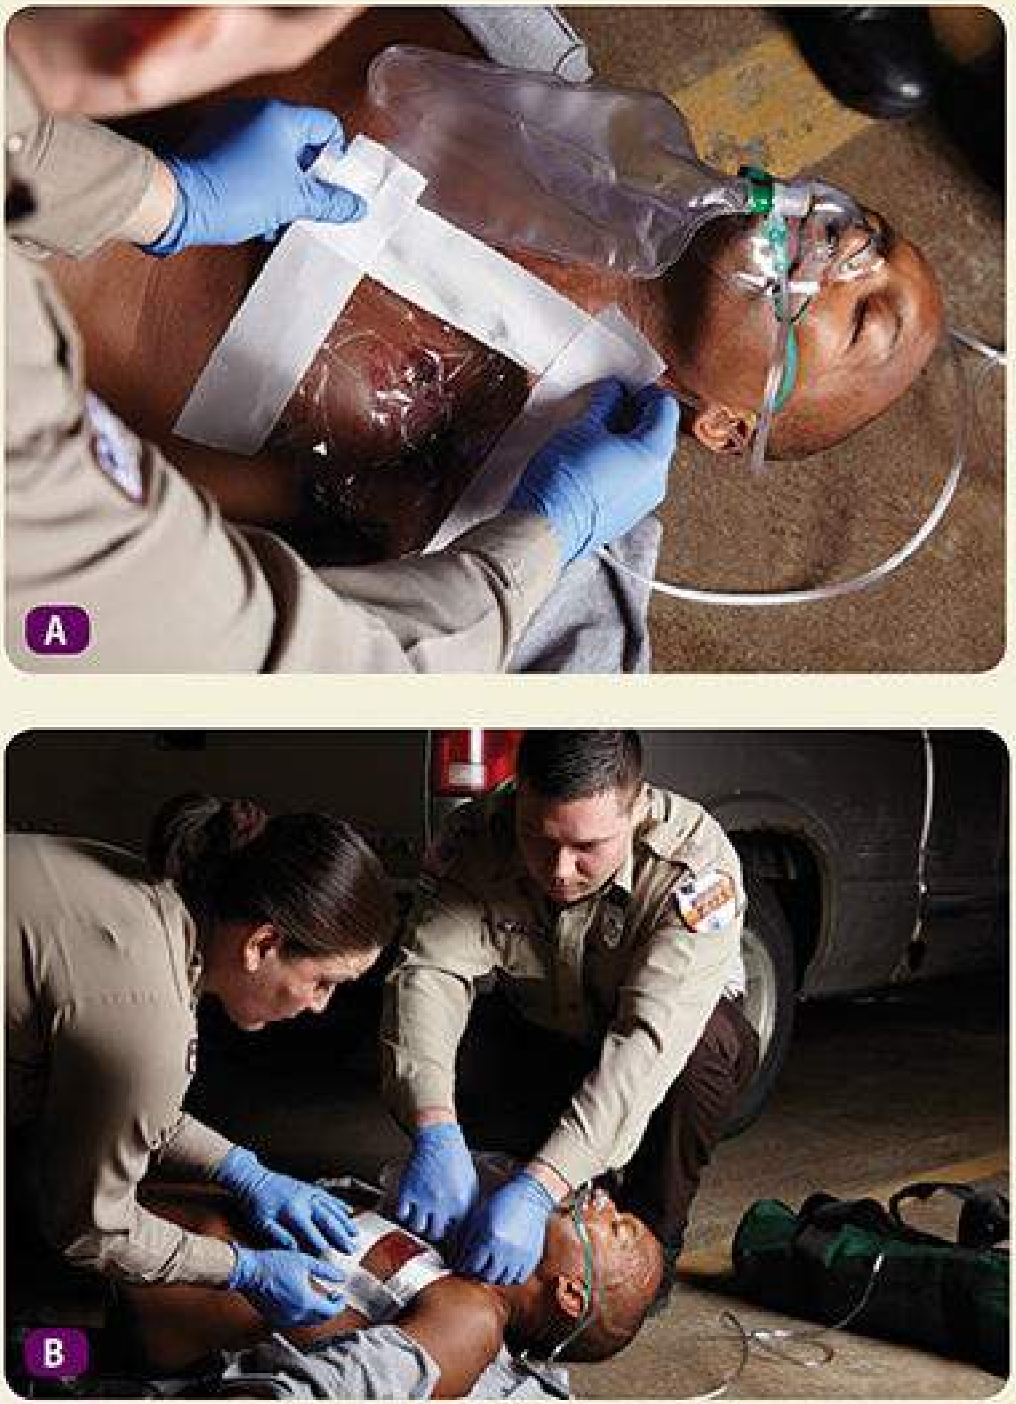

Figure 29-10 **A.** An improvised vented occlusive dressing seals three sides of a sucking chest wound, with the fourth left open as a flutter valve. **B.** Sealing the fourth side makes the dressing unvented, which limits drainage and air flow but increases the possibility of tension pneumothorax developing.

Simple Pneumothorax

Any pneumothorax that does not result in major changes in the patient's cardiac physiology is referred to as a **simple pneumothorax**. These are commonly the result of blunt trauma that results in fractured ribs. As in the spontaneous pneumothorax, the simple pneumothorax is often difficult to diagnose. The lung has to collapse a significant amount before the effects will be heard as decreased breath sounds. The more common findings are similar to other types of pneumothoraces: dyspnea or increased work of breathing exhibited as increased rate; tachypnea, and accessory muscle use; and decreasing oxygen saturation on the pulse oximeter. Another sign of pneumothorax can be a crackling sensation felt on palpation of the skin (also called *subcutaneous emphysema*), which indicates that air escaping from a lacerated lung is leaking into the tissues of the chest wall. Late findings can be decreased breath sounds on the injured side as well as lethargy and cyanosis. Be vigilant because the simple pneumothorax can often worsen or deteriorate into a tension pneumothorax or develop complications like bleeding or hemothorax. The treatment for a simple pneumothorax is much like any treatment for respiratory compromise; provide a high concentration of oxygen. Monitor oximeter readings and breath sounds, and treat underlying causes of the injury. As in all pneumothorax treatment, adding positive-pressure ventilation will cause the pathology to advance rapidly and possibly cause a tension pneumothorax to develop. However, you should not withhold positive-pressure ventilation if the patient needs the support. Simply be aware of the risk, and plan on how to resolve complications. Most patients with this problem require ALS intervention, so call for it early.

Words of Wisdom

Be cautious about providing positive-pressure ventilation to a patient with a suspected pneumothorax. The positive pressure may cause the size of the pneumothorax to increase. If the patient requires positive-pressure ventilation, you must provide it, but be certain to communicate your concerns about the underlying pneumothorax at the receiving hospital.

Tension Pneumothorax

A potential complication that may develop following chest injuries with pneumothorax is a **tension pneumothorax** **Figure 29-11**. This can occur when there is significant ongoing air accumulation in the pleural space. This air gradually increases the pressure in the chest, first causing the complete collapse of the affected lung and then pushing the mediastinum (the central part of the chest containing the heart and great vessels) into the opposite pleural cavity. This prevents blood from returning through the venae cavae to the heart, decreasing cardiac output, causing shock, and ultimately leading to death.

Tension pneumothorax occurs more commonly as a result of closed, blunt injury to the chest in which a fractured rib lacerates a lung or bronchus. Only very rarely does a tension pneumothorax arise spontaneously.

A patient with a tension pneumothorax will have chest pain, tachycardia, marked respiratory distress, and absent or severely decreased lung sounds on the affected side with signs of shock such as hypotension or altered mental status. The patient may also exhibit jugular vein distention (JVD), cyanosis, or tracheal deviation, but these signs are not always present. Jugular vein distention is best assessed for with the patient sitting at a 45-degree angle. Tracheal deviation, if seen, is a late and grave finding and is a sign that the patient requires immediate intervention.

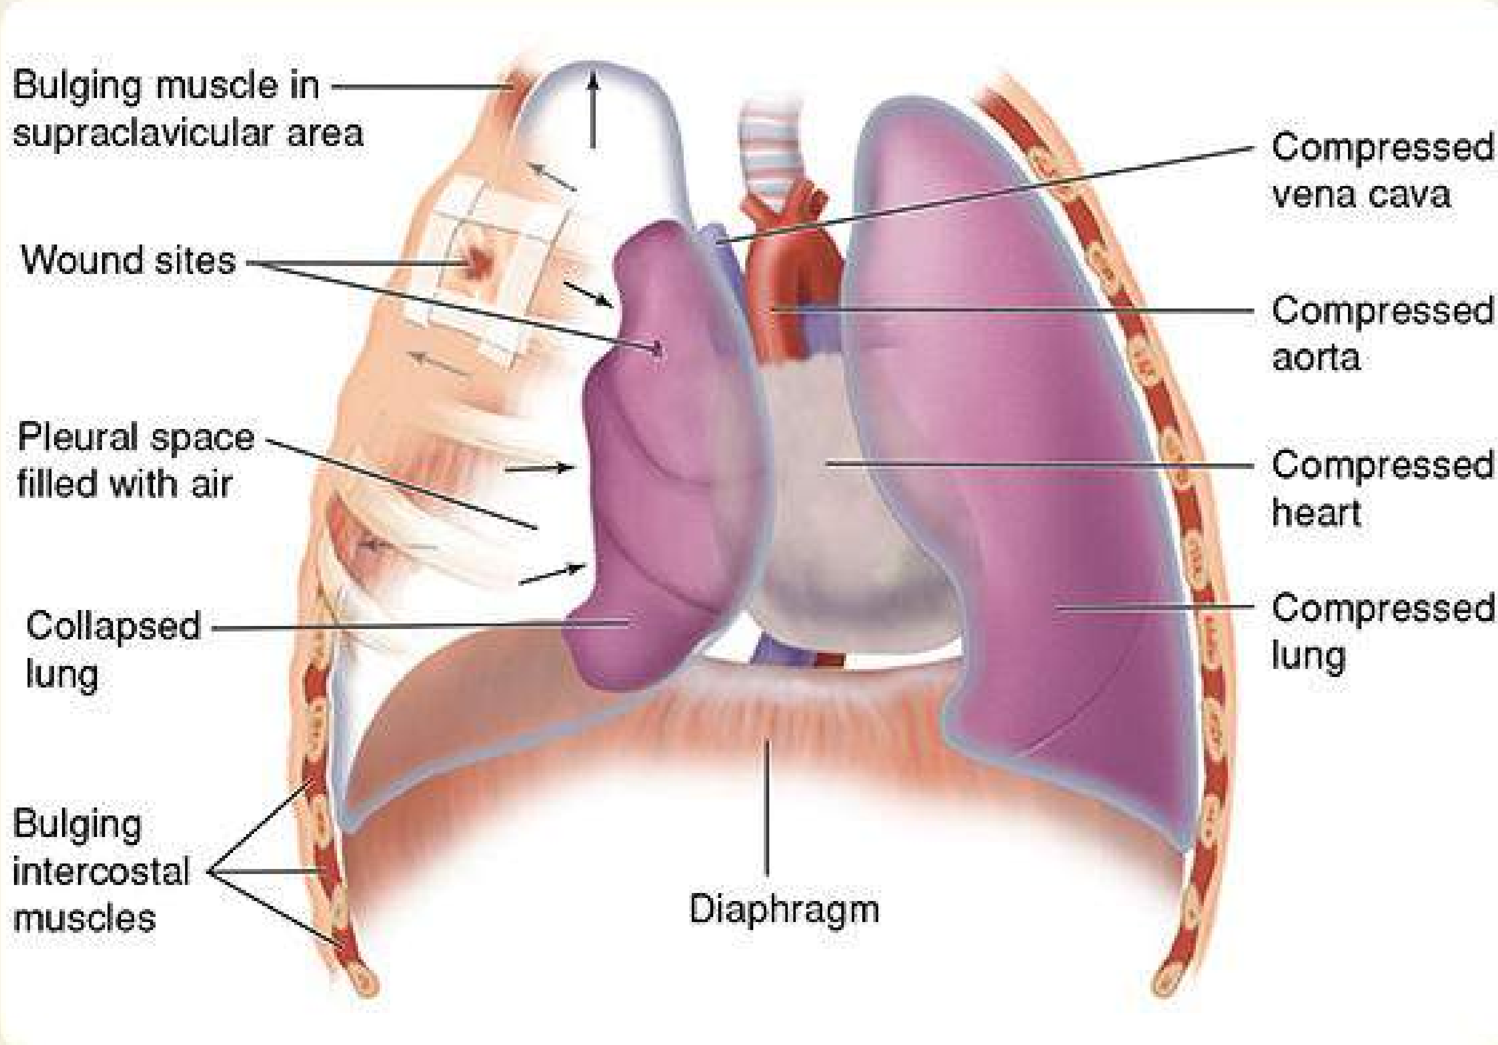

Figure 29-11 A tension pneumothorax can develop if a penetrating chest wound is bandaged tightly and air from a damaged lung cannot escape. The air then accumulates in the pleural space, eventually causing compression of the heart and great vessels. If a dressing sealed on four sides with no vent is used, monitor for signs of tension pneumothorax developing and prepare to vent one side of the dressing.

Relieving a tension pneumothorax that is the result of blunt trauma is often done by inserting a needle through the rib cage into the pleural space; however, this procedure typically is performed by ALS personnel or emergency department staff depending on local protocols. A tension pneumothorax is a life-threatening condition. Be prepared to support ventilation with high-flow oxygen, and request ALS support or transport immediately to the closest hospital.

Hemothorax

In blunt and penetrating chest injuries, blood can collect in the pleural space from bleeding around the rib cage or from a lung or great vessel. This condition is called a **hemothorax** **Figure 29-12**. Suspect a hemothorax if the patient has signs and symptoms of shock without any obvious external bleeding or apparent reason for the shock state, or decreased breath sounds on the affected side, an indication that the lung is being compressed by the blood. Because the bleeding is typically caused by severe damage within the chest cavity, there is virtually no way to control the bleeding in the prehospital setting. The only person who can treat this condition is a surgeon. The presence of air and blood in the pleural space is known as a **hemopneumothorax**. Again, because the injury has occurred within the walls of the chest, the treatment involves providing rapid transport to the nearest facility capable of performing surgery.

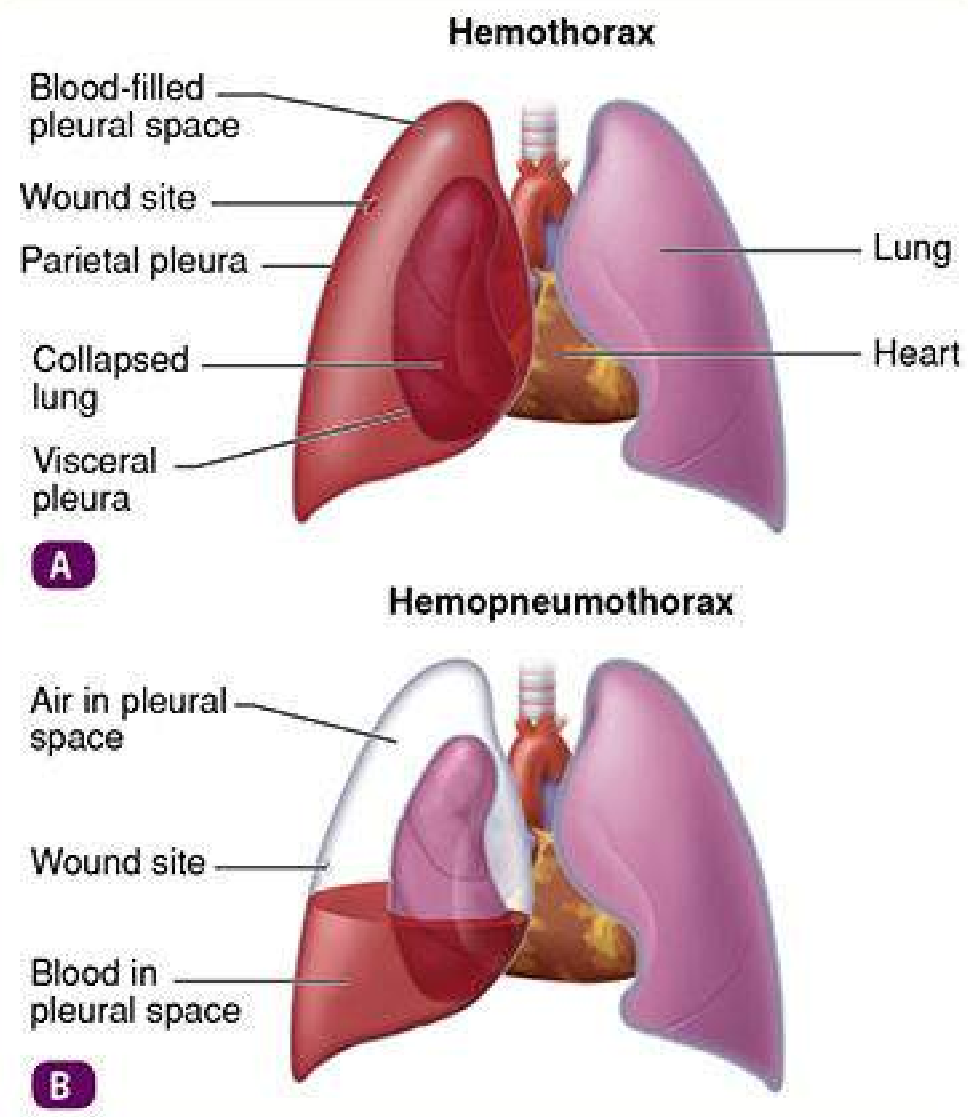

Figure 29-12 **A.** A hemothorax is a collection of blood in the pleural space produced by bleeding within the chest. **B.** When both blood and air are present, the condition is a hemopneumothorax.

YOU are the Provider PART 4

The patient is placed onto the stretcher and loaded into the ambulance. While continuing to provide high-flow oxygen via nonrebreathing mask, you reassess his condition and vital signs shortly before departing the scene.

Recording Time: 10 Minutes	
Level of consciousness	Conscious, but confused and restless
Respirations	28 breaths/min; labored and shallow
Pulse	124 beats/min; weak at the radial artery
Skin	Cool, clammy, and pale; cyanosis around the mouth
Blood pressure	104/58 mm Hg
Spo_2	88% (on oxygen)

Breath sounds are now inaudible on the entire left side of his chest, and you note that cyanosis is developing around his mouth. His jugular veins appear somewhat distended, and his trachea is midline. The closest appropriate facility is about 10 minutes away, so you instruct your partner to begin transport at once.

6. What is most likely happening to your patient?
7. Should you adjust your current treatment? If so, how?

Cardiac Tamponade

Cardiac tamponade (pericardial tamponade) occurs more commonly in the presence of penetrating chest trauma, although it may occur in blunt trauma. Cardiac tamponade occurs when the protective membrane around the heart (**pericardium**), the pericardial sac, fills with blood or fluid, perhaps from a ruptured, torn, or lacerated coronary artery or vein **Figure 29-13**. The pericardial sac can also fill as a result of cancer or an autoimmune disease such as lupus. As the fluid amount increases, the heart is less able to fill with blood during each relaxation phase. As a result, the heart cannot pump an adequate amount of blood and the patient experiences a decrease in systemic blood flow, or cardiac output. The signs of this condition are often subtle until the situation is dire. The signs and symptoms, referred to as Beck's Triad, include distended or engorged jugular veins seen on both sides of the trachea, a narrowing pulse pressure (the difference between the systolic and diastolic blood pressure numbers), and muffled heart sounds. An associated and more commonly noticed sign is a decrease in mental status as blood flow decreases to the brain. The heart muscle is unique in that it needs to be stretched to create a good contraction to pump blood out of the ventricles. This mechanism can fail because of tamponade and can be directly related to a decrease in blood returning to the heart from a loss of blood or from some blockage of the returning veins. Because this injury is inaccessible, your role in treatment is supportive. Oxygen should never be withheld from a patient who needs it; provide positive-pressure ventilation to any patient who is hypoventilating or apneic. Rapidly transport the patient to a facility that is capable of intervention.

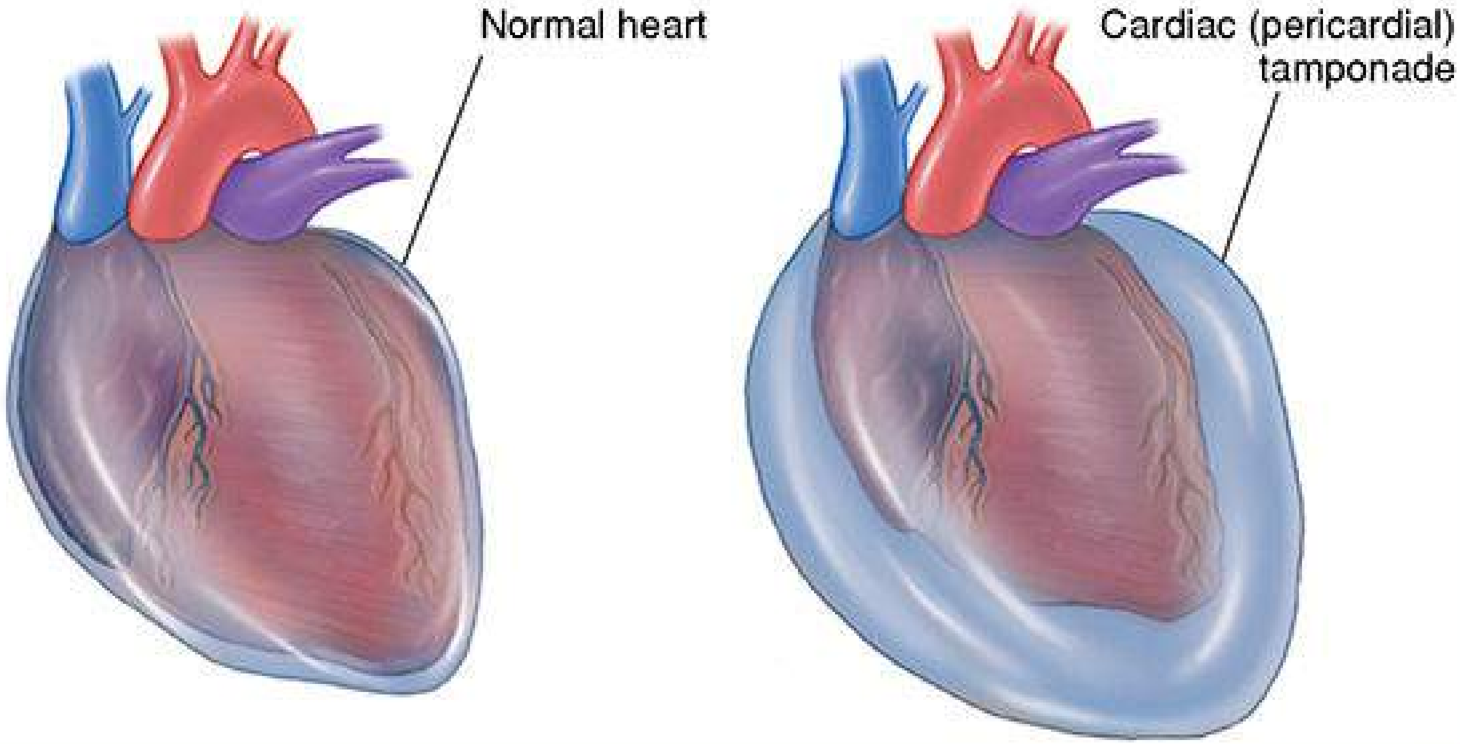

Figure 29-13 Cardiac pericardial tamponade is a potentially fatal condition in which fluid builds up within the pericardial sac, causing compression of the heart's chambers and dramatically impairing its ability to pump blood to the body.

Words of Wisdom

In a trauma situation, even a small amount of fluid in the pericardial sac is enough to cause fatal pericardial tamponade. (Occasionally, fluid in surprisingly large amounts may collect in the pericardial sac as a result of chronic medical conditions like cancers and autoimmune diseases, or due to infection.)

Rib Fractures

Rib fractures are very common, particularly in older people, whose bones are brittle. Because the upper four ribs are well protected by the bony girdle of the clavicle and scapula, a fracture of one of these upper ribs is a sign of a very substantial MOI.

Be aware that a fractured rib that penetrates into the pleural space may lacerate the surface of the lung, causing a pneumothorax, a tension pneumothorax, a hemothorax, or a hemopneumothorax.

Patients with one or more cracked ribs will report localized tenderness and pain when breathing. The pain is the result of broken ends of the fracture rubbing against each other with each inspiration and expiration. Patients will tend to avoid taking deep breaths, and their breathing will be rapid and shallow instead. They will often hold the affected portion of the rib cage in an effort to minimize the discomfort. Patients with rib fractures should receive supplemental oxygen during assessment and transport if they are experiencing any respiratory distress.

Flail Chest

Ribs may be fractured in more than one place. If three or more ribs are fractured in two or more places or if the sternum is fractured along with several ribs, a segment of chest wall may be detached from the rest of the thoracic cage Figure 29-14. This condition is known as **flail chest**. In what is called paradoxical motion, the detached portion of the chest wall moves opposite of normal: It moves in instead of out during inhalation and out instead of in during exhalation. This occurs because of negative pressure that has built up in the thorax. Breathing with a flail chest can be painful and ineffective, and hypoxemia easily results. A flail segment seriously interferes with the body's normal mechanics of ventilation and must be addressed quickly. Paradoxical motion is a late sign of flail segment; therefore, an absence of paradoxical motion does not mean the patient does not have a flail segment.

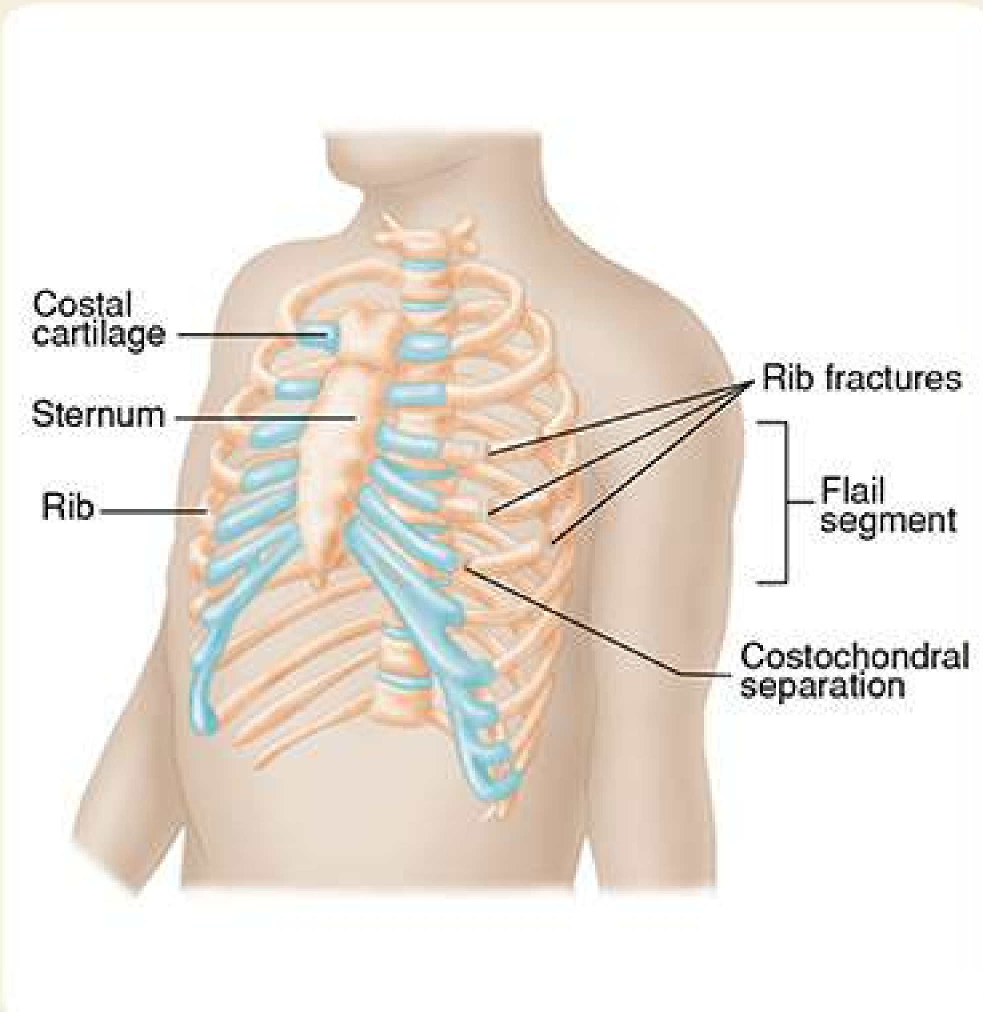

Figure 29-14 When three or more adjacent ribs are fractured in two or more places, a flail chest results. A flail segment will move paradoxically when the patient breathes.

Treatment of a patient with a flail chest should include maintaining the airway, providing respiratory support if necessary, giving supplemental oxygen, and performing ongoing assessments for possible pneumothorax or other respiratory complications. Treatment may also include positive-pressure ventilation with a BVM. In the past, treatment included splinting of the flail segment with bulky dressings. However, restricting chest wall movement is no longer recommended and positive-pressure ventilation is now preferred.

Keep in mind that although flail chest itself is a serious condition, it suggests an injury that was forceful enough to cause other serious internal damage and possible spinal injury. Often the flail chest contributes less to the patient's ventilation difficulties than does the underlying pulmonary contusion (bruised lung segment).

YOU are the Provider — PART 5

You call for ALS support but find out that the closest unit is 15 miles away, so you elect to continue treatment and transport. After reassessing the patient's condition, you have your partner call a radio report to the receiving facility.

Recording Time: 15 Minutes	
Level of consciousness	Conscious, but confused and restless
Respirations	28 breaths/min; labored and shallow
Pulse	128 beats/min; weak at the radial artery
Skin	Cool and clammy; cyanosis around the mouth
Blood pressure	90/60 mm Hg
Spo_2	92% (on oxygen)

You arrive at the hospital and find a physician and nurse waiting for you in the ambulance bay. The patient is quickly taken into a treatment room, where further assessment is performed. After the physician performs a needle thoracentesis, the patient's condition improves. After returning to service, you follow up with the hospital and learn that the patient had a tension hemopneumothorax.

8. What is a tension hemopneumothorax?
9. Should you attempt to distinguish a tension pneumothorax from a tension hemopneumothorax? Why or why not?

Other Chest Injuries

Pulmonary Contusion

In addition to fracturing ribs, any severe blunt trauma to the chest can also injure or bruise the lung. The pulmonary alveoli become filled with blood, and fluid accumulates in the injured area, leaving the patient hypoxic. Severe **pulmonary contusion** should always be suspected in patients with a flail chest and usually develops over a period of hours. If you believe that a patient may have a pulmonary contusion, provide supplemental oxygen and positive-pressure ventilation as needed to ensure adequate oxygenation and ventilation.

Other Fractures

In addition to the rib fractures you have already learned about, there are other types of fractures that should be discussed.

Sternal Fractures

Any suspected fracture of the sternum should increase your index of suspicion for injuries to the underlying organs because the amount of force required to break the sternum is significant. There may be involvement of the lungs, great vessels, and the heart itself.

Clavicle Fractures

Whereas this fracture is also covered under skeletal injuries, it is important to mention here that the clavicle overlies and protects a large neurovascular bundle (nerve, artery, and vein) that can be significantly damaged or disrupted should injury to the clavicle occur. The pain, deformity, and swelling that accompany a clavicle fracture can also detract from assessment of the first and second ribs in proximity to the fracture. Suspect upper rib fractures in medial clavicle fractures, and be alert to possible signs of pneumothorax development.

Traumatic Asphyxia

Sometimes a patient will experience a sudden, severe compression of the chest, which produces a rapid increase in pressure within the chest. This may occur in an unrestrained driver who hits a steering wheel, a pedestrian who is compressed between a vehicle and a wall, or a patient who is pinned under a vehicle. The sudden increase in intrathoracic pressure results in a characteristic appearance, including distended neck veins, cyanosis in the face and neck, and hemorrhage into the sclera of the eye, signaling the bursting of small blood vessels **Figure 29-15**. This is called **traumatic asphyxia**. These findings suggest an underlying injury to the heart and possibly a pulmonary contusion. Provide ventilatory support with supplemental oxygen and monitor the patient's vital signs as you provide immediate transport.

Figure 29-15 Traumatic asphyxia.

Blunt Myocardial Injury

Blunt trauma to the chest may injure the heart itself, making it unable to maintain adequate blood pressure. There is much debate in the medical literature about how to assess **myocardial contusion**, or bruising of the heart muscle. Often the pulse is irregular, but dangerous rhythms such as ventricular tachycardia and ventricular fibrillation are uncommon. There is no specific diagnostic test at this time, and there is no prehospital treatment for the condition. Still, you should suspect myocardial contusion in all cases of severe blunt injury to the chest. Carefully check the patient's pulse, and note any irregularities. Also note any change in blood pressure because this can be a direct result of the injury to the myocardium. Often the patient's signs and symptoms can mimic a heart attack in which the patient may report chest pain or discomfort that is similar in nature to cardiac symptoms. Provide supplemental oxygen, and transport immediately.

Commotio Cordis

Commotio cordis is a blunt chest injury caused by a sudden, direct blow to the chest (over the heart) that occurs only during a critical portion of a person's heartbeat. The result may be immediate cardiac arrest. This phenomenon has occurred after patients were struck with softballs, baseballs, bats, snowballs, fists, and even kicks during kickboxing. The force of the blow to the chest is commonly at speeds of 35 to 40 miles per hour. The blunt force causes a lethal abnormal heart rhythm called ventricular fibrillation. The ventricular fibrillation responds positively to early defibrillation if provided within the first 2 minutes after the injury. Commotio cordis is more commonly associated with sports-related injuries, although it should be suspected in all cases in which the person is unconscious and unresponsive after a blow to the chest. Due to the risk of commotio cordis in sports, many youth baseball and softball leagues now recommend or require the use of chest protectors.

Laceration of the Great Vessels

The chest contains several large blood vessels: the superior vena cava, the inferior vena cava, the pulmonary arteries, four main pulmonary veins, and the aorta, with its major branches distributing blood throughout the body. Injury to any of these vessels may be accompanied by massive, rapidly fatal hemorrhage. Any patient with a chest wound who shows signs of shock may have an injury to one or more of these vessels. Frequently, significant blood loss is unseen because it remains within the chest cavity. Remain alert to signs and symptoms of shock and to changes in the baseline vital signs, such as tachycardia and hypotension.

Words of Wisdom

Transection of the aorta may cause up to 15% of deaths from motor vehicle crashes. Given that the body's entire blood volume passes through this vessel, the high mortality associated with such an injury comes as no surprise. Aortic injuries are rapidly fatal, often causing cardiac arrest prior to hospital arrival, or even prior to arrival of EMS. Most of the people who are still alive when EMS personnel arrive can survive with prompt management, including surgical intervention.

Emergency treatment in these cases includes cardiopulmonary resuscitation, if appropriate, ventilatory support, and supplemental oxygen. Immediate transport to the hospital may be critical. Occasionally, some of the patients can be treated. The overwhelming majority of injuries to the great vessels in the chest are rapidly fatal.

YOU are the Provider — SUMMARY

1. What major organs and structures lie within the chest cavity?

Critical organs and structures in the chest cavity include the trachea, large bronchi, lungs, great vessels (eg, aorta, venae cavae), heart, esophagus, and the left and right subclavian arteries and their branches. The heart, trachea, great vessels, and a portion of the esophagus reside within the mediastinum—the space between the lungs.

Each side of the chest (hemithorax) contains lung tissue that is separated into lobes. The right lung has three lobes, and the left lung has two lobes to allow space for the heart. The space in the left hemithorax where the heart resides is called the cardiac notch.

A thin lining called the visceral pleura covers the lungs, and the parietal pleura covers the inner chest wall. A small amount of pleural fluid is found between the pleurae. The space in between the visceral and parietal pleurae—the pleural space—is a potential space because the pleurae are in direct contact with each other. However, if trauma occurs to the lungs, blood or air could accumulate between the two pleurae, creating an actual space.

2. What injuries commonly result from blunt chest trauma? Penetrating chest trauma?

Blunt (closed) chest trauma occurs when an object strikes the chest (eg, a steel pipe during an assault) or when the chest strikes an object (eg, chest impacts the steering wheel during a car crash). The severity of the injury depends on the amount of energy that the chest wall absorbs. Although the skin and chest wall are not penetrated by blunt force trauma, injury to the intrathoracic organs may be severe.

Rib fractures are a common injury associated with blunt chest trauma. In some cases, a single rib is fractured; in other cases, several ribs are fractured in more than one place (flail chest). A flail chest can impair ventilation because the section of fractured ribs collapses and puts pressure on the lung during inhalation. A fractured rib can also perforate an internal chest organ, such as the lung, causing air to leak out of the lung and into the pleural space (pneumothorax). If air moves freely between the pleural space and lung, the injury is called a simple pneumothorax. In a tension pneumothorax, the lung is completely collapsed, and the heart and great vessels (eg, aorta, venae cavae) are compressed as pressure shifts across the mediastinum. This causes ventilatory compromise, decreased cardiac output, and shock. A hemothorax, which may be caused by blunt or penetrating chest trauma, occurs when blood, rather than air, fills the pleural space.

Blunt force chest trauma can also cause bruising of the lung (pulmonary contusion) or the heart muscle (myocardial contusion). Other injuries include shearing injuries of the aorta, traumatic asphyxia, and commotio cordis.

In a penetrating (open) chest injury, the chest wall itself is penetrated by an object such as a knife or bullet, resulting in injury to vital organs in the thoracic cavity. Two common injuries caused by penetrating chest trauma are sucking chest wounds (open pneumothorax) and cardiac (pericardial) tamponade. Sucking chest wounds cause various degrees of ventilatory compromise, depending on the size of the hole in the chest wall. As a result of cardiac tamponade, the amount of blood pumped decreases and the patient will experience shock from a decrease in systemic blood flow.

3. How should you proceed with your secondary assessment?

For patients with an isolated injury, your secondary assessment should focus on that area of the body—in this case, the chest and adjacent structures.

Expose the patient's chest, and assess for obvious signs of injury, such as bruising, lacerations, or abrasions. Observe the chest wall for symmetry. Asymmetrical chest movement indicates decreased airflow into one lung. Look for any sections of the rib cage that collapse during inhalation and bulge during exhalation (paradoxical chest movement); this indicates a flail chest injury.

Palpate the chest wall to determine if it is stable, if there are any deformities, or if you feel crepitus—the sensation felt when broken bone ends grind together. Chest wall crepitus is a clear indicator of one or more fractured ribs.

Auscultate the apices (top) and bases (bottom) of both lungs. Decreased or absent breath sounds over the injured side of the chest indicate decreased or absent airflow into that lung and should immediately increase your index of suspicion for a pneumothorax.

Based on the mechanism of injury—blunt chest trauma—you should also assess the trachea and jugular veins. Note whether the trachea is in the midline position or if it appears to be deviated to one side or the other. Bear in mind that if the patient has a tension pneumothorax, tracheal deviation is an extremely late sign; a midline trachea does not rule out such an injury. Observe the jugular veins to determine if they appear to be normal, distended, or flat. Jugular vein distention is best assessed with the patient sitting at a 45-degree angle. The presence of jugular vein distention in the context of chest trauma suggests a tension pneumothorax or cardiac tamponade, although it is often not present until the injury is well progressed. Conversely, collapsed jugular veins suggest a hemothorax or shock.

Further assessment beyond that discussed is based on any other symptoms the patient may report and any obvious injuries that you observe.

4. On the basis of your assessment findings, what injury or injuries should you suspect?

On the basis of the mechanism of injury—blunt trauma to the chest—and the findings of your primary and secondary assessments, you should suspect that your patient has rib fractures and a pneumothorax. He has obvious chest wall bruising, labored breathing, crepitus to palpation (indicates at least one fractured rib), and diminished breath sounds on the same side that the injury occurred.

Depending on the size of the lung perforation and the rate at which air fills the pleural space, the lung may collapse in a few seconds or a few hours. Breath sounds on the injured side are diminished because the collapsing lung is not fully expanding during inhalation.

Because a pneumothorax impairs oxygenation and ventilation, begin treatment immediately and prepare for rapid transport to the hospital. If the lung on the injured side collapses totally, pressure will shift to the opposite side of the chest—compressing the heart, aorta, and venae cavae in the process—and begin collapsing the unaffected lung; this condition is called a tension pneumothorax and is an immediately life-threatening condition that can result in profound shock and cardiac arrest.

5. How should you proceed with your treatment of this patient?

Patients with a pneumothorax need high-flow oxygen, continual close monitoring, and prompt transport to the hospital.

Be especially concerned about the adequacy of the patient's breathing, and continuously monitor it. Your patient is tachypneic, which is common in patients with chest injuries; his respirations are labored, and it hurts when he breathes. Patients with chest injuries often breathe shallowly on purpose in an attempt to minimize the pain (respiratory splinting). It may be helpful to allow the patient to hold a pillow or similar object to his chest; this will help stabilize any rib fractures and may make it easier for him to breathe.

If his respirations become too shallow (indicating a marked tidal volume reduction), he will not move adequate amounts of air into his lungs during inhalation; this will only worsen any hypoxemia that already exists from the pneumothorax itself. If this occurs, begin assisting his ventilations with a BVM attached to high-flow oxygen. Other signs of inadequate breathing, which may also necessitate assisted ventilations, include a falling oxygen saturation (despite administration of high-flow oxygen), cyanosis, and a decreasing level of consciousness.

Continue to monitor the patient's level of consciousness and vital signs. If he begins experiencing signs of shock (decreased level of consciousness, pallor, weak pulses, hypotension), suspect a developing tension pneumothorax. If this occurs, consider an ALS intercept, if possible. Paramedics can perform a needle thoracentesis (also called a chest decompression). If an ALS ambulance is not available, continue rapid transport, frequently reassess the patient, and notify the receiving facility as early as possible.

6. What is most likely happening to your patient?

Compared with previous assessments, your patient's clinical condition has obviously deteriorated. He is now confused; is more tachypneic; his respirations are still labored, but are now shallow; cyanosis is developing around his mouth (perioral cyanosis); his radial pulses are weak; and his oxygen saturation has fallen to 88% despite high-flow oxygen via nonrebreathing mask. Although his systolic blood pressure is still above 100 mm Hg, compared with your previous reading of 138/88 mm Hg, this is a significant decrease. The patient's signs and symptoms indicate worsened hypoxemia and hypoperfusion (shock).

The additional signs of inaudible (absent) breath sounds on the injured side of his chest and the appearance of jugular vein distention indicate that the entire left lung has collapsed, and pressure is now shifting across the mediastinum toward the unaffected lung. Your patient now has a tension pneumothorax!

7. Should you adjust your current treatment? If so, how?

A tension pneumothorax is an immediate life threat and requires aggressive treatment.

The patient now has clear evidence of inadequate breathing (decreased level of consciousness [confusion]; falling oxygen saturation; labored, shallow breathing; and cyanosis), which is causing inadequate oxygenation and ventilation. Begin assisting his ventilations with a BVM. In doing so, however, exercise caution; ventilating too rapidly or with too much force could worsen his condition.

You must also initiate shock treatment. At a minimum, cover the patient with a blanket to keep him warm. Patients with any injury or condition that impairs their ability to breathe are often resistant to being placed in a supine position; this is especially true if they are conscious. If the patient becomes unconscious, however, place him in a supine position and continue to assist his ventilations.

Patients with a tension pneumothorax need an immediate needle thoracentesis (chest decompression). If it will not delay your transport time (you are only 10 minutes away from the hospital), intercept an ALS unit, if possible. Otherwise, notify the receiving facility, continue ventilation assistance and shock treatment, and get the patient to the emergency department as soon as possible.

8. What is a tension hemopneumothorax?

In some cases, when a fractured rib perforates a lung, blood from the injured lung also accumulates in the pleural space; this is called a hemopneumothorax because the pleural space contains both blood and air. The amount of blood that accumulates in the pleural space depends on the size and severity of the lung injury.

As blood and air continue to accumulate in the pleural space, the lung on the injured side collapses and pressure shifts across the mediastinum toward the uninjured lung. In a tension hemopneumothorax, the patient experiences respiratory impairment from both blood and air in the pleural space, but also experiences internal blood loss of varying severity.

9. Should you attempt to distinguish a tension pneumothorax from a tension hemopneumothorax? Why or why not?

It is impractical to attempt to distinguish a tension pneumothorax from a tension hemopneumothorax in the prehospital setting. Both conditions cause impaired ventilation and perfusion; this is what you should focus on when treating the patient. Provide high-flow oxygen, assist ventilations as needed, initiate shock treatment, and transport without delay.

Attempting to distinguish one injury from the other may only delay treatment and transport, thereby increasing the chance of a negative outcome.

EMS Patient Care Report (PCR)

Date: 11-5-16	**Incident No.:** 012709	**Nature of Call:** Chest injury		**Location:** 233 Indian Hills Dr.	
Dispatched: 1020	**En Route:** 1020	**At Scene:** 1028	**Transport:** 1035	**At Hospital:** 1045	**In Service:** 1053

Patient Information

Age: 19
Sex: M
Weight (in kg [lb]): 66 kg (145 lb)

Allergies: Penicillin
Medications: None
Past Medical History: None
Chief Complaint: Difficulty breathing secondary to chest injury

Defibrillation / **Bleeding Control**	**Bandaging**	**Splinting**	**Other:** Shock treatment, blanket for warmth, pillow to chest for pain relief

Narrative

Medic 30 dispatched to a construction site for a patient with a "chest injury." On arrival at the scene, a coworker directed the EMS crew to the patient, a 19-year-old man. He was found sitting on the ground. He was conscious, but restless; his airway was patent; his breathing was labored; and no gross external bleeding was noted. Patient reports chest pain and difficulty breathing after being struck in the left anterior part of the chest by a 2 × 4 board, which was thrown from a table saw when another coworker was cutting it. He denies any other injuries, and coworkers confirm that there was no loss of consciousness. Applied oxygen at 15 L/min via nonrebreathing mask and performed further assessment. Obvious bruising was noted to left anterior part of the chest, as was crepitus on palpation. Remainder of chest wall was stable. Breath sounds were diminished to left side of the chest. No paradoxical chest wall movement was noted, jugular veins were nondistended, and trachea was midline. Obtained vital signs, placed patient onto stretcher, and loaded him into the ambulance. Reassessed patient's condition and vital signs and noted obvious deterioration. He was now confused, more tachypneic, and his respirations were markedly shallow. Oxygen saturation read 88%, and skin was now cool and clammy, with perioral cyanosis. Breath sounds were now absent on the left side of the chest. Began assisting ventilations with BVM attached to high-flow oxygen and initiated transport. Intercept with ALS unit was not possible because it would have caused a significant delay in transport. Covered patient with a blanket for warmth, continued ventilation assistance, and reassessed patient every 5 minutes throughout transport. Delivered patient to hospital, gave verbal report to attending physician, and transferred patient care to hospital staff. Medic 30 returned to service at 1053.**End of report**

Prep Kit

Ready for Review

- A penetrating chest injury has the potential to penetrate the lung and diaphragm and injure the liver or stomach.
- Chest injuries are classified as closed or open. Closed injuries are often the result of blunt force trauma, and open injuries are the result of an object penetrating the skin and/or chest wall.
- Blunt trauma may result in fractures to the ribs and the sternum.
- Life-threatening hemorrhage must be addressed immediately during the primary assessment, even before airway or breathing concerns.
- During the primary assessment, if an injury is encountered that interferes with the ability of the patient to oxygenate or ventilate, the injury must be addressed quickly.
- Any penetrating injury to the chest may result in air entering the pleural space and may cause pneumothorax. An occlusive dressing should be placed on this injury as soon as it is identified.
- When a penetrating injury creates a hole in the chest wall, you may hear a sucking sound as the patient inhales. This is called an open pneumothorax.
- A simple pneumothorax is a result of blunt trauma, such as fractured ribs.
- A spontaneous pneumothorax may be the result of rupture of a weak spot on the lung, allowing air to enter the pleural space and accumulate. This often results from nontraumatic injuries and may occur during times of physical activity such as exercise.
- A pneumothorax may progress to a tension pneumothorax and cause cardiac arrest.
- Hemothorax is the result of blood accumulating in the pleural space after a traumatic injury when the vessels of the lung are lacerated and leak blood.
- A flail chest segment is three or more ribs broken in two or more places. Positive-pressure ventilation may be particularly important for the patient with a flail chest that compromises ventilation.
- All patients with chest injuries should receive high-flow oxygen or ventilation with a BVM.
- Pulmonary contusion, which is bruising of or injury to lung tissue after traumatic injury, may interfere with oxygen exchange in the lung tissue.
- Myocardial contusion is bruising of the heart muscle after traumatic injury. This condition may have the same signs and symptoms as a heart attack, including an irregular pulse. Remember that this is an injury to the heart muscle from trauma, not from a heart attack.
- Commotio cordis occurs from a direct blow to the chest during a critical portion of the patient's heartbeat. It may result in immediate cardiac arrest.
- Cardiac tamponade is when blood collects in the space between the pericardial sac and the heart. This condition results in pressure building up inside the pericardial sac until the heart cannot pump effectively; cardiac arrest may occur quickly.
- The great vessels of the body are located in the mediastinum. These large vessels may be lacerated or tear after traumatic injury and cause heavy, unseen bleeding inside the patient's chest cavity.
- Any patient who has signs of shock with a chest injury, even with unseen bleeding, should make you suspicious of unseen, life-threatening bleeding inside the chest cavity.

Vital Vocabulary

cardiac tamponade (pericardial tamponade) Compression of the heart as the result of buildup of blood or other fluid in the pericardial sac, leading to decreased cardiac output.

closed chest injury An injury to the chest in which the skin is not broken, usually caused by blunt trauma.

commotio cordis A blunt chest injury caused by a sudden, direct blow to the chest that occurs only during the critical portion of a person's heartbeat.

crepitus A grating or grinding sensation caused by fractured bone ends or joints rubbing together.

flail chest A condition in which three or more ribs are fractured in two or more places or in association with a fracture of the sternum so that a segment of the chest wall is effectively detached from the rest of the thoracic cage.

flutter valve A one-way valve that allows air to leave the chest cavity but not return; formed by taping three sides of an occlusive dressing to the chest wall, leaving the fourth side open as a valve; may also be part of a commercial vented occlusive dressing.

hemopneumothorax The accumulation of blood and air in the pleural space of the chest.

hemothorax A collection of blood in the pleural cavity.

myocardial contusion Bruising of the heart muscle.

occlusive dressing An airtight dressing that protects a wound from air and bacteria; a commercial vented version allows air to passively escape from the chest, while an unvented dressing may be made of petroleum jelly-based (Vaseline) gauze, aluminum foil, or plastic.

open chest injury An injury to the chest in which the chest wall itself is penetrated by a fractured rib or, more frequently, by an external object such as a bullet or knife.

open pneumothorax An open or penetrating chest wall wound through which air passes during inspiration and expiration, creating a sucking sound; also referred to as a sucking chest wound.

paradoxical motion The motion of the portion of the chest wall that is detached in a flail chest; the motion—in during inhalation, out during exhalation—is exactly the opposite of normal chest wall motion during breathing.

pericardium The fibrous sac that surrounds the heart.

pneumothorax An accumulation of air or gas in the pleural cavity.

pulmonary contusion Injury or bruising of lung tissue that results in hemorrhage.

simple pneumothorax Any pneumothorax that is free from significant physiologic changes and does not cause drastic changes in the vital signs of the patient.

spontaneous pneumothorax A pneumothorax that occurs when a weak area on the lung ruptures in the absence of major injury, allowing air to leak into the pleural space.

sucking chest wound An open or penetrating chest wall wound through which air passes during inspiration and expiration, creating a sucking sound. See also *open pneumothorax*.

tachypnea Rapid respirations.

tension pneumothorax An accumulation of air or gas in the pleural cavity that progressively increases pressure in the chest that interferes with cardiac function with potentially fatal results.

traumatic asphyxia A pattern of injuries seen after a severe force is applied to the chest, forcing blood from the great vessels back into the head and neck.

Assessment *in Action*

You and your partner are dispatched to the rodeo arena for a person reporting shortness of breath and chest pain. On arrival you are escorted to a first aid trailer where you find a man in his mid 30s seated in a chair and leaning forward clutching his chest. He tells you that he was riding a bull when he was thrown off. He states that he landed hard on his right side and heard a "loud pop."

1. The patient finds it difficult to take a deep breath and speak. On the basis of this information, what should be your first intervention?

   A. Take vital signs.
   B. Apply a bulky dressing to the right side of the chest.
   C. Administer high-flow oxygen.
   D. Immobilize the patient on a backboard.

2. Exposure of the patient's chest reveals a large bruise on the lateral aspect of the right side of the chest. When you palpate the area, the patient yells out in extreme pain and states that he cannot take a deep breath. What condition should you suspect?

   A. Cardiac tamponade
   B. Rib fractures
   C. Spontaneous pneumothorax
   D. Pulmonary contusion

3. Potential complications associated with fractured ribs may include all of the following EXCEPT*:*

   A. pneumothorax.
   B. tension pneumothorax.
   C. hemothorax.
   D. upper airway obstruction.

4. Which of the following blood vessels can be lacerated by a fractured rib?

A. Aorta
B. Brachial artery
C. Intercostal artery or vein
D. Jugular vein

5. How often should this patient be reevaluated?

A. Every 5 minutes
B. Every 10 minutes
C. Every 15 minutes
D. Every 20 minutes

6. Diagnostic tools are used to assist you in assessing the severity of your patient's condition. What diagnostic tool is most commonly used to evaluate the effectiveness of the respiratory system?

A. End-tidal carbon dioxide detector
B. Peak flow meter
C. Pulse oximeter
D. Automated blood pressure

7. While en route to the hospital, the patient suddenly grabs your arm and states that he can't breathe. He appears pale, diaphoretic, and extremely anxious. Reassessment of the chest reveals diminished breath sounds on the right side and subcutaneous emphysema. You suspect which of the following conditions is developing in the patient?

A. Cardiac tamponade
B. Tension pneumothorax
C. Myocardial contusion
D. Pulmonary contusion

8. You are still 30 minutes away from the hospital. On the basis of the patient's current signs and symptoms, what is the most appropriate management?

A. Assist ventilations with a BVM and continue transport.
B. Call for ALS assistance and continue transport.
C. Reassure the patient and continue transport.
D. Attempt to place a needle in the right side of the chest.

9. How can a tension pneumothorax develop as the result of fractured ribs?

10. Spinal cord injury should be suspected in patients with chest injury. The intercostal muscles receive nerve impulses from specific spinal nerves. Where are these nerves located?

Abdominal and Genitourinary Injuries

© Chuck Stewart, MD.

National EMS Education Standard Competencies

Trauma

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

Abdominal and Genitourinary Trauma

› Recognition and management of
- Blunt versus penetrating mechanisms (pp 1059–1062, 1069–1071, 1073–1075, 1077–1078)
- Evisceration (pp 1062, 1071–1072)
- Impaled object (pp 1068, 1078)

› Pathophysiology, assessment, and management of
- Solid and hollow organ injuries (pp 1058–1059, 1062–1072, 1075–1078)
- Blunt versus penetrating mechanisms (pp 1059–1062, 1064–1071, 1073–1079)
- Evisceration (pp 1062, 1064–1069, 1071–1072)
- Injuries to the external genitalia (pp 1074–1079)
- Vaginal bleeding due to trauma (pp 1074–1079)
- Sexual assault (p 1079)

Knowledge Objectives

1. Describe the anatomy and physiology of the abdomen; include an explanation of abdominal quadrants and boundaries and the difference between hollow and solid organs. (pp 1057–1059)
2. Describe some special considerations related to the care of pediatric patients and geriatric patients who have experienced abdominal trauma. (pp 1058–1059, 1065)

3. Define closed abdominal injuries; provide examples of the mechanisms of injury (MOI) likely to cause this type of trauma, and common signs and symptoms exhibited by patients who have experienced this type of injury. (pp 1059–1060)
4. Define open abdominal injuries; include the three common velocity levels that distinguish these injuries, provide examples of the MOI that would cause each, and common signs and symptoms exhibited by patients who have experienced this type of injury. (pp 1061–1062)
5. Describe the different ways hollow and solids organs of the abdomen can be injured and include the common signs and symptoms exhibited by patients depending on the organ(s) involved. (pp 1062–1064)
6. Explain assessment of a patient who has experienced an abdominal injury; include common indicators that help determine the MOI and whether it is a significant or insignificant MOI. (pp 1064–1069)
7. Explain the emergency medical care of a patient who has sustained a closed abdominal injury, including blunt trauma caused by a seat belt or air bag. (pp 1069–1070)
8. Explain the emergency medical care of a patient who has sustained an open abdominal injury, including penetrating injuries and abdominal evisceration. (pp 1070–1072)
9. Describe the anatomy and physiology of the female and male genitourinary system; include the differences between the hollow and solid organs. (pp 1072–1073)
10. Discuss the types of traumatic injuries sustained by the male and female genitourinary system, including the kidneys, urinary bladder, and internal and external genitalia. (pp 1073–1075)
11. Explain assessment of a patient who has experienced a genitourinary injury; include special considerations related to patient privacy and determining the MOI. (pp 1075–1077)
12. Explain the emergency medical care of a patient who has sustained a genitourinary injury to the kidneys, urinary bladder, external male genitalia, female genitalia, and rectum. (pp 1077–1079)
13. Explain special considerations related to a patient who has experienced a genitourinary injury caused by a sexual assault, including patient treatment, criminal implications, and evidence management. (p 1079)

Skills Objectives

1. Demonstrate proper emergency medical care of a patient who has experienced a blunt abdominal injury. (pp 1069–1070)
2. Demonstrate proper emergency medical care of a patient who has a penetrating abdominal injury with an impaled object. (pp 1070–1071)
3. Demonstrate how to apply a dressing to an abdominal evisceration wound. (pp 1071–1072)

Introduction

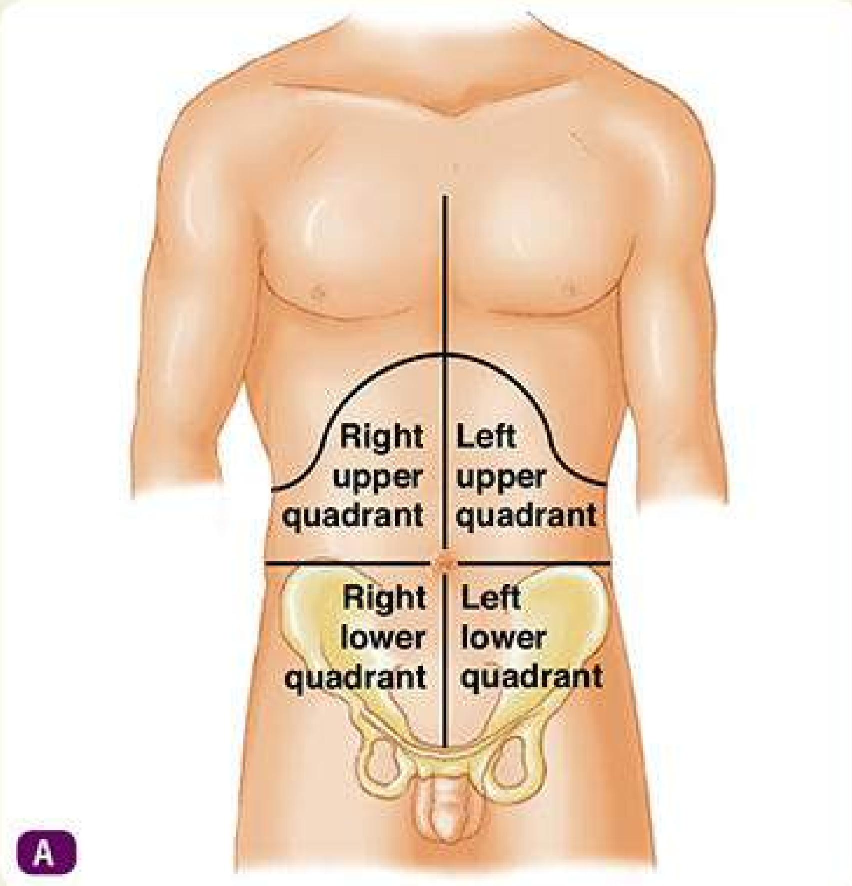
The abdomen is the major body cavity extending from the diaphragm to the pelvis. It contains organs that make up the digestive, urinary, and genitourinary systems. Although any of these organs can be injured, some organs are better protected than others. It is important for you to know the anatomy of the abdominal and pelvic cavities and where the organs are located. You must also understand the functions of the organs so that if an injury occurs, you can assess its seriousness.

Significant trauma to the abdomen can occur from blunt trauma, penetrating trauma, or both. Injuries to the abdomen that go unrecognized or untreated are a leading cause of traumatic death. Similarly, trauma to the genitourinary system is often overlooked, despite 10% of all trauma patients having some form of genitourinary injury. Such injuries can result in life-altering consequences, such as incontinence, infertility, or impotence. It is paramount that you maintain a high index of suspicion if there is a mechanism of injury (MOI) that suggests an abdominal or genitourinary injury and share those findings with the receiving hospital prior to and on arrival.

Anatomy and Physiology of the Abdomen

Abdominal Quadrants

The abdomen is divided into four general quadrants **Figure 30-1**. Two imaginary lines intersect at the umbilicus, dividing the abdomen into four equal areas. These areas are the right upper quadrant (RUQ), left upper quadrant (LUQ), right lower quadrant (RLQ), and left lower quadrant (LLQ). Remember, right and left refer to the patient’s right and left, not yours.



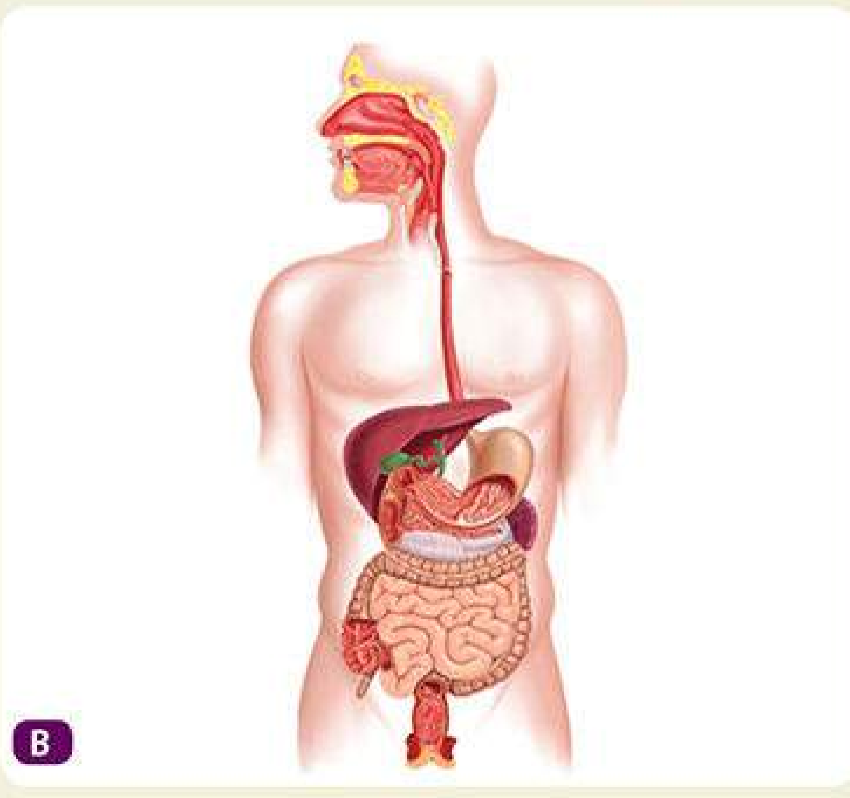


Figure 30-1 **A.** The abdomen is often referred to by quadrants. **B.** Many organs in the abdomen lie in more than one quadrant.

YOU are the Provider — PART 1

You and your partner are working a special event—the annual rodeo. While on standby, you witness a rider being thrown and trampled by a bull. After a rodeo clown distracts and corrals the bull, the rider, a 20-year-old man, slowly gets up and begins to walk. He is clutching his abdomen with one hand and rubbing his lower back with the other hand.

1. How do hollow organ injuries differ from solid organ injuries?
2. How should you focus your assessment of a patient with potential intra-abdominal bleeding?

The quadrant location of bruising or pain can show which organs are possibly involved in a traumatic injury. Organs commonly found in the right upper quadrant are the liver, gallbladder, duodenum of the intestines, and a small portion of the pancreas. The stomach occupies most of the left upper quadrant but it shares this space with the spleen. The pancreas occupies some of this space but is mostly posterior to the region. The left lower quadrant holds both the large and small intestines, notably the descending colon and the left half of the transverse colon. The right lower quadrant also holds portions of the large and small intestines that include the ascending colon and the right half of the transverse colon. The distal end of the descending colon, called the appendix, is located in this region. Swelling and inflammation are common in this region, because the appendix is a common source of intra-abdominal infection—severe infection and even septic shock may occur if it ruptures.

Special Populations

In pediatric patients, the liver and spleen are very large in proportion to the size of the abdominal cavity and are more easily injured. The soft, flexible ribs of infants and young children do not protect these two organs very well and may allow injury to underlying organs, even without fracturing the ribs.

Hollow and Solid Organs

The abdomen contains both hollow and solid organs, any of which may be damaged. **Hollow organs**, including the stomach, large and small intestines, ureters, and urinary bladder, are actually structures through which materials pass **Figure 30-2**. Most of these organs will contain food that is in the process of being digested, urine that is being passed to the urinary bladder for release, or bile. When ruptured or lacerated, these organs spill their contents into the **peritoneal cavity** (the abdominal cavity), causing an intense inflammatory reaction and possible infection. The lining of the peritoneal cavity, the **peritoneum**, may become inflamed and painful—a condition known as *peritonitis*. The intestines and stomach contain acid-like substances that aid in the digestive process. When these substances spill or leak into the peritoneal cavity, they cause pain and irritate the peritoneum. The first signs of peritonitis are severe abdominal pain, tenderness, and muscular spasm. Later, bowel sounds diminish or disappear as the bowel stops functioning. A patient may feel nauseous and may vomit; the abdomen may become distended and firm to touch; and infection may occur. Peritonitis is serious and may become life threatening.

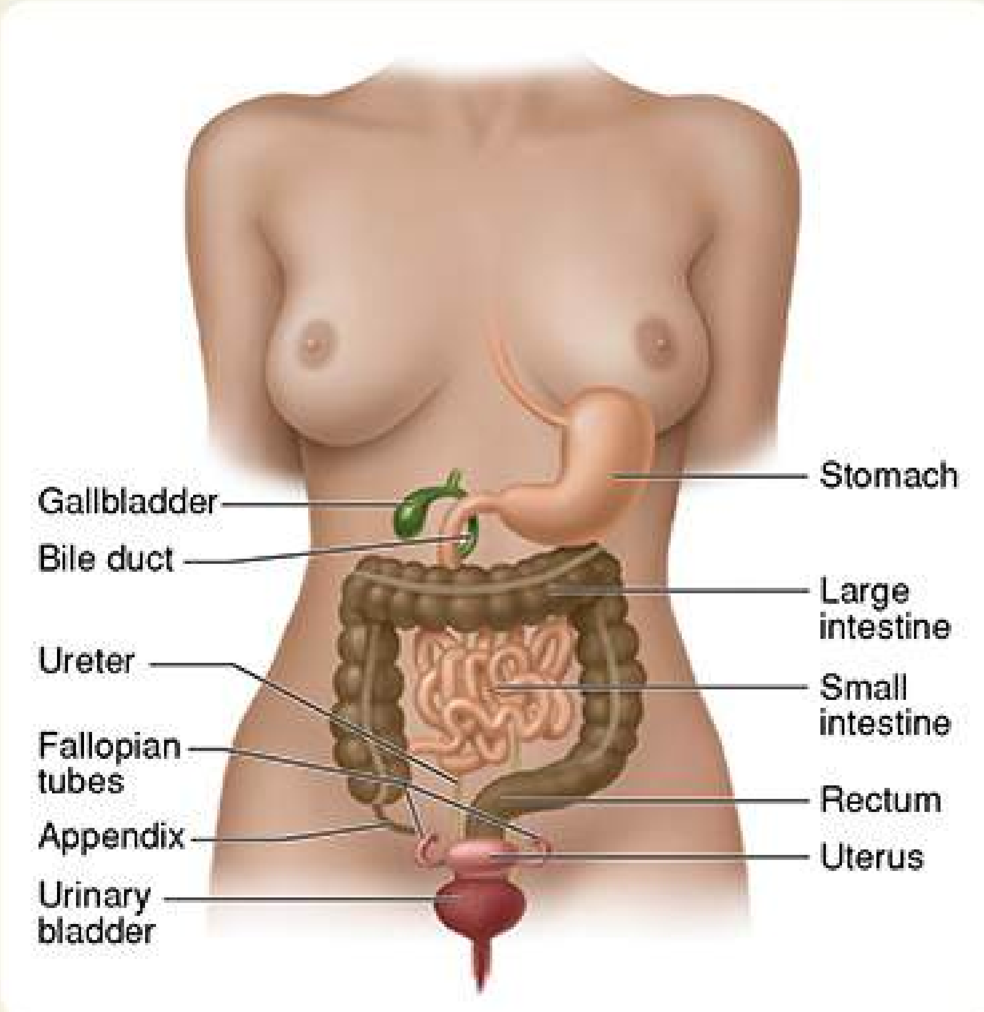

Figure 30-2 The hollow organs in the abdominal cavity are structures through which materials pass.

The small intestine is composed of the duodenum, the jejunum, and the ileum. The large intestine includes the cecum, the colon, and the rectum. The intestinal blood supply comes from the mesentery. The term *mesentery* refers to any fold of tissue that attaches an organ to the body wall. However, the majority of time the term is used in reference to the intestinal mesentery: a fold of tissue that contains a web of vessels, both arteries and veins, as well as nerves and lymphatic tissues. It connects the small intestine to the posterior of the abdominal wall. Both blunt and penetrating abdominal injuries affect this vasculature, and patients with injuries to the mesentery can bleed significantly into the peritoneal cavity. A common sign of bleeding in the abdomen is rigidity, with an almost boardlike feeling to the abdomen. Occasionally you will find bruising around the belly button (periumbilical bruising) or ecchymosis.

The **solid organs**, as their name suggests, are solid masses of tissue. They include the liver, spleen, pancreas, and kidneys **Figure 30-3**. It is here that much of the chemical work of the body—enzyme production, blood cleansing, and energy production—takes place. Solid organs have a rich blood supply, so injury can cause severe and unseen hemorrhage. The same is true of the aorta or inferior vena cava, whether the injury is open or closed. Blood may irritate the peritoneal cavity and cause the patient to report abdominal pain; however, this may not always occur. Therefore, the absence of pain and tenderness does not necessarily mean the absence of major bleeding in the abdomen.

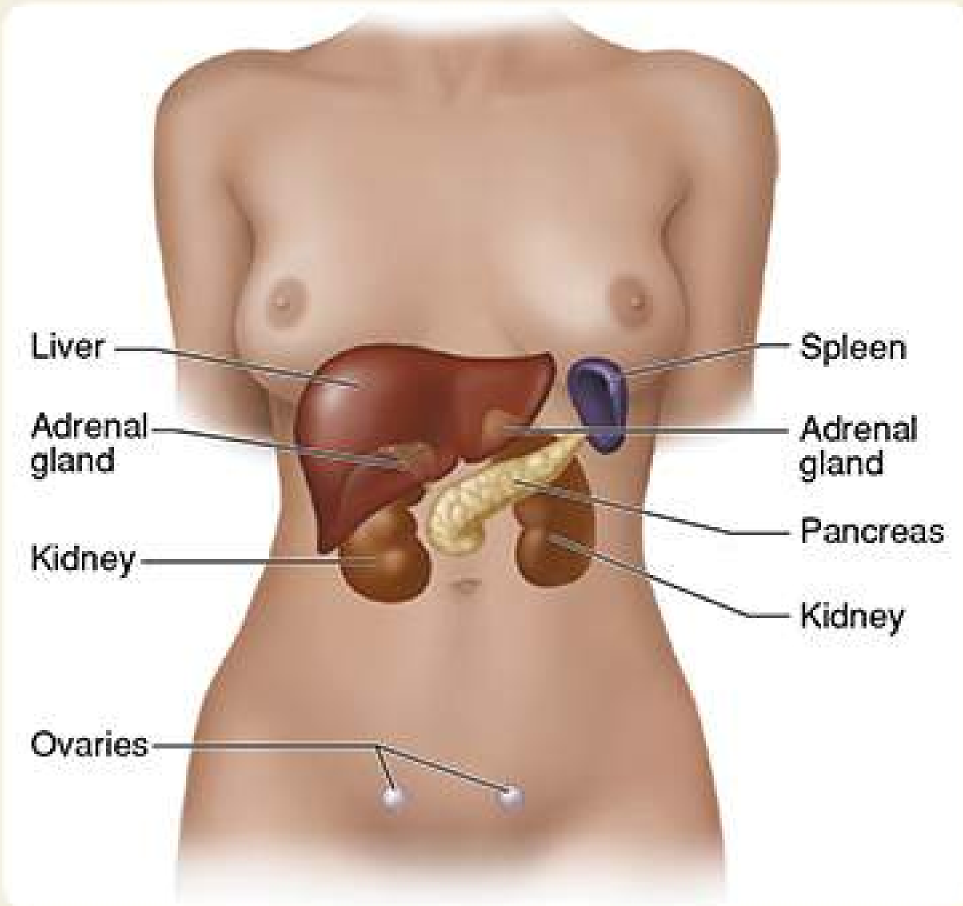

Figure 30-3 The solid organs are solid masses of tissue that do much of the chemical work in the body and receive a large, rich supply of blood.

Many solid organs, in addition to the great vessels, the abdominal aorta, and the inferior vena cava, are found in the retroperitoneal region (behind the peritoneum). This area also houses the kidneys, ureters, and urinary bladder. The majority of the pancreas is located in this region, which is why the pancreas is referred to as a retroperitoneal organ. The last portion of a hollow organ, the colon, occupies the lowest portion of the retroperitoneal space.

Special Populations

Falls are the most common mechanism of injury in geriatric patients. In addition to the typical orthopaedic injuries that a geriatric patient sustains in a fall, the abdominal organs that have lost some elasticity over time are exposed to forces that can damage them. Specifically, the aorta, liver, and spleen are at risk of injury from falls. If a geriatric patient's bones are brittle, they can fracture in a fall, creating dangerously sharp edges that can puncture internal organs.

Injuries to the Abdomen

Abdominal injuries may be as obvious as loops of intestines protruding from a penetrating injury, or they may be unseen such as a laceration to the liver or spleen. Traumatic injuries to the abdomen are considered open or closed, and can involve hollow and/ or solid organs.

Closed Abdominal Injuries

Closed abdominal injuries are those in which blunt force trauma, some type of impact to the body, results in injury to the abdomen without breaking the skin. Such a blow might come from the patient striking the handlebar of a bicycle or the steering wheel of a car, or when the patient is struck by a wooden board or baseball bat during a fight or assault Figure 30-4. Other mechanisms of injury include the following:

- Motorcycle crashes
- Falls
- Blast injuries
- Pedestrian injuries
- Compression
- Deceleration

Compression injuries are typically caused by a poorly placed lap belt. This creates an injury pattern called a clasp-knife injury, an exaggerated resistance of muscles, resembling the opening of a penknife or clasp knife. A compression injury can also be caused when a person is run over or rolled over by a vehicle or object. Deceleration injuries commonly occur when a person or the vehicle the person is traveling inside strikes a large immovable mass, such as a larger vehicle, a bridge abutment, or the ground.

Signs and Symptoms of a Closed Injury

Pain in the abdomen can often be deceiving because it is often diffuse in nature and may be referred from the site of injury to another location in the body. Most injured organs irritate the surrounding tissues. This commonly predictable radiation pattern can help you determine the source of the pain and possibly the site of the injury. In patients with liver and spleen injuries, and bleeding into the peritoneal space, pain is referred to the shoulder. For example, bleeding from an injury to the spleen can result in referred pain to the tip of the left shoulder. However, shoulder pain can be misleading, and injury to the liver or spleen could possibly be overlooked if the shoulder is also injured or if the MOI suggests that an impact or injury may have occurred in the shoulder girdle.

Figure 30-4 Blunt trauma to the abdomen can occur when a patient strikes the steering wheel of a vehicle as a result of a crash.

When a patient reports pain that is tearing and describes it as going from the abdomen posteriorly, he or she is often describing symptoms of an abdominal aneurysm that is dissecting. Pain that is following the angle from the lateral hip to the midline of the groin can be the result of damage to the kidneys or the ureters. Pain primarily located in the right lower quadrant can indicate an inflamed or ruptured appendix. Pain from the gallbladder due to direct injury or inflammation can be found just under the margin of the ribs on the right side or between the shoulder blades.

As blood and fluid from damaged organs flow into the peritoneal cavity, the common response is acute pain in the entire abdomen, which spreads as the blood or contaminant seeks out the voids in the peritoneal cavity. The resulting peritonitis or inflammation of the peritoneum can produce pain if the affected area is exposed to any jarring motion. This is commonly referred to as rebound tenderness. As an EMT, you do not need to produce rebound tenderness intentionally when examining the patient. It is often discovered when you are moving the patient onto the stretcher or into the ambulance.

Determining the location of the pain or referred pain can be more difficult when the patient has voluntary or involuntary guarding. In **guarding**, the patient either consciously or unintentionally stiffens the muscles of the surface of the abdomen. Most often it is the rectus abdominis muscles that are held tight, and the tightness can be mistaken for abdominal rigidity. This stiffening is a natural response to abdominal pain; the body is attempting to splint the area to prevent unnecessary movement and to avoid further pain.

Abdominal distention or swelling that occurs between the xiphoid process and the groin is often the result of free fluid, blood, or organ contents spilling into the peritoneal cavity. Swelling can also be the result of air in the form of gases from the bowel or from infection. Tenderness is another sign of a closed abdominal injury.

Additional signs of abdominal injury are bruising and discoloration. Another likely injury is lower rib fractures—a trauma that was forceful enough to break the ribs may also have damaged internal organs.

Closed abdominal injuries may initially appear as abrasions to the surface of the skin depending on the MOI, such as a physical assault or a pedestrian struck by a motor vehicle. In some circumstances, depending on how deep in the abdomen the injury occurs, it may take several minutes to hours for the contusion or hematoma to become present on the surface. Therefore, it is not prudent for you to rule out injury simply on the basis of absence of these findings.

Injuries From Seat Belts and Air Bags

Seat belts have prevented many thousands of injuries and saved many lives, including those of people who otherwise would have been ejected during a motor vehicle crash. However, seat belts occasionally cause blunt injuries of the abdominal organs. When worn properly, a seat belt lies below the anterior superior iliac spines of the pelvis and against the hip joints. If the seat belt lies too high, it can squeeze abdominal organs or great vessels against the spine when the vehicle suddenly decelerates or stops **Figure 30-5**. Occasionally, fractures of the lumbar spine have been reported. If you are called to the scene of such a crash, keep in mind that the use of seat belts in many cases turns what could have been a fatal injury into a manageable one. In later stages of pregnancy the gravid uterus displaces the urinary bladder to the anterior. This anatomic change allows the normally protected bladder to become more susceptible to injuries from impacts and the seat belt. Pregnant patients who adjust the lap belt portion for comfort as opposed to functionality can sustain further injuries.

In all current-model vehicles, the lap and diagonal (shoulder) safety belts are combined into one so that they may not be used independently. Of course, people can still place the diagonal portion of the belt behind their back, significantly reducing the effectiveness of this design. Remember to inspect beneath the air bag for signs of damage to the steering column.

Words of Wisdom

Hospital personnel depend on you to record scene findings that explain the mechanism of injury. For example, thoroughly document your observations about the vehicle the patient was driving or riding in as a passenger. Notes about deployment of air bags and the condition of the exterior and the steering column help in the assessment of possible internal injuries.

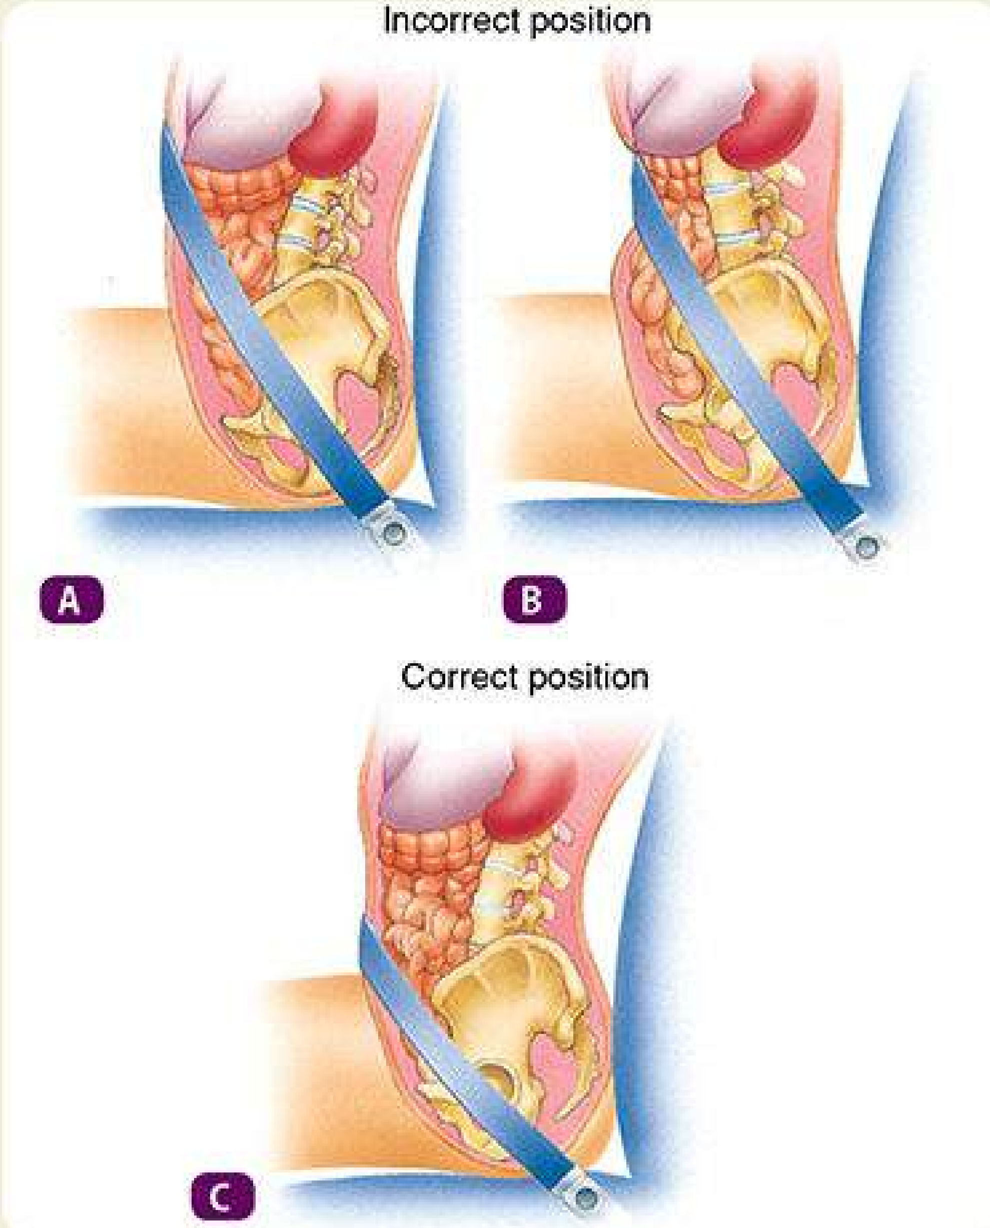

Figure 30-5 Diagrams **(A)** and **(B)** show improper positioning of lap seat belts. The proper position for a seat belt is below the anterior superior iliac spines of the pelvis and against the hip joints, as shown in diagram **(C)**.

Open Abdominal Injuries

Open abdominal injuries are those in which a foreign object enters the abdomen and opens the peritoneal cavity to the outside; these are also known as penetrating injuries **Figure 30-6**. Stab wounds and gunshot wounds are examples of open injuries, or penetrating trauma. Open wounds may not be deeper than the muscular wall of the abdomen; however, this cannot be determined in the prehospital setting. Therefore, you should maintain a high index of suspicion for unseen injuries, internal damage to organs, and potential life-threatening injuries and provide rapid transport. Patients with open abdominal injuries must be assessed and evaluated at the hospital.

Figure 30-6 Because it is difficult to know how deep a penetrating injury is, assume organ damage and transport promptly.

When a patient has sustained a penetrating injury to the abdomen, it is important to attempt to determine the velocity of the object that penetrated the abdominal wall because this can predict the amount of damage to tissue that has occurred. There are three levels of velocity that are commonly discussed in traumatic injuries.

- Low-velocity injuries. Caused by hand-held or handpowered objects such as knives and other edged weapons
- Medium-velocity penetrating wounds. Caused by smaller caliber handguns and shotguns
- High-velocity injuries. Caused by larger weapons such as high-powered rifles and the higher-powered handguns

High- and medium-velocity injuries have temporary wound channels in addition to the exit and entrance wounds. These temporary channels are caused by cavitation. A cavity forms as the pressure wave from the projectile is transferred to the tissues. This causes microscopic tears to the blood vessels and nerves, expanding the width and length of the wound beyond what you can see during physical examination. Cavitation can produce significant bleeding depending on the speed or velocity of the penetrating object. The higher the velocity of the projectile, the larger the cavity it produces, typically resulting in a larger amount of tissue damage.

Low-velocity penetrations also have the capacity to damage underlying organs. This internal injury may not be apparent during the physical examination. The bleeding entrance wound may hide the fact that the object went farther and deeper into the peritoneal cavity and injured other organs and tissues. This is especially important information to remember when an injury occurs in the region where the thoracic cavity and the peritoneal cavity are separated by the diaphragm. Any time your patient has an injury at or below the xiphoid process, it should be assumed that both cavities have been violated.

An open abdominal injury that goes through the skin and muscle layer and through the fascia or the interior covering of the abdomen, such that organs now protrude from the peritoneum, is an evisceration. This visually shocking injury can be extremely painful. Do not push down on the patient's abdomen, and perform only a visual assessment when there is any suspicion of this type of injury. If there is clothing close to the wound, carefully cut the clothing around the wound, leaving a border of intact cloth outside the injured area. Never pull, even gently, on any clothing stuck to or inside the wound channel because this may remove even more of the abdominal contents.

Signs and Symptoms of an Open Injury

Patients with any type of abdominal injury generally have one concern: pain. But other significant distracting injuries may at first mask the pain, and some patients may not be able to tell you about pain because they are unconscious or unresponsive, such as after a head injury or a drug or alcohol overdose. A very common early sign of a significant abdominal injury is tachycardia because the heart is increasing its pumping action to compensate for blood loss. Later signs include evidence of shock, such as decreased blood pressure and pale, cool, moist skin, or changes in the patient's mental status, combined with trauma to the abdomen. In some cases, the abdomen may become distended from the accumulation of blood and fluid.

As an EMT, you must look for other signs and symptoms of potential trauma and injuries to the abdomen. A patient may have both closed and open injuries. Blunt injuries include bruises (often indicated by red areas of skin at this early stage) or other visible marks, whose location should guide your attention to underlying structures **Figure 30-7**. For example, bruises in the right upper quadrant, left upper quadrant, or **flank** (the region below the rib cage and above the hip) might suggest an injury to the liver, spleen, or kidney, respectively **Figure 30-8**. Bruises around the umbilicus can predict significant internal abdominal bleeding **Figure 30-9**.

Figure 30-7 Bruising on the abdomen can provide clues to the possible injury of underlying organs.

Figure 30-8 Bruises in the right upper quadrant, left upper quadrant, or flank suggest an injury to the liver, spleen, or kidney, respectively.

Hollow Organ Injuries

Injuries that involve the hollow organs often have delayed signs and symptoms. The hollow organs commonly spill their contents into the abdomen and then an infection develops, which can take a few hours to days to develop. When the stomach and the intestines are injured, they can spill gastrointestinal contents such as food, waste, and digestive liquids that are highly toxic and acidic. These substances cause significant tissue damage to the entire peritoneum.

Words of Wisdom

The signs of abdominal injury are usually more definite than the symptoms, including firmness on palpation of the abdomen, obvious penetrating wounds, bruises, and altered vital signs, such as increased pulse rate, increased respiratory rate, decreased blood pressure, and shallow respirations (although these signs might not appear until later). Common symptoms include abdominal tenderness, particularly localized tenderness and difficulty moving because of pain.

Figure 30-9 Bruising around the umbilicus indicates the possibility of significant bleeding inside the abdomen.

Both blunt and penetrating trauma can cause injuries to the hollow organs. Blunt trauma causes the organ to "pop," thus releasing fluids or air. Penetrating trauma causes direct injury such as laceration and punctures. In open wounds, patients typically report an intense pain that can be out of character for the size of the injury. Patients may also report intense pain with open wounds of the stomach or small bowel.

The gallbladder and the urinary bladder, which are filled with bile and urine, are two additional hollow organs whose contents are potentially irritating and damaging to the tissues of the abdomen if ruptured by injury. These fluids move via gravity into the loose spaces and voids in the peritoneal cavity, eventually leading to infection.

Free air in the peritoneal cavity is abnormal and usually indicates that a hollow organ or loop of bowel has perforated. Perforation with free air is usually very painful. If the site of perforation is not rapidly identified and repaired, severe infection and septic shock may develop. Any air in the peritoneal cavity seeks the most superior space or void; thus the location of the air can change with positioning of the patient.

Solid Organ Injuries

Solid organs (liver, spleen, diaphragm, kidneys, and pancreas) can bleed significantly and cause rapid blood loss that can be hard to identify from a physical examination because the patient is not experiencing significant pain. Conversely, solid organs can slowly ooze blood into the peritoneal cavity, causing pain to increase slowly over time and increasing the chance for toxicity to develop. Blood in the peritoneal cavity irritates tissue and fills any voids or spaces, which can make it difficult for you to determine the exact source of the bleeding. Because of the structures in the retroperitoneal space and the spaces in the abdominal cavity, the peritoneal cavity can hold a large volume of blood following traumatic injuries of solid organs and major blood vessels.

YOU are the Provider — PART 2

When you reach the patient, he is lying supine on the ground outside of the arena area. The scene is safe and the bull has been penned up. The patient is conscious, but restless. He reports pain over his entire abdomen, both flank areas, and the back of his head. Your partner manually stabilizes his head while you perform a primary assessment.

Recording Time: 0 Minutes	
Appearance	In obvious pain; restless
Level of consciousness	Conscious and alert; restless
Airway	Open, clear of secretions or foreign bodies
Breathing	Increased rate; adequate depth
Circulation	Radial pulses, rapid and weak; skin is pale, cool, and moist; no obvious bleeding

3. How should you interpret your primary assessment findings?
4. What immediate treatment is indicated for this patient?

The liver is the largest organ in the abdomen. It is very vascular; therefore, it can contribute to hypoperfusion if it is injured. It is often injured by a fractured lower right rib or a penetrating trauma, such as a stab wound. A common finding during assessment of patients with an injured liver is referred pain to the right shoulder.

Like the liver, the pancreas and spleen are organs responsible for filtering blood and are therefore very vascular. Both organs are prone to heavy bleeding when fractured by blunt force or lacerated or punctured by penetrating injury. The spleen is often injured during motor vehicle crashes, especially in the cases of improperly placed seat belts or impact from the steering wheel, falls from heights or onto sharp objects, and bicycle and motorcycle crashes where the patient hits the handlebars on impact. Referred left shoulder pain also occurs in some cases of splenic injury.

If the diaphragm is penetrated or ruptured, loops of bowel may herniate into the thoracic cavity. Because the bowel will now be displacing lung tissue and vital capacity, patients will exhibit dyspnea or feel short of breath. Patients with a ruptured diaphragm after a motor vehicle crash may become very anxious and short of breath if placed in the supine position on a backboard. Change in position from upright to supine results in more abdominal contents spilling into the thoracic cavity and compressing the lungs, prohibiting the lungs from fully expanding.

In the retroperitoneal space, the kidneys can be impacted or penetrated by trauma. The kidneys are filtration organs; therefore, they are supplied with large quantities of blood. They can be sheared from their base, crushed, or fractured—causing significant blood loss. If the kidney is injured, a common finding is **hematuria**, or blood in the urine. This may be obvious to the naked eye or impossible to detect in the field. You may find drops of blood or blood-tinged urine on the patient's underwear, leading you to inspect the exterior of the genitals. Blood visible on inspection of the urinary meatus (opening of the urethra situated on the glans penis in men and in the vulva in women) indicates significant trauma to the genitourinary system. If blood is not present, do not take this as a sign that the patient is free from injury; the blood may not be visible yet.

Patient Assessment of Abdominal Injuries

The assessment of abdominal injuries is one of the more difficult assessments that you will perform. The causes of the injury may be readily apparent as a result of the MOI or the visibility of a penetrating wound, but the resulting tissue damage may not be so apparent. Often other injuries, such as a fractured bone, may be painful and distracting for the patient. The patient may not tell you about more subtle pain that could indicate an abdominal injury. Additionally, some abdominal injuries develop and worsen over time, making reassessment critical.

Scene Size-up

Your scene size-up begins with the information reported from dispatch. This information may be vague or incomplete, but can still provide information to consider as you prepare to respond. For example, is the patient injured or ill? Could one have led to the other? What equipment might you need to assess and treat the patient? Standard precautions should be taken prior to arrival at the scene; gloves and eye protection should be a minimum.

When you arrive at the scene, you will continue to gather information that will help manage the incident. Observe the scene for hazards and threats to your safety. Make sure the scene is safe and that law enforcement personnel have controlled the scene if necessary. If additional resources are needed, call for them early, and consider early ALS intercept for patients who may become unstable.

As you observe the scene, look for indicators of the MOI, and consider early spinal stabilization. This helps you develop an early index of suspicion for underlying injuries in the patient who has sustained a significant MOI. As you put together information from dispatch and your observations of the scene, consider the possible injuries the MOI could have produced.

As you inspect a vehicle, look at the damage. Could this damage result in an abdominal injury? In the case of an assault, think about how many times the patient was struck, where the patient was struck, and with what object.

If the wound is penetrating, inspect the object of penetration if possible. Does the object have a serrated, smooth, or jagged edge? Is it clean or dirty? How long is it? The MOI may also provide indications of potential safety threats. For example, a stab wound may indicate the presence of a violent individual. Weapons can provide useful information for hospital staff; however, do not spend too much time searching for a weapon, and be careful not to contaminate evidence in the process.

Special Populations

In pediatric patients, a common mechanism of injury is a motor vehicle versus pedestrian or motor vehicle versus bicycle crash. In the pediatric patient, the chest and abdomen are less protected by bony structures than in the adult. The pediatric patient may experience significant transfer of energy on impact. In the pediatric patient, the rib cage is so flexible that the chest can be flattened almost to the spine before rib fractures occur. This extensive compression can involve not only the organs of the chest, but also the abdomen. The ribs then recoil to their normal position, and the patient is left with very few outward signs that an injury has occurred.

Primary Assessment

Your goal in the primary assessment is to evaluate the patient's ABCs and then immediately care for any life threats. First perform a primary assessment.

The general impression, including an evaluation of the level of consciousness, will help you establish the seriousness of the patient's condition. Some abdominal injuries will be obvious and graphic; however, most will be very subtle and may go unnoticed. Considering the MOI together with the general impression will help you focus on the immediate problem. Remember, in some cases of trauma or blows to the abdomen, the injury may have occurred hours or even days earlier and the pain has now reached a point where it is severe enough for the patient to seek help.

As you approach the trauma patient with a suspected closed abdominal injury, important indicators will alert you to the seriousness of the patient's condition. Is the patient awake and interacting with his or her surroundings, or is he or she lying still, not making sounds? Does the patient have any apparent life threats? What color is the patient's skin? Is he or she appropriately or inappropriately responding to you? Your general impression will help you develop an index of suspicion for serious injuries and determine how urgently your patient needs care.

Trauma patients with closed abdominal injuries may have what appear to be minor injuries; however, you must not be distracted from looking for more serious hidden injuries. For example, an abrasion to the abdomen may appear to be a superficial injury when in actuality it may be the only outward clue that abdominal organs are injured.

Check for responsiveness using the AVPU scale. Ask the alert patient about his or her chief complaint. Unresponsiveness may indicate a life-threatening condition. You should administer high-flow oxygen via a nonrebreathing mask to trauma patients whose level of consciousness is less than alert and oriented and provide rapid transport to the emergency department (ED).

Trauma patients with open injuries may have obvious significant injuries that indicate a serious condition. However, other injuries may not be as obvious but may still indicate a very serious condition. Your general impression of how the patient is doing is based on information as simple as the MOI and the patient's level of consciousness. Observations such as bleeding from open injuries, skin color and condition, and gasping respirations also contribute to your general impression and help you determine your treatment priorities and the urgency of care needed. A good question to ask yourself is, "How sick is my patient based on what I know right now?"

In trauma patients, life-threatening external hemorrhage must be addressed before airway or breathing concerns. Next, ensure the patient has a clear and patent airway. If a spinal injury is suspected, prevent the patient from moving by having a team member hold the patient's head still and verbally remind the patient not to move. Patients may report feeling nauseous, and they may vomit. Remember to keep the airway clear of vomitus so that it is not aspirated into the lungs, especially in a patient who is unconscious or has an altered level of consciousness. Turn the patient on one side, stabilizing the spine if necessary, and try to clear any material from the throat and mouth. Note the nature of the vomitus: undigested food, blood, mucus, or bile.

You must also quickly assess the patient for adequate breathing. A distended abdomen or pain may prevent adequate inhalation. When these guarded respirations decrease the effectiveness of the patient's breathing, providing supplemental oxygen with a nonrebreathing mask will help improve oxygenation. If the patient's level of consciousness is decreased and respirations are shallow, consider supplementing respirations with a bag-valve mask (BVM). Use airway adjuncts as necessary to ensure a patent airway and assist with breathing.

Superficial abdominal injuries usually do not produce significant external bleeding. However, internal bleeding from open or closed abdominal injuries can be profound. Trauma to the kidneys, liver, and spleen can cause significant internal bleeding. If you suspect shock, evaluate the patient's pulse and skin color, temperature, and condition to determine the stage of shock. Treat the patient aggressively by providing oxygen, positioning the patient supine, and keeping the patient warm. Wounds should be covered and bleeding should be controlled as quickly as possible.

Because of the nature of abdominal injuries, a short on-scene time and rapid transport to the hospital are generally indicated. Abdominal pain together with an MOI that suggests injury to the abdomen or flank is a good indication for rapid transport. In the prehospital environment, it is difficult to determine whether the liver, spleen, or kidney has been injured. Hollow organs that have ruptured are also difficult to identify without more advanced diagnostic equipment. A delay in medical evaluation may result in an unnecessary and dangerous progression to shock. Patients who have visible significant bleeding or signs of significant internal bleeding may quickly become unstable. Treatment should be directed at quickly addressing life threats and providing rapid transport to the nearest appropriate hospital.

Patients with abdominal injuries should be evaluated at the highest level trauma center available because of the hidden or occult nature of most abdominal injuries. Transport to a trauma center is indicated for any patient who has an MOI that produces a high index of suspicion and who has any visible significant trauma, blunt or penetrating. Follow local protocols when considering a lower level care center such as acute care sites and clinics. Only the lowest levels of MOI should be considered eligible for these types of facilities.

History Taking

Once you have identified and treated life threats, you can then gather a history from the patient. You should clarify the chief complaint and MOI, as well as any associated symptoms. You can quickly assess the patient's chief complaint with a simple inspection, noting the position in which he or she is lying. Movement of the body or the abdominal organs irritates the inflamed peritoneum, causing additional pain. To minimize this pain, patients will lie still, usually with their knees drawn up, and their breathing will be rapid and shallow. For the same reason, they will contract their abdominal muscles, a sign called guarding. Ask about previous injuries associated with a chief complaint of abdominal pain.

Next, obtain a SAMPLE history from your patient. Using OPQRST to help explain an abdominal injury may provide some helpful information such as the description of the pain and if the pain is radiating. Take this time to confirm that you have all the necessary history to inform the hospital staff. If the patient is not responsive, attempt to obtain the SAMPLE history from friends or family members.

Be sure to ask the patient if he or she has experienced any nausea, vomiting, or diarrhea when you are investigating the details of the current injury. If the patient has experienced any of these symptoms, ask how many times and over what time period. Ask about the appearance of any bowel movements and urinary output to determine if there was any blood in the urine or black tarry stools (**melena**). This can help determine if the patient has gastrointestinal bleeding and if there is bleeding in the lower intestinal tract.

Secondary Assessment

In some instances, such as with a critically injured patient or a short transport time, you may not have time to conduct a secondary assessment.

Usually, you will perform the physical examination on all patients with abdominal injuries in the same manner, as follows:

- Remove or loosen clothes to expose the injured regions of the body. Inspect the patient for bleeding before removing clothing to prevent damaging any exposed tissues, such as in the case of an evisceration.
- Provide privacy as needed or wait until you are in the back of the ambulance.
- The patient without suspected spinal injury should be allowed to stay in the position of comfort—with the legs pulled up toward the abdomen. This position will relieve some of the tension on the abdomen and thus provide pain relief.
- For a patient with spinal injury, place padding such as blankets or pillows under the his or her knees to help alleviate tension on the abdominal wall. Keep in mind that you can worsen the spinal injury if you are too aggressive when placing these items.

The patient without suspected spinal injury should not be forced to lie flat for the physical examination or transport. The fetal position may provide the patient with the most comfort during the physical examination or transport.

Examine the entire abdomen including all posterior, anterior, and lateral surfaces. This is a critical step when patients have an injury with an entrance wound. Examine the axillae (armpits) for entrance wounds.

Words of Wisdom

It is not typical for EMTs to auscultate bowel sounds, but if you are trained to do this, note that bowel sounds can be difficult to hear in the prehospital setting. Even in a quiet environment, you may not have enough time to wait to hear them. If you hear nothing, do not state that bowel sounds are absent; use the term decreased. If you hear a lot of gurgling and the sounds of gas moving about frequently, the term increased may be used. Most bowel sounds can be difficult to interpret and diverse in cause, so they are considered to be of limited value to you in your assessment.

Use DCAP-BTLS to help identify specific signs and symptoms of injury. Inspect and palpate the abdomen for the presence of deformity, which may be subtle in abdominal injuries. Look for the presence of contusions and abrasions, which can help localize focal points of impact and may indicate significant internal injury. Puncture wounds and other penetrating injuries must not be overlooked because the intra-abdominal extent of these injuries may be life threatening. The presence of burns, as in the case of flash burns or scalding fluids spilled onto the abdomen, must be noted and managed appropriately. Palpate for tenderness and attempt to localize to a specific quadrant of the abdomen. Identify and treat any lacerations with appropriate dressings. Swelling may involve the entire abdomen and indicates significant intra-abdominal injury.

Remember to palpate the abdomen when examining the region. Palpation is typically performed first with a light touch, progressing to applying gentle increasing pressure deeper into the tissues to draw out a pain response for injuries. The object is not to cause the patient further pain but to identify the location of the pain. Start by palpating the quadrant farthest away from the quadrant that is exhibiting signs and symptoms of injury and pain. This technique allows you to investigate the possibility of radiation and extension of the pain into other quadrants without causing the patient to guard the rest of the abdomen. If a light touch causes pain, deep palpation is not required or recommended.

YOU are the Provider — PART 3

After applying high-flow oxygen to the patient, you perform a secondary assessment. Your partner continues to manually stabilize the patient's head in a neutral position. During your physical examination, you find numerous abrasions to his anterior abdomen and flanks, and he has pain to palpation of his right upper abdominal quadrant. The rest of your secondary assessment is unremarkable for gross injuries. An off-duty EMT from your agency, who was a spectator at the rodeo, provides assistance and obtains a set of vital signs.

Recording Time: 6 Minutes	
Respirations	24 breaths/min; adequate depth
Pulse	120 beats/min; weak and regular
Skin	Pale, cool, and clammy
Blood pressure	104/54 mm Hg
Oxygen saturation (Spo_2)	97% (on oxygen)

The patient's spine is fully immobilized and he is loaded into the ambulance. He is still, conscious, and alert, but is restless and reports being very thirsty. You begin transport to the hospital while continuing to assess and treat the patient en route.

5. What are some common bruising patterns and clinical signs associated with intra-abdominal bleeding?

If the patient has been subjected to a significant MOI, an exam of the entire body will help you quickly identify any injuries your patient may have, not just abdominal injuries. Begin with the head and finish with the lower extremities, moving in a systematic manner. Your goal is not to identify the extent of all the injuries but to determine whether other injuries are present. This requires you to work quickly but thoroughly. If you find a life-threatening injury, stop and treat it immediately; otherwise move on. The injuries you find will guide your decisions in packaging your patient for transport. Assess the patient's need for spinal immobilization and apply per local protocol. In some EMS systems, full spinal immobilization of the patient with penetrating trauma is not performed in the interest of rapid transport for surgical intervention. Up to this point in the patient assessment process you may have been stabilizing the patient's spine by simply holding the head still and asking the patient not to move. If a cervical collar has not been applied, place one on the patient now before you log roll the patient to inspect the posterior part of the body and place the patient on a backboard.

The kidneys are located in the flank region of the back. Inspect and palpate this area for tenderness, bruising, swelling, or other signs of trauma. Remember, you may not be able to trigger pain from the specific organ, but the tissues around it may exhibit symptoms of pain. Hollow organs will spill their contents into the peritoneal cavity and will typically produce a significant peritonitis, which may be seen as diffuse pain with guarding and reaction to sudden jarring movements. Bowel sounds may help confirm these findings, but you should not depend on these sounds to rule out a specific injury.

Quickly obtain the patient's vital signs. Many abdominal emergencies, in addition to injuries or illnesses that result in severe bleeding, can cause a rapid pulse and low blood pressure. Record vital signs as early as possible and periodically thereafter (every 5 minutes in the patient whom you suspect has a serious injury). This will help you identify changes in the patient's condition and be alert to signs of decompensation from blood loss. If the patient is experiencing external or internal hemorrhaging, as in the case of a stab wound or a direct blow to the abdomen, closely monitor the vital signs with a degree of suspicion and pay close attention to changes in the vital signs.

Use pulse oximetry and noninvasive blood pressure devices when these monitoring devices are available. It is recommended you always assess the patient's first blood pressure manually with a sphygmomanometer (blood pressure cuff) and stethoscope.

Assessment of an Isolated Abdominal Injury

If the MOI suggests an isolated injury to the abdomen, focus your physical examination only on the injured area. Inspect the skin of the abdomen for wounds through which bullets, knives, or other missile-type foreign bodies may have passed. Keep in mind that the size of the wound does not necessarily indicate the extent of the underlying injuries. If you find an entry wound, you must always check for a corresponding exit wound in the patient's back or sides. If the injury was caused by a very high–velocity missile from a rifle, you may see a small, harmless-looking entrance wound with a large, gaping exit wound. Do not attempt to remove a knife or other object that is impaled in the patient. Instead, stabilize the object with supportive bandaging. Bruises or other visible marks are important clues to the cause and severity of any blunt injury. Steering wheels and seat belts produce characteristic patterns of bruising on the abdomen or chest.

Words of Wisdom

Occasionally you will have a patient who is extremely sensitive to palpation or is ticklish. This can make the physical examination process more difficult. Because it is difficult for a patient to tickle himself or herself, use the technique of placing the patient's hand on the surface of his or her abdomen and then palpate and compress the abdomen with the patient's hand between your hand and the patient's skin.

Words of Wisdom

Log rolling the patient onto a backboard always provides a valuable chance to examine the back for signs of injury. Instruct and position helpers to ensure your ability to inspect and palpate the back briefly while the patient is rolled onto his or her side. If possible, pad the long backboard before returning the patient to a supine position. This action helps reduce discomfort and prevents soft-tissue injury. Avoid log rolling patients with an evisceration because this can cause more of the abdominal organs to protrude from the wound. Instead, keep the patient in the supine position and allow him or her to flex the knees when possible to help relieve tension on the abdomen.

Reassessment

Repeat the patient's primary assessment and vital signs. Reassess the interventions and treatment you have provided to the patient. Identify trends in pain, vital signs, and the progress of treatments to determine whether the patient's condition is improving or getting worse. Adjustments in care can be based on these objective findings.

Manage airway and breathing conditions based on signs and symptoms found during the primary assessment. Provide spinal immobilization to the patient with suspected spinal injuries. If the patient has signs of hypoperfusion, provide aggressive treatment of shock and rapid transport to the appropriate hospital. If an evisceration is discovered, place a sterile dressing moistened with normal saline over the wound, apply a bandage, and transport. Never attempt to push eviscerated tissue or organs back into the abdominal cavity. A patient who has a ruptured diaphragm may have an abdomen with a sunken anterior wall and difficulty breathing because of bowel contents in the chest cavity. These patients should receive positive-pressure ventilation with a BVM, which may be more difficult to perform without a patent diaphragm and with bowel contents impairing lung expansion. Do not delay transport of the seriously injured trauma patient to complete nonlifesaving treatments such as splinting extremity fractures. Instead, complete these types of treatments en route to the hospital.

Communicate to the hospital the MOI and injuries found during your assessment. It is important to use appropriate medical and anatomic terminology; however, when in doubt just describe what you see. The content of your radio report will depend on your local protocols. The information you provide helps the hospital staff prepare for the patient.

Documentation of your assessment and trends in vital signs is a tremendous help to physicians in evaluating the problem when the patient arrives in the ED. Document the results of the physical examination and any pertinent negatives such as no blood loss noted in bowel movements. Also document if you passed over any step of the physical examination such as with a patient with acute abdominal pain in whom you opted to not perform palpation. Continuity of care is maintained when the ED has an accurate record of your findings at the scene as well as the treatments you have provided. It is imperative that you be able to describe the scene in enough detail so the trauma team has a clear idea of the circumstances. Some services and departments now carry digital or other instant cameras to be able to show the trauma team the MOI that the patient was exposed to. Remember, your written report is also a legal record of your care. If assault is suspected, you may have a legal requirement to inform the hospital staff of your suspicions; however, this information can wait until you have transported the patient to the hospital and had a chance to discuss it privately with appropriate hospital personnel.

Be cautious and diligent when dealing with patients who refuse transport to the hospital after sustaining an injury to the abdomen or genitourinary system. These patients are at high risk for complications; therefore, that information should be explained to them in great detail. Contacting medical control for assistance to convince the patient of the need for transport can be very useful. Always document in detail the information you provide to the patient and, if the patient continues to refuse transport, have the patient sign a document of refusal or an “against medical advice” form.

Emergency Medical Care of Abdominal Injuries

Closed Abdominal Injuries

An urgent concern in patients with closed abdominal injuries is that you do not know the true extent of the injury. Because of this, the patient requires rapid transport to the nearest and highest level of care available, primarily a trauma center with a surgeon. If possible, position the patient for optimal comfort and apply high-flow oxygen if the patient has signs of hypoxia or shock. Treat for shock.

Blunt Abdominal Injuries

A patient with a blunt abdominal injury may have one or more of the following injuries:

- Severe bruising of the abdominal wall
- Laceration of the liver and spleen
- Rupture of the intestine
- Tears in the mesentery, the membranous folds that attach the intestines to the walls of the body, and injury to blood vessels within them
- Rupture of the kidneys or avulsion of the kidneys from their arteries and veins
- Rupture of the urinary bladder, especially in a patient who had a full and distended bladder at the time of the injury
- Severe intra-abdominal hemorrhage
- Peritoneal irritation and inflammation in response to the rupture of hollow organs

A patient who has sustained a blunt abdominal injury should be log rolled to a supine position onto a backboard. Ensure you protect the spine while you roll him or her. If the patient vomits, turn him or her to one side and clear the mouth and throat of vomitus. Monitor the patient’s vital signs for any indication of shock such as pallor; cold sweat; rapid, thready pulse; or low blood pressure. If you see any of these signs, administer high-flow supplemental oxygen via a nonrebreathing mask, or a BVM if needed, and take all the appropriate measures to treat for shock. Patients with dyspnea due to a diaphragmatic rupture may require assistance with a BVM. Keep the patient warm with blankets, and provide rapid transport to the ED.

Open Abdominal Injuries

Penetrating Abdominal Injuries

Patients with penetrating injuries generally have obvious wounds and external bleeding **Figure 30-10A**; however, significant external bleeding is not always present. As an EMT, you should have a high index of suspicion that the patient has serious unseen blood loss occurring inside the body. A large wound may have protrusions of bowel, fat, or other structures. In addition to pain, these patients often report nausea and vomiting. Patients with peritonitis generally prefer to lie very still with their legs drawn up because it hurts to move or straighten their legs. They may express grief or pain after every bump in the road during transport.

In caring for a patient with a penetrating wound to the abdomen, follow the general procedures previously described for care of a blunt abdominal injury as well as following the specific steps for the penetrating wound. Inspect the patient's back and sides for exit wounds, and apply a dry, sterile dressing to all open wounds. If the penetrating object is still in place, apply a stabilizing bandage around it to control external bleeding and to minimize movement of the object **Figure 30-10B**.

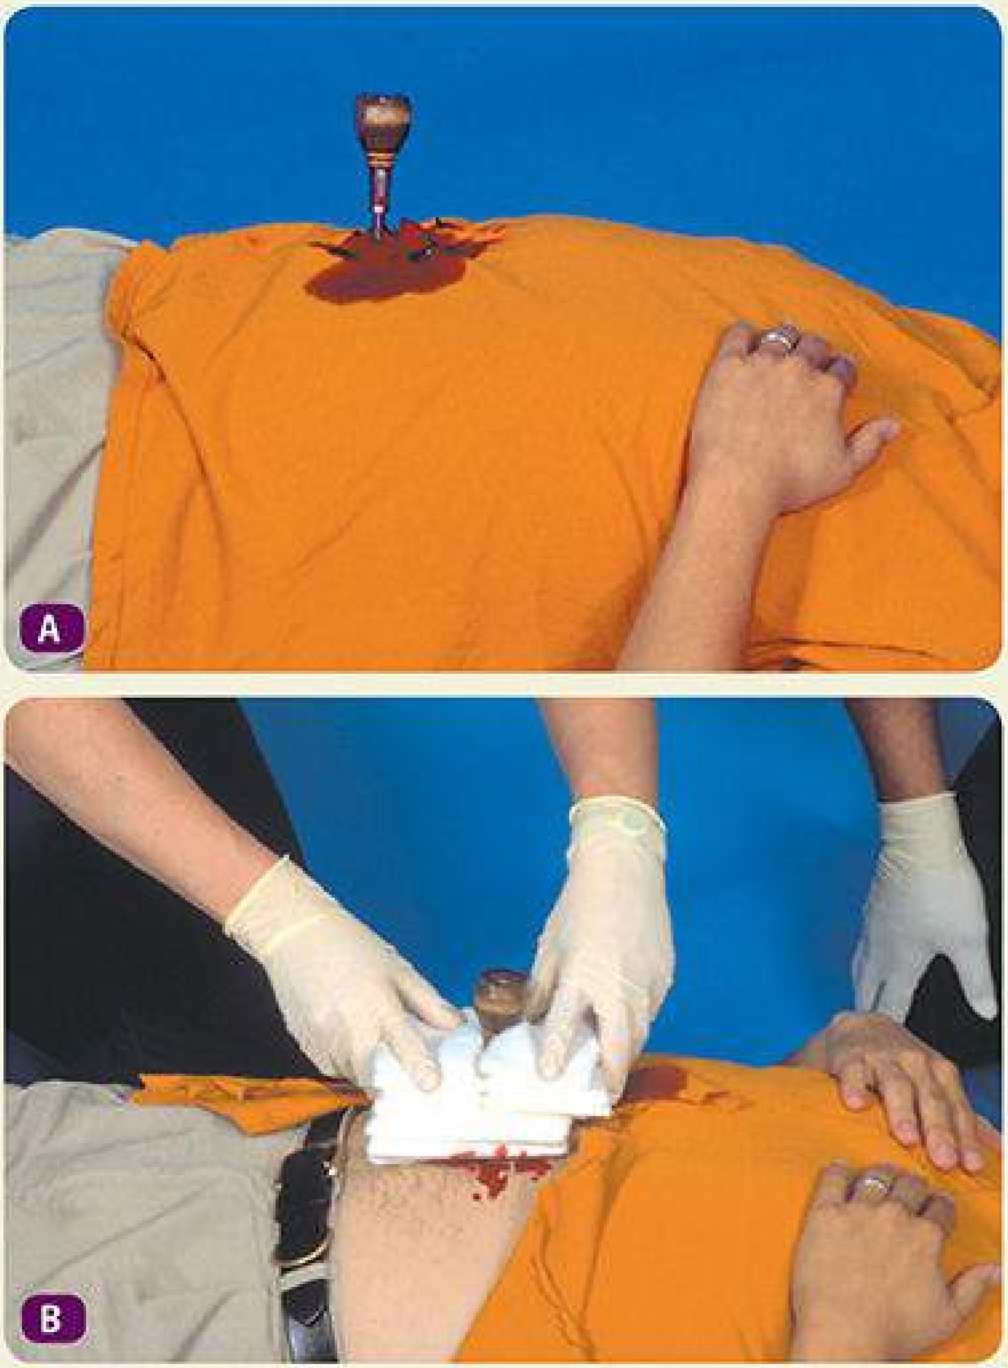

Figure 30-10 **A.** Penetrating injuries have obvious wounds and may also have external bleeding. **B.** If the penetrating object is still in place, use a roller bandage to stabilize the object and to control bleeding.

YOU are the Provider — PART 4

You reassess the patient en route and note that his clinical status has deteriorated. You ask your driver to notify the receiving facility as you continue to treat the patient. There are no ALS units available to rendezvous with and assist you.

Recording Time: 12 Minutes	
Level of consciousness	Responsive to pain only
Respirations	28 breaths/min; shallow
Pulse	134 beats/min; absent radial pulses
Skin	Cool, pale, and clammy
Blood pressure	82/54 mm Hg
Spo_2	88% (on oxygen)

6. Why is your patient's condition deteriorating? How should you modify your treatment?

Abdominal Evisceration

Severe lacerations of the abdominal wall may result in an evisceration, in which internal organs or fat protrude through the wound **Figure 30-11**. Never try to replace an organ that is protruding from an abdominal laceration, whether it is a small fold of peritoneum or nearly all of the intestines. Instead, cover it with sterile dressings moistened with sterile saline solution and secure with a bandage and tape. (Protocols in some EMS systems call for an occlusive dressing over the dressings.) Because the open abdomen radiates body heat very effectively, and because exposed organs lose fluid rapidly, you must keep the organs moist and warm **Figure 30-12**. Do not use any material that is adherent or loses its substance when wet, such as toilet paper, facial tissue, paper towels, or absorbent cotton.

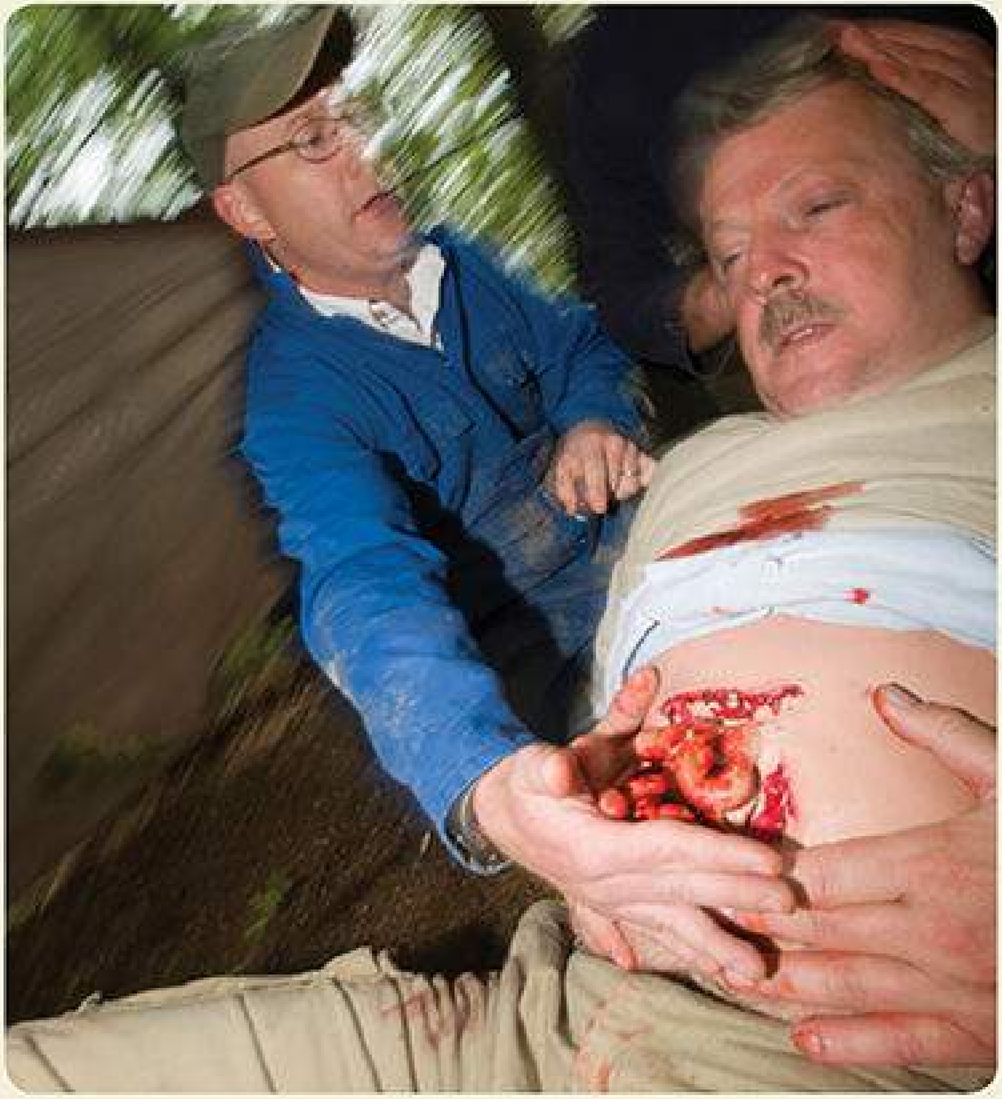

Figure 30-11 An abdominal evisceration is an open abdominal wound from which internal organs or fat protrude.

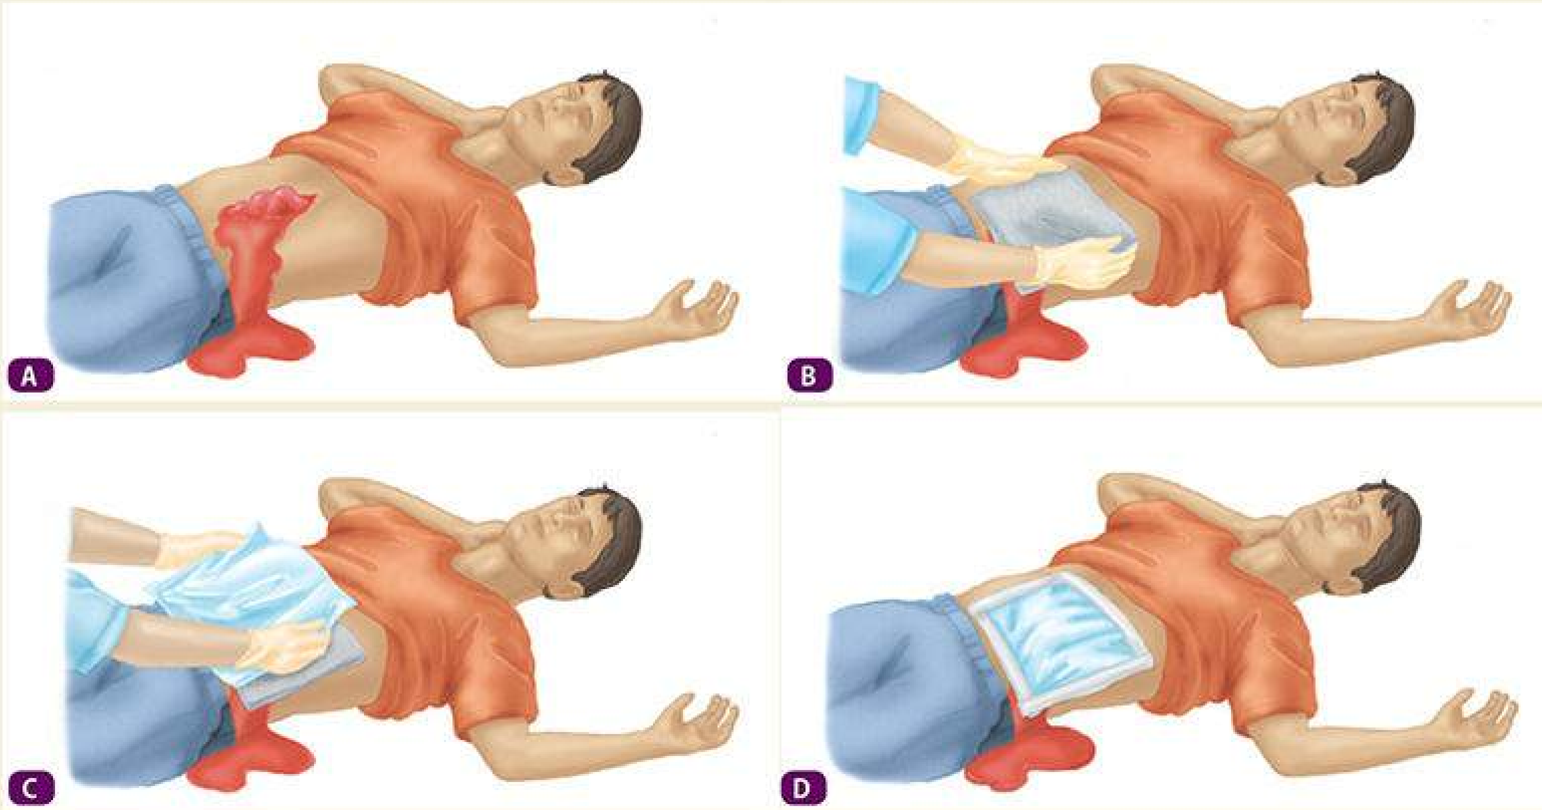

Figure 30-12 **A.** The open abdomen radiates body heat rapidly and must be covered. **B.** Cover the wound with moistened, sterile dressings and with an occlusive dressing, depending on local protocol. **C.** Secure the dressing with a bandage. **D.** Secure the bandage with tape.

Treat the patient for shock by keeping the patient warm and placing the patient in the supine position. Provide high-flow oxygen and transport according to local protocols and destination policy. Transport the patient to the highest level trauma center available.

Anatomy of the Genitourinary System

The genitourinary system controls both the reproductive functions and the waste discharge system, which are generally considered together. The organs of the genitourinary system, such as the kidneys and urinary bladder, are located in the abdomen.

The urinary system controls the discharge of certain waste materials filtered from the blood by the kidneys. In the urinary system, the kidneys are solid organs; the ureters, urinary bladder, and urethra are hollow organs Figure 30-13.

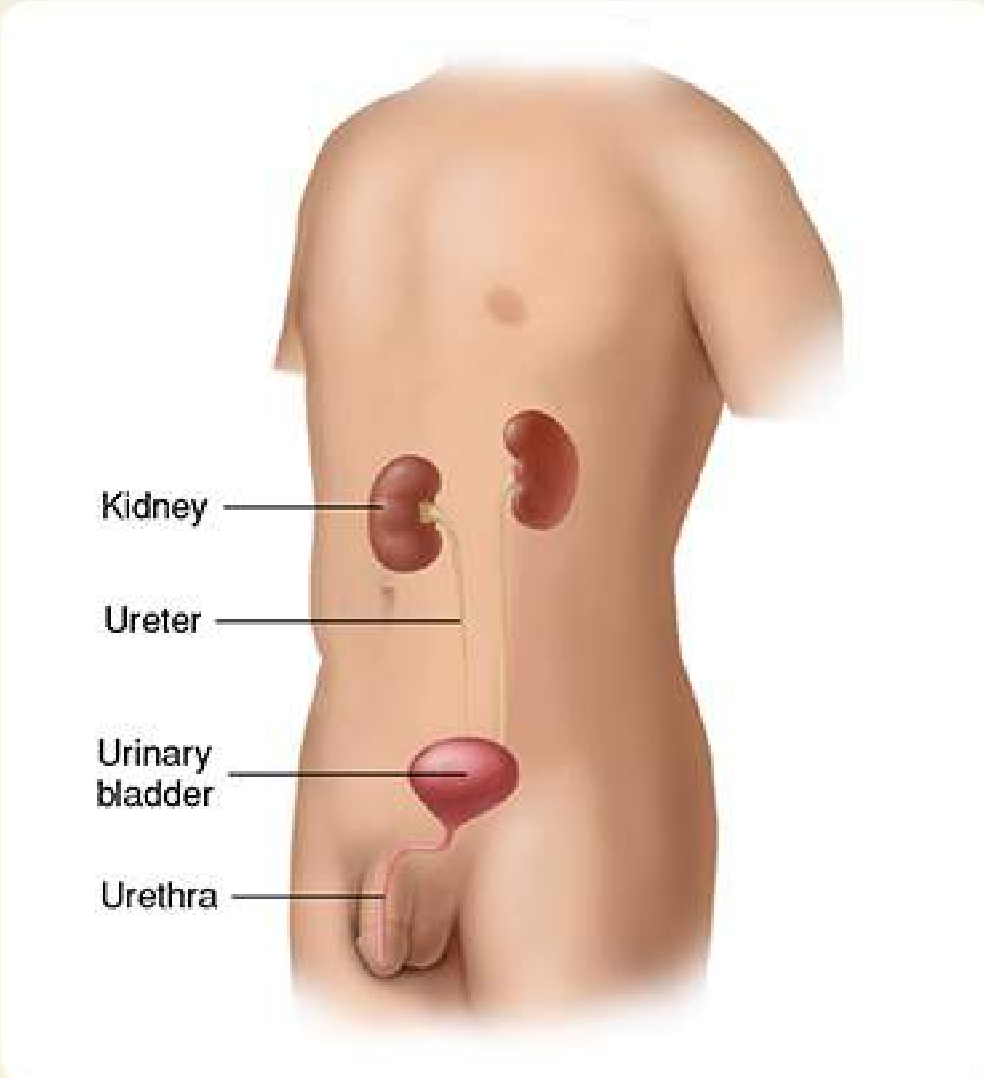

Figure 30-13 The urinary system lies behind the digestive tract. The kidneys are solid organs; the ureter, urinary bladder, and urethra are hollow organs.

The genital system is also important to the reproductive processes. The male genitalia, except for the prostate gland and the seminal vesicles, lie outside the pelvic cavity **Figure 30-14**. The female genitalia, except for the vulva, clitoris, and labia, are contained entirely within the pelvis **Figure 30-15**. The male and female reproductive organs have certain similarities and, of course, basic differences. They allow for the production of sperm and egg cells and appropriate hormones, the act of sexual intercourse, and, ultimately, reproduction.

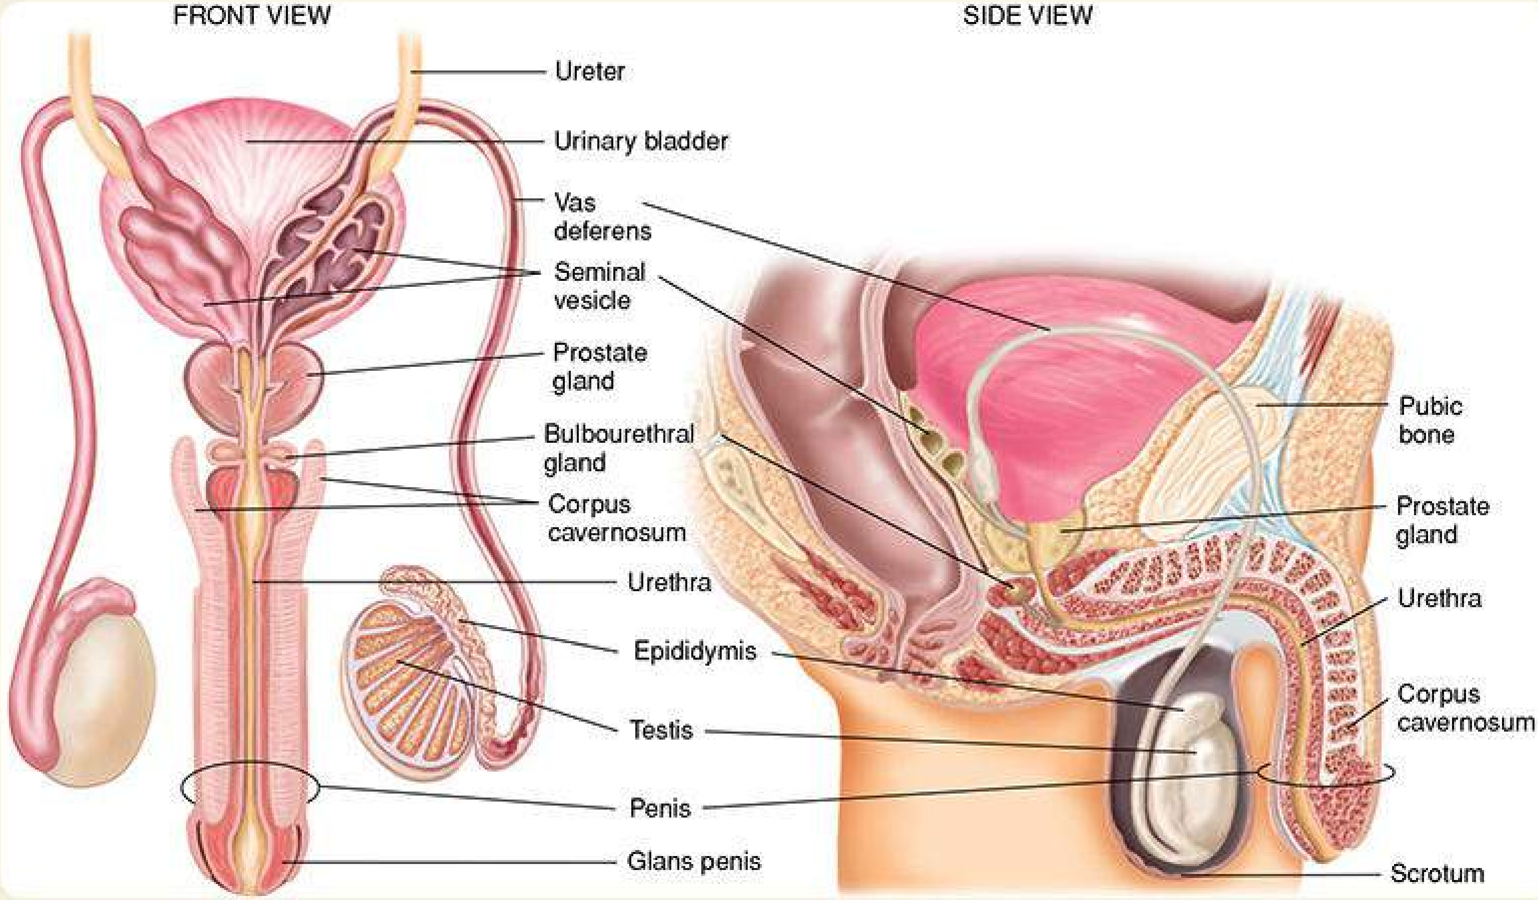

Figure 30-14 The male reproductive system includes the testicles, vas deferens, seminal vesicles, prostate gland, urethra, and penis.

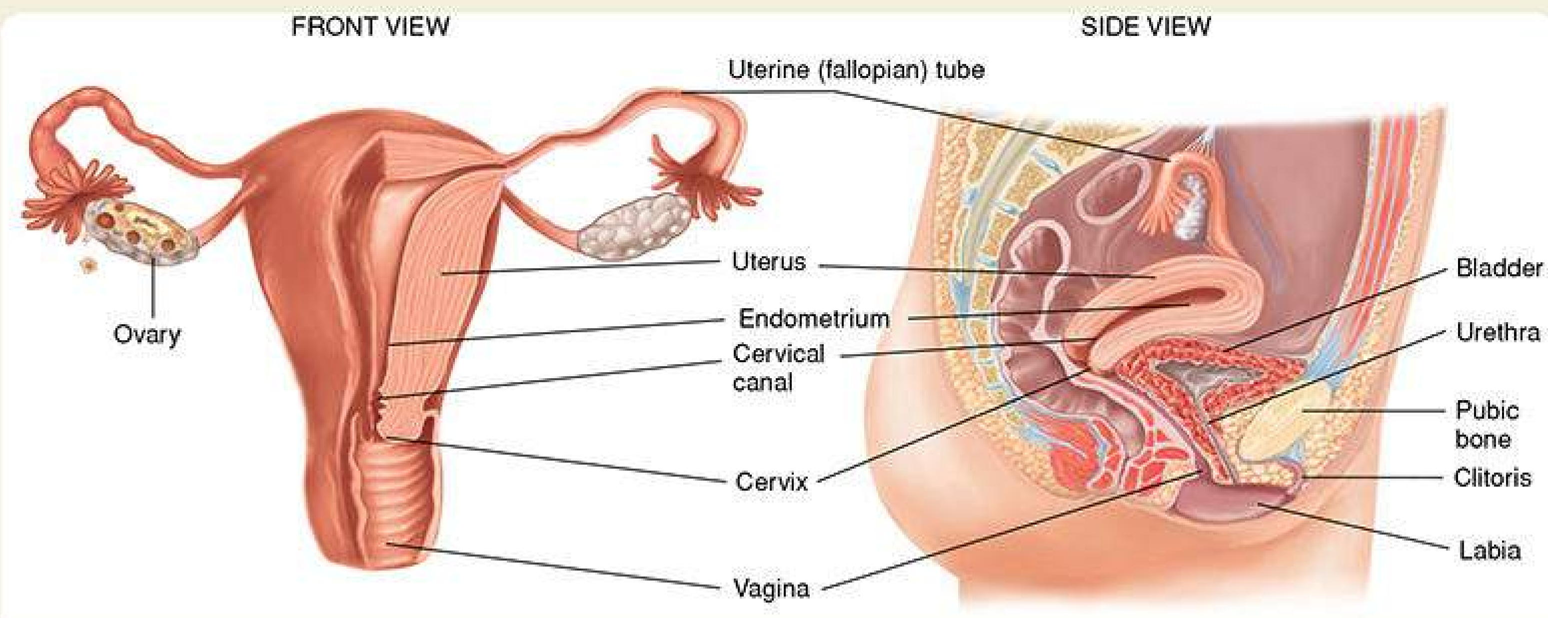

Figure 30-15 The female reproductive system includes the ovaries, fallopian tubes, uterus, cervix, and vagina.

Injuries of the Genitourinary System

Injuries of the Kidneys

Injuries of the kidneys are not unusual and rarely occur in isolation. This is because the kidneys lie in such a well-protected area of the body. A penetrating wound that reaches the kidneys almost always involves other organs. The same is true with blunt injuries. A blow that is forceful enough to cause significant kidney damage often results in damage to other intra-abdominal organs. Less significant injuries to the kidneys may result from a direct blow or even from a tackle in football **Figure 30-16**. Suspect kidney damage if the patient has a history or physical evidence of any of the following:

- An abrasion, laceration, or contusion in the flank
- A penetrating wound in the flank (the region below the rib cage and above the hip) or the upper abdomen
- Fractures on either side of the lower rib cage or of the lower thoracic or upper lumbar vertebrae
- A hematoma in the flank region

Figure 30-16 A tackle in football that results in blunt trauma to the lower rib cage or the flank can cause kidney injury.

Injuries to the Urinary Bladder

Injury to the urinary bladder, either blunt or penetrating, may result in its rupture. When this happens, urine spills into the surrounding tissues, and any urine that passes through the urethra is likely to be bloody. Blunt injuries of the lower abdomen or pelvis often cause rupture of the urinary bladder, particularly when the bladder is full and distended. Sharp, bony fragments from a fracture of the pelvis often perforate the urinary bladder **Figure 30-17**. Penetrating wounds of the lower midabdomen or the perineum (the pelvic floor and associated structures that occupy the pelvic outlet) can directly involve the urinary bladder. In men, sudden deceleration from a motor vehicle or motorcycle crash can literally shear the bladder from the urethra. Remember, in the second and third trimesters of pregnancy, the incidence of injury to the urinary bladder is increased by displacement of the uterus.

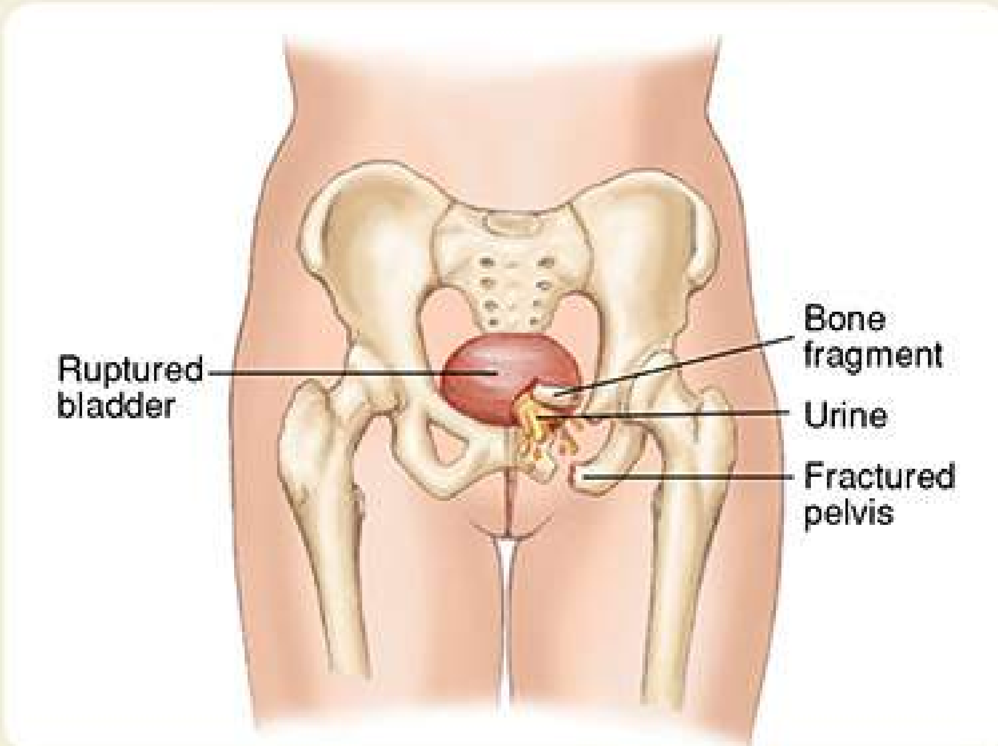

Figure 30-17 Fracture of the pelvis can result in perforation of the bladder by the bony fragments. Urine then leaks into the pelvis.

▶ Injuries of the External Male Genitalia

Injuries of the external male genitalia include all types of soft-tissue wounds. Although these injuries are uniformly painful and generally a source of great concern to the patient, they are rarely considered life threatening. They should not be given priority over other, more severe wounds, unless the rich blood supply causes significant bleeding. It is important to know that pain from an injury to the testicles or another cause, such as infection or cancer, may be referred to the lower abdomen. As a result, when assessing men with lower abdominal pain you should also consider injury or other causes of pain to the testicles.

▶ Injuries of the Female Genitalia

Internal Female Genitalia

The uterus, ovaries, and fallopian tubes are subject to the same kinds of injuries as any other internal organ. However, they are rarely damaged because they are small, deep in the pelvis, and well protected by the pelvic bones. Unlike the urinary bladder, which lies adjacent to the bony pelvis, they are usually not injured as a result of a pelvic fracture.

An exception is the pregnant uterus. As pregnancy progresses, the uterus enlarges substantially and rises out of the pelvis, becoming vulnerable to both penetrating and blunt injuries. These injuries can be particularly severe because the uterus has a rich blood supply during pregnancy. You must also keep in mind that the fetus is at risk. You can expect to see the signs and symptoms of shock with these patients; be prepared to provide all necessary support and prompt transport. Note also that contractions may begin. If possible, ask the patient when she is due to deliver, and report this information to the hospital staff.

In the third trimester of pregnancy, the uterus is large and may obstruct the vena cava, leading to a decrease in the amount of blood returning to the heart if the patient is placed in a supine position (supine hypotensive syndrome). As a result, blood pressure may decrease. The patient should be carefully placed on her left side so that the uterus will not lie on the vena cava. If the patient is secured to a backboard, tilt the board to the left. Chapter 23, *Gynecologic Emergencies,* and Chapter 33, *Obstetrics and Neonatal Care,* cover gynecologic emergencies and the special considerations for pregnant trauma patients in detail.

External Female Genitalia

The external female genitalia include the vulva, the clitoris, and the major and minor labia (lips) at the entrance of the vagina. Injuries of the external female genitalia can include all types of soft-tissue injuries. Because these genital parts have a rich nerve supply, injuries are very painful. Vaginal bleeding may occur because of penetrating or blunt trauma. These injuries can be accidental, as in the case of straddle injuries from bicycles or motorcycles; or they can be intentional as in the case of assaults. Determining the MOI will assist you in deciding if you need to call for additional resources, as in the case of sexual assault.

In any case of trauma, it is important to determine the possibility of pregnancy. Ask the patient for the date of her last known menstrual period or if she has been sexually active. Assume all women of childbearing age are possibly pregnant. This information is medically relevant because there are medications and tests that are harmful for a fetus and there is the potential for another source of blood loss in the gravid uterus.

In cases of external bleeding and trauma, a sterile absorbent sanitary napkin or pad may be applied to the labia. Do not insert instruments, gloved fingers, or a tampon into the vagina because this can cause further damage.

Patient Assessment of the Genitourinary System

When assessing a genitourinary injury, there is a potential for the patient to become embarrassed, so it is very important for you to maintain a professional presence at all times when dealing with these injuries. Remember to provide privacy for the patient during the assessment process. Whenever possible, have a provider perform the assessment who is the same gender as the patient. First look for blood on the patient's underwear and inspect only the external genitalia when there are concerns of pain or external signs of injury.

Scene Size-up

As you arrive at the scene, observe it for hazards and threats to the safety of the crew, bystanders, and the patient. Assess the impact the hazards have on patient care and address those hazards. Assess the potential for violence and assess for environmental hazards.

Ensure that you and your crew have taken standard precautions—a minimum of gloves and eye protection. Control of blood and bloody contaminants can be difficult unless you are careful about what you touch and where. Apply standard precautions before you approach the scene to minimize your direct exposure to body fluids. Because of the color of blood and how well it soaks through clothing, you can often identify patients with an open injury as you approach the scene. However, blood can be hidden under thick clothing such as denim and leather. Eye protection is required when managing open injuries. Determine the number of patients and consider if you need additional or specialized resources on the scene.

As you observe the scene, look for indicators of the MOI. Consider information from dispatch, your observations of the scene, and the MOI to help develop your list of expected injuries. Be aware that the patient may avoid discussing the injury to avoid undergoing a physical examination. Also, the patient may provide an MOI that seems "less embarrassing" than the actual MOI. By maintaining a professional demeanor, respecting the patient's privacy, and maintaining the patient's dignity, you will earn the patient's trust. If the patient trusts you, you are more likely to discover the true facts behind the injury.

YOU are the Provider **PART 5**

The patient is becoming combative and resists your attempts to assist his ventilations, but he will tolerate oxygen via a nonrebreathing mask. During your reassessment, you note blood on the front of the patient's underwear, which was not there during previous assessments. You examine the area more carefully but do not see any open injuries to the genitalia or adjacent areas. You call your radio report in to the receiving facility.

Recording Time: 17 Minutes	
Level of consciousness	Responsive to pain only
Respirations	28 breaths/min; shallow
Pulse	128 beats/min; weak and regular
Skin	Cool, pale, and clammy
Blood pressure	90/58 mm Hg
Spo_2	93% (on oxygen)

The patient begins vomiting bright red blood. You quickly turn the backboard to the side to allow the vomitus to drain and then suction his mouth to ensure that his airway remains clear.

7. On the basis of your reassessment, what additional injuries should you suspect?
8. How will your reassessment findings change your current treatment plan?

Primary Assessment

During the primary assessment, you must quickly scan the patient to identify and treat potential life threats and determine the priority of patient care and transport. The genitourinary system is very vascular, and injuries to it can produce a significant volume of blood loss. Do not avoid this area during the primary assessment. In fact, life-threatening hemorrhage must be addressed immediately, even before airway or breathing concerns. Look externally at the patient's undergarments for signs of bleeding and injury. If bleeding is present, maintain privacy for the patient and inspect the exterior genitals for visible injury.

As you approach the trauma patient, important indicators will alert you to the seriousness of the patient's condition. Is the patient awake and interacting with his or her surroundings, or lying still, not making sounds? Does the patient have any apparent life threats? What color is the patient's skin? Is he or she appropriately or inappropriately responding to you? Your general impression will help you develop an index of suspicion for serious injuries and determine how urgently your patient needs care.

As stated, the genitourinary system is very vascular and can be a significant source of bleeding.

If visible significant bleeding is seen, you must begin the steps necessary to control bleeding. Significant bleeding is an immediate life threat and must be controlled quickly using appropriate methods. In dark environments, bleeding can be hard to see because of its color. Thick clothing may also hide bleeding. After you consider the MOI and form suspicions as to where bleeding may occur, expose that part of the body.

Ensure the patient has a clear and patent airway. Because trauma was involved, protect the patient from further spinal injury as you manage the airway. If the patient is unresponsive or has a significant altered level of consciousness, consider inserting an oropharyngeal airway or nasopharyngeal airway. Quickly assess the patient for adequate breathing. Provide assisted ventilations using a BVM as needed, depending on the level of consciousness and if your patient is breathing inadequately.

Quickly assess the patient's pulse rate and quality; determine the skin condition, color, and temperature; and check the capillary refill time. These assessments will help you determine the presence of circulatory conditions or shock. Closed injuries do not always have visible signs of bleeding. Because the bleeding is occurring inside the body, shock may be present. Your assessment of the pulse and skin will indicate to you how aggressively you need to treat your patient for shock.

A patient with a genitourinary system injury should be taken to a trauma center for evaluation and treatment. Any injury to this system can prove to be life altering and often requires specialized care from a medical specialist. When possible and protocols allow, transport the patient to a facility capable of treating this subset of injuries.

History Taking

When determining the chief complaint, you are seeking the primary reason that the patient called for assistance. Begin your interview by establishing why the patient called 9-1-1. Ask about associated complaints, but be cautious not to put words in the patient's mouth, such as when describing pain. This can be avoided by asking, "What else is wrong?" or "Is anything else bothering you?" Common associated complaints with genitourinary injuries are nausea, vomiting, diarrhea, blood in urine (hematuria), vomiting blood (hematemesis), or abnormal bowel and bladder habits such as an increase in frequency or the absence of the need to void. You can use the SAMPLE history to further gather more facts and specifics about the chief complaint.

Use the SAMPLE mnemonic device to help determine the patient's baseline. Establish the signs and symptoms of the injury. Use OPQRST to learn more about any pain the patient reports. Ask the patient about output from the genitourinary system, specifically the presence of blood in the urine. This may or may not be visible, and the simple lack of it does not preclude your patient from having internal genitourinary injuries. Ask your patient about any allergies to medications or environmental triggers. Medications mask the signs and symptoms of injuries or make them more severe, so it is important to determine what your patient is prescribed and what over-the-counter or herbal remedies the patient may have taken. The importance of past medical history cannot be overstated. Incidence of repeated or previous injury or illness involving the genitourinary system can help determine the extent of the current injury and possibly the MOI. The last intake of both food and fluids is important because it can predict what is contained in the genitourinary system and if the symptoms are related to the ingestion of those foods and fluids. Finally, addressing the events that led to the injury help determine the MOI and help you draw conclusions and develop an index of suspicion.

Secondary Assessment

The secondary assessment is a more detailed, comprehensive examination of the patient that is used to uncover injuries that may have been missed during the primary assessment. In some instances, such as with a critically injured patient or a short transport time, you may not have time to conduct a secondary assessment.

Genitourinary system injuries can be awkward to evaluate and can be even more awkward to treat. Privacy is a genuine concern. When examining the patient, expose only what is needed. If an area must be exposed, cover it after it has been examined. Being professional helps reduce anxiety for both you and your patient. If possible, a provider who is the same gender as the patient should perform direct assessment of the genitalia. However, never delay treatment of any reason if hemorrhage is significant and potentially life threatening.

When your patient has an isolated injury to the genitourinary system with a limited MOI, focus your assessment on the isolated injury, the patient's concern, and the body region affected. Look for DCAPBTLS. Ensure that wounds are identified and the bleeding is controlled. Note the location and extent of the injury.

If there is significant trauma (such as a blunt trauma) likely affecting multiple systems, start with an exam of the entire body looking for DCAP-BTLS to determine the nature and extent of genitourinary injury. This examination will help determine all the injuries and the extent of those injuries. Inspect or visualize the region looking for deformities that may reveal the presence of multiple rib fractures (that could injure the kidneys). Identify small areas of contusions or abrasions that may pinpoint a specific point of impact. The presence of penetrating injuries indicates a possible internal injury that should be managed accordingly. The presence of burns must be noted and managed appropriately. Palpate for tenderness to localize the injury and the presence of fractures. Look for lacerations and local swelling. Applying this systematic approach to patient assessment minimizes the chance of missing a significant injury.

With genitourinary injuries, it is important to not focus only on one area of the body. With significant trauma, you should quickly assess the entire patient from head to toe.

Obtain the patient's vital signs. Patients who have hidden injuries may have internal bleeding and their condition may rapidly become unstable. It is important to reassess the vital signs to identify how quickly the patient's condition is changing. Signs such as tachycardia, tachypnea, low blood pressure, weak pulse, and cool, moist, and pale skin indicate hypoperfusion and imply the need for rapid treatment at the hospital. The reassessment of your patient's vital signs will give you a good understanding of how well or how poorly your patient is tolerating the injury.

Reassessment

Repeat the patient's primary assessment and vital signs. Reassess the interventions and treatment you have provided to the patient. Identify trends in pain, vital signs, and the progress of treatments to determine whether the patient's condition is improving or getting worse. Adjustments in care should be based on these objective findings.

When treating patients with trauma to the genitourinary system, the concerns are similar to those for other injuries to other body systems. Provide oxygen if there are signs of dyspnea or shock and maintain a patent airway. Attempt to control bleeding and treat for shock. Place the patient in a position of comfort and transport to the appropriate facility.

Communicate your suspicions and concerns early with the receiving facility staff so they can be adequately prepared and, if required, have a specialist en route to evaluate and treat the patient. Your documentation should be complete and thorough. Describe all injuries and the treatment given. Remember, your documentation is your legal record of what happened.

Emergency Medical Care of Genitourinary Injuries

Kidneys

Damage to the kidneys may not be obvious on inspection of the patient. You may or may not see bruises or lacerations on the overlying skin. However, you will see signs of shock if the injury is associated with significant blood loss. Because one of the functions of the kidneys is the formation of urine, another sign of kidney damage is blood in the urine (hematuria). Treat shock and associated injuries in the appropriate manner. Provide rapid transport to the hospital, carefully monitoring the patient's vital signs en route.

Urinary Bladder

Suspect a possible injury of the urinary bladder if you see blood at the urethral opening or physical signs of trauma on the lower abdomen, pelvis, or perineum. There may be blood at the tip of the penis or a stain on the patient's underwear.

The presence of associated injuries or of shock will dictate the urgency of transport. In most instances, provide rapid transport, and monitor the patient's vital signs en route.

External Male Genitalia

A few general rules apply to the treatment of injuries involving the external male genitalia:

- These injuries are very painful. Make the patient as comfortable as possible.
- Use sterile, moist compresses to cover areas that have been stripped of skin.
- Apply direct pressure with dry, sterile gauze dressings to control bleeding.
- Never move or manipulate impaled instruments or foreign bodies in the urethra.
- If possible, always identify and take avulsed parts to the hospital with the patient. Label the bag with the patient's name.

If you encounter a patient with an avulsion (tearing away) of skin of the penis, wrap the penis in a soft, sterile dressing moistened with sterile saline solution, and rapidly transport the patient. Use direct pressure to control any bleeding. You should try to save and preserve the avulsed skin, but do not delay treatment or transport for more than a few minutes to do so.

Managing blood loss is your top priority in amputation of the penile shaft, whether partial or complete. You should use local pressure with a sterile dressing on the remaining stump. Never apply a constricting device to the penis to control bleeding. Surgical reconstruction of even a completely amputated penis is possible if you can locate the amputated part. Wrap it in a moist, sterile dressing; place it in a plastic bag; and transport it in a cooled container; do not allow it to come in direct contact with ice.

If the connective tissue surrounding the erectile tissue in the penis is severely damaged, the shaft of the penis can be fractured or severely angled, sometimes requiring surgical repair. The injury may occur during particularly active sexual intercourse. It is associated with intense pain, bleeding into the tissues, and fear. Provide rapid transport to the ED.

Accidental laceration of the skin about the head of the penis usually occurs when the penis is erect and is associated with heavy bleeding. Local pressure with a sterile dressing is usually sufficient to stop the hemorrhage.

It is not uncommon for the skin of the shaft of the penis or the foreskin to get caught in the zipper of pants. If a small segment of the zipper is involved (one or two teeth), you can try to unzip the pants. If a longer segment is involved or the patient is agitated, use heavy scissors to cut the zipper out of the pants to make the patient more comfortable during transport. Explain to the patient how you are going to use the scissors before you begin cutting. Be particularly careful not to cause injury to the scrotum while cutting the zipper away from the penis.

Urethral injuries in men are not uncommon. Lacerations of the urethra can result from straddle injuries, pelvic fractures, or penetrating wounds of the perineum. These injuries may bleed profusely, although bleeding may not be evident externally. Direct pressure with a dry, sterile dressing usually controls any external hemorrhage. Because the urethra is the channel for urine, it is very important to know whether the patient can urinate and whether hematuria is present. For this reason, you should save any voided urine for later examination at the hospital. Any foreign bodies that may be protruding from the urethra will have to be removed in a surgical setting.

Avulsion of the skin of the scrotum may damage the scrotal contents. If possible, preserve the avulsed skin in a moist, sterile dressing for possible use in reconstruction. Wrap the scrotal contents or the perineal area with a sterile, moist compress, and use a local pressure dressing to control bleeding. Promptly transport the patient to the ED.

Direct blows to the scrotum can result in the rupture of a testicle or significant accumulation of blood around the testes. In either case, you should apply an ice pack to the scrotal area while transporting the patient.

Female Genitalia

Lacerations, abrasions, and avulsions should be treated with moist, sterile compresses. Use local pressure to control bleeding and a diaper-type bandage to hold dressings in place. Under no circumstances should you pack or place dressings into the vagina. Leave any foreign bodies in place after you stabilize them with bandages.

In general, although these injuries are painful, they are not life threatening. Bleeding may be heavy, but it can usually be controlled by local compression. Contusions and other blunt injuries all require careful in-hospital evaluation. However, the urgency for transport will be determined by associated injuries, the amount of hemorrhage, and the presence of shock.

Rectal Bleeding

Rectal bleeding is a common complaint and something that you may hear as a chief complaint or secondary to abdominal or pelvic complaints. Bleeding from the rectum may present as blood stains or blood soaking through underwear or patients may report blood in the toilet after a bowel movement or attempted bowel movement. Rectal bleeding can be caused by a sexual assault, rectal foreign bodies, hemorrhoids, colitis, or ulcers of the digestive track. Significant rectal bleeding can occur after hemorrhoid surgery and can lead to significant blood loss and shock.

Sexual Assault and Rape

Sexual assault and rape are all too common. According to the US Department of Justice's National Crime Victimization Survey, there are 293,066 victims (age 12 or older) of rape and sexual assault each year. The definition of rape, sexual assault, and similar terms differs by state. Although most victims are women, men and children are also victimized. Often, you can do little beyond providing compassion and transportation to the ED. On some occasions, patients will have sustained multiple-system trauma and will also need treatment of shock.

Do not examine the genitalia of a victim of sexual assault unless obvious bleeding requires you to apply a dressing. Treat all other injuries according to appropriate procedures and protocols for your EMS system. Observe standard precautions. Take care to shield the patient from curious onlookers. Because you may have to appear in court as much as 2 or 3 years later, you must document in detail the patient's history, assessment, treatment, and response to treatment. Do not speculate. Record only the facts.

Follow any crime scene policy established by your system to protect the scene and any potential evidence for police. Advise the patient not to wash, bathe, shower, douche (if female), urinate, or defecate until after a physician has examined him or her; this will help preserve any evidence of a crime. If oral penetration has occurred, advise the patient not to eat, drink, brush teeth, or use mouthwash until he or she has been examined. If the patient will tolerate being wrapped in a sterile burn sheet, this may help investigators find any hair, fluid, or fiber from the alleged offender. Handle the patient's clothes as little as possible, placing articles and any other evidence in paper bags. Do not use plastic bags. If a female patient insists on urinating, have her do so in a sterile urine container (if available). Also, have her deposit the toilet paper in a paper bag. Seal and label the bag for the police because these items can be critical evidence.

To reduce the patient's anxiety, whenever possible the EMT who is caring for the patient should be the same gender as the patient. Remember, a victim of rape or sexual assault, whether a man or a woman, may need medical assistance. In these cases, you must treat the medical injuries but also provide privacy, support, and reassurance. Chapter 23, *Gynecologic Emergencies*, covers this topic in detail.

YOU are the Provider — SUMMARY

1. How do hollow organ injuries differ from solid organ injuries?

Hollow organs—the stomach, intestines, and urinary bladder—are structures through which materials pass. When hollow organs are ruptured or lacerated, they release their contents into the pelvis or peritoneal (abdominal) cavity. The release of hollow organ contents into the peritoneal cavity causes an intense inflammatory response (peritonitis), which can result in a life-threatening infection. Hollow organ injury may be associated with some internal bleeding; however, the major cause of death is sepsis, which typically occurs later in the hospital.

Solid organs—the liver, spleen, pancreas, and kidneys—are highly vascular and tend to bleed profusely when injured by blunt or penetrating trauma. Unlike hollow organ injury, the major cause of death following injury to the solid organs is internal hemorrhage, which can very quickly lead to death.

2. How should you focus your assessment of a patient with potential intra-abdominal bleeding?

When you are caring for a patient with blunt or penetrating abdominal trauma, you should focus on recognizing signs and symptoms of shock, initiating treatment without delay, and providing rapid transport to the hospital.

If your patient sustained blunt abdominal trauma, has external evidence of injury (eg, bruising, distention, rigidity), and signs of shock—all signs that clearly suggest intra-abdominal bleeding—does the origin of the hemorrhage affect the treatment that you provide in the field? The answer, of course, is no. What *does* matter is that *the patient is bleeding from a source that you cannot control*, and that his or her outcome depends on you recognizing the situation, initiating prompt treatment, and providing rapid transport.

3. How should you interpret your primary assessment findings?

Rarely do EMS providers actually witness the injury when it occurs; this is why it is so important for you to pay attention to clues that suggest a particular mechanism of injury (MOI). However, in this situation you did witness the patient being trampled by a bull and were able to see that his injuries appear to be to the abdomen and flanks.

On the basis of the MOI and your primary assessment findings, your initial impression should be that your patient is in shock, which is likely the result of intra-abdominal bleeding. Although you will need to perform a head-to-toe secondary assessment to identify any other injuries, intra-abdominal bleeding is the most plausible field impression given the information that you have. You should quickly identify this patient as a "load and go," begin immediate treatment, and arrange for rapid transport to the hospital.

4. What immediate treatment is indicated for this patient?

Apply high-flow oxygen via a nonrebreathing mask. Oxygen is a critical treatment for any patient with signs and symptoms of shock and should be administered as soon as possible. Carefully monitor the patient's breathing and be ready to assist his ventilations if signs of inadequate breathing (eg, shallow breaths [reduced tidal volume], decreased mental status) are observed.

Cover the patient with a blanket to keep him warm. Patients in shock are less able to maintain body temperature because heat production requires energy, and energy requires oxygen; shock is a problem caused by a lack of oxygen!

5. What are some common bruising patterns and clinical signs associated with intra-abdominal bleeding?

As blood accumulates in the abdominal cavity, the abdomen typically becomes distended and rigid. Palpation of the patient's abdomen can be challenging in the presence of abdominal guarding. Guarding is a conscious (voluntary) or unintentional (involuntary) response to abdominal trauma and it is characterized by stiffening of the rectus abdominis muscles in an attempt to minimize the pain. Although guarding may be seen in patients who do not have significant intra-abdominal injury, *any abdominal rigidity following trauma should be assumed to be the result of internal bleeding*.

If bruising is observed following abdominal trauma, there are several patterns that you should look for during your assessment of the abdomen. Periumbilical (around the umbilicus) bruising is an indicator of blood in the peritoneal cavity. Bruising to the flank area is also an indicator of blood behind the peritoneal cavity and suggests injury to the kidneys, pelvis, or bladder.

Injury to the liver or spleen may present with referred pain to the shoulders. Unlike radiating pain, which is characterized by pain that "moves" from one area of the body to another, referred pain is characterized by pain in two separate locations.

It is important to note that some patients with intra-abdominal bleeding may not present with external signs of injury. The retroperitoneal space is a common location for hidden bleeding and can accommodate a large volume of blood.

6. Why is your patient's condition deteriorating? How should you modify your treatment?

Your patient was exhibiting signs of shock on initial contact with him. His level of consciousness has decreased, he is hypotensive, his breathing is inadequate, and his oxygen saturation is falling despite the use of high-flow oxygen. This indicates that he is now in decompensated shock; the compensatory mechanisms that help maintain adequate perfusion to the tissues and cells of the body are failing.

Any deterioration in a patient's clinical status should prompt you to immediately repeat the primary assessment. His oxygen saturation is falling, which is likely the result of the combined effects of internal bleeding and inadequate breathing. At this point, you should begin assisting his ventilations with a BVM attached to high-flow oxygen. Consider inserting a nasopharyngeal airway; his level of consciousness has decreased to the point that he may not be able to completely maintain his own airway.

Patients who have experienced trauma and who are in shock should be transported in the supine position.

As you continue to treat the patient, you must continuously monitor his ABCs. His condition is critical, and he is at high risk for cardiac arrest. If he becomes apneic and pulseless, begin cardiopulmonary resuscitation and ask your partner to update the receiving facility.

7. On the basis of your reassessment, what additional injuries should you suspect?

Blood stains on the front of the patient’s underwear without evidence of any open genitalia injuries indicates that he has blood in his urine (hematuria) and suggests injury to his kidneys, urinary bladder, or both.

Remember, the patient had diffuse abdominal pain and abrasions to both the anterior part of his abdomen and flanks. In addition to injury to his liver or spleen, which is likely what is causing his shock, it is clearly possible that he experienced injury to his genitourinary organs as well.

If you will recall from your evaluation of the patient, he had pain and abrasions of his flanks; this indicates direct trauma to that area, which overlies the kidneys. Injury to the kidneys may not be obvious during your assessment. If anything, you may see only abrasions or redness over the flanks; flank bruising typically does not manifest until later. Because one of the functions of the kidney is the formation of urine, another sign of kidney injury is hematuria.

Hematuria can also indicate rupture of the urinary bladder. Blood at the urethral opening should also make you suspicious for urinary bladder rupture.

Hematemesis, the vomiting of blood, indicates bleeding within the gastrointestinal tract. More specifically, vomiting bright red blood indicates injury to some part of the upper gastrointestinal tract. You should suspect injury to the patient’s stomach.

8. How will your reassessment findings change your current treatment plan?

Despite the presence of indicators that suggest injury to both solid and hollow abdominal and genitourinary organs, you should maintain the patient’s airway, ensure adequate oxygenation and ventilation, and treat for shock. Rapid transport to a trauma center is critical!

Blunt trauma with internal bleeding is often more fatal than penetrating abdominal trauma with external bleeding. Open injuries are obvious, whereas internal injuries are often hidden and may be missed. In the absence of obvious external injury, a trauma patient with signs of shock should be assumed to be bleeding into his or her abdomen.

EMS Patient Care Report (PCR)

Date: 12-16-16	**Incident No.:** 012809	**Nature of Call:** Traumatic injury		**Location:** 1333 Rodeo Blvd.	
Dispatched: 1904	**En Route:** 1904	**At Scene:** 1904	**Transport:** 1914	**At Hospital:** 1925	**In Service:** 1934

Patient Information

Age: 20 **Sex:** M **Weight (in kg [lb]):** 61 kg (135 lb)	**Allergies:** No known drug allergies **Medications:** None **Past Medical History:** None **Chief Complaint:** Pain in abdomen, flanks, and back of head

Vital Signs

Oxygen @ 15 **L/min via (circle one):** **NC NRM BVM**		**Assisted Ventilation**	**Airway Adjunct**	**CPR**
Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** Thermal management, shock treatment, spinal immobilization, suctioning

Narrative

Medic 4 was standing by at a rodeo event when a bull rider was thrown from a bull and trampled. On contact with the patient, a 20-year-old man, he was found to be conscious, but restless, and in severe pain. His airway was patent and his breathing was adequate; radial pulses were rapid and weak. Manual c-spine stabilization was initiated immediately. Patient reports pain in the RUQ of his abdomen, his flank areas, and the back of his head. Administered high-flow oxygen via nonrebreathing mask and performed secondary assessment. Assessment revealed abrasions of the anterior part of the abdomen and both flanks and palpable tenderness in the RUQ. Breath sounds were clear to auscultation bilaterally, and the remainder of the assessment was unremarkable. Applied full spinal immobilizaion, covered patient with a blanket, loaded him into the ambulance, obtained vital signs, and began transport to the hospital. En route, patient's mental status and vital signs deteriorated; he was now responsive only to pain; his respirations increased in rate, but decreased in depth; a marked decrease in his blood pressure was observed; and his oxygen saturation decreased. Began assisting the patient's ventilations with a BVM attached to high-flow oxygen. Patient became somewhat combative and would no longer tolerate assisted ventilation. However, he would tolerate oxygen via nonrebreathing mask. Reassessment of patient revealed little improvement in his vital signs. Noted blood on patient's underwear, which was previously not present. Assessment of genitalia and adjacent areas revealed no signs of open injury. Continued to monitor patient and contacted receiving facility. Patient then began vomiting bright red blood, so the backboard was immediately turned to the side and the patient's mouth was suctioned to ensure airway patency. Suctioned remaining vomitus from the patient's mouth and returned the backboard to a supine position. Called radio report to receiving facility to provide update on patient's status, and closely monitored his condition throughout the duration of the transport. Patient was delivered to emergency department staff without further incident, and verbal report was given to attending physician. Medic 4 cleared the hospital and returned to service at 1934.**End of report**

Prep Kit

Ready for Review

- Abdominal injuries are categorized as either open (penetrating trauma) or closed (blunt force trauma).
- Either classification of injury can result in injury to the hollow or solid organs of the abdomen and cause significant life-threatening bleeding.
- Blunt force trauma that causes closed injuries results from an object striking the body without breaking the skin, such as being hit with a baseball bat or when the patient's body strikes the steering wheel during a motor vehicle crash.
- Penetrating trauma is often a result of a gunshot wound or stab wound. Other mechanisms of injury such as a fall on an object can also cause penetrating trauma to the abdomen.
- Injury to the solid organs often causes significant internal bleeding that can be life threatening.
- Injury to the hollow organs of the abdomen may cause irritation and inflammation to the peritoneum as caustic digestive juices leak into the peritoneum. A serious infection may also occur over several hours.
- Always maintain a high index of suspicion for serious intra-abdominal injury in the trauma patient, particularly in the patient who exhibits signs of shock.
- Assess the abdomen for signs of bruising, rigidity, penetrating injuries, and reports of pain.
- Never remove an impaled object from the abdominal region. Secure it in place with a large bulky dressing and provide rapid transport. When a penetrating injury exists, spinal immobilization is usually not indicated (follow local protocol).
- Be prepared to treat the patient for shock. Place the patient supine, keep the patient warm, and provide high-flow oxygen.
- Never replace an organ that protrudes from an open injury to the abdomen (evisceration). Instead, keep the organ moist and warm. Cover the injury site with a large, sterile, moist, bulky dressing and an occlusive dressing, if specified by local protocol.
- Injuries to the kidneys may be difficult to detect because they are located in the well-protected region of the body. Be alert to bruising or a hematoma in the flank region.
- Injury to the solid organs often causes significant internal bleeding that can be life threatening.
- In the case of sexual assault or rape, treat for shock if necessary, and record all the facts in detail. Follow any crime scene policy established by your system to protect the scene and any potential evidence. Advise the patient not to wash, bathe, shower, douche (if female), or void until after a physician has examined him or her.

Vital Vocabulary

closed abdominal injury An injury in which there is soft-tissue damage inside the body but the skin remains intact.

evisceration The displacement of organs outside of the body.

flank The region below the rib cage and above the hip.

guarding Contracting the stomach muscles to minimize the pain of abdominal movement; a sign of peritonitis.

hematuria Blood in the urine.

hollow organs Structures through which materials pass, such as the stomach, small intestines, large intestines, ureters, and urinary bladder.

melena Black, tarry stools.

open abdominal injury An injury in which there is a break in the surface of the skin or mucous membrane, exposing deeper tissue to potential contamination.

peritoneal cavity The abdominal cavity.

peritoneum The membrane lining the abdominal cavity (parietal peritoneum) and covering the abdominal organs (visceral peritoneum).

solid organs Solid masses of tissue where much of the chemical work of the body takes place (eg, the liver, spleen, pancreas, and kidneys).

Assessment *in Action*

You are dispatched to a private residence for a person reporting abdominal pain. You arrive to find a 25-year-old man lying on the couch in the fetal position. The patient states he was tackled while playing football 3 days ago and he now has pain that is becoming progressively worse. He is pale and diaphoretic. A physical examination of the abdomen shows bruising over the right and left upper quadrants, rebound tenderness, and guarding. The patient states the pain radiates to his right shoulder. Assessment of his vital signs shows a pulse rate of 130 beats/min, a blood pressure of 90/60 mm Hg, and respirations of 24 breaths/min.

1. Bruising over the right upper quadrant could indicate injury to which of the following?

   A. Liver
   B. Colon
   C. Kidney
   D. Appendix

2. Appropriate management of this patient would include:

   A. advanced life support intercept.
   B. semi-Fowler positioning.
   C. assisted ventilation.
   D. oxygen via Venturi mask.

3. On the basis of your findings, which of the following best describes the patient's condition?

   A. Respiratory distress
   B. Altered mental status

C. Multisystem trauma
D. Shock resulting from blunt trauma

4. The patient's pain radiating to the right shoulder is most likely referred from the:

   A. bladder.
   B. liver.
   C. kidney.
   D. intestine.

5. What potentially injured organs are found in the left upper quadrant?

   A. Spleen and liver
   B. Spleen and ascending colon
   C. Spleen and gallbladder
   D. Spleen and stomach

6. Bleeding from solid organs may be causing shock in this patient. Which of the following are considered solid organs?

   A. Liver and intestines
   B. Kidneys and bladder
   C. Spleen and stomach
   D. Pancreas and spleen

7. The most concerning assessment finding for the patient is:

   A. passage of time since injury.
   B. tachypnea and tachycardia.
   C. fetal position.
   D. progressive pain level.

8. Which of the following signs would indicate that an injury to the kidney has occurred?

   A. Hemoptysis
   B. Hematuria
   C. Hematoma
   D. Hematemesis

9. What is the cause of peritonitis?

10. What would guarding tell you about this patient's potential injuries?

CHAPTER

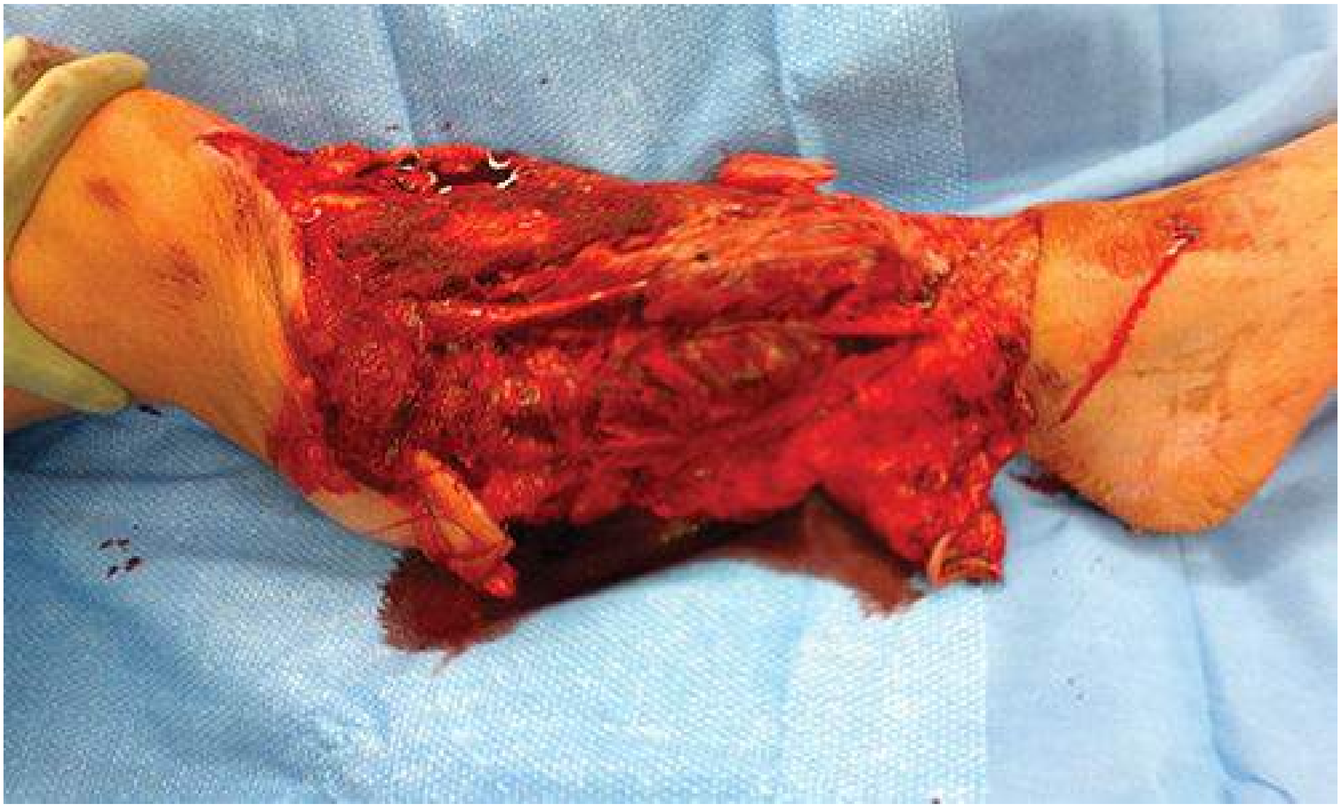
Orthopaedic Injuries



National EMS Education Standard Competencies

Trauma

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

Orthopaedic Trauma

› Recognition and management of
- Open fractures (pp 1093–1096, 1103–1131)
- Closed fractures (pp 1093–1096, 1103–1131)
- Dislocations (pp 1096, 1103–1131)
- Amputations (pp 1097–1098, 1122–1123, 1132)

› Pathophysiology, assessment, and management of
- Upper and lower extremity orthopaedic trauma (pp 1092–1132)
- Open fractures (pp 1093–1096, 1099–1131)
- Closed fractures (pp 1093–1096, 1099–1131)
- Dislocations (pp 1096, 1099–1131)
- Sprains/strains (pp 1096–1097, 1099–1103, 1120–1121, 1130–1132)
- Pelvic fractures (pp 1093–1095, 1098–1103, 1114–1115, 1123–1125)
- Amputations/replantation (pp 1097–1103, 1122–1123, 1132)

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Nontraumatic Musculoskeletal Disorders

Anatomy, physiology, pathophysiology, assessment, and management of

› Nontraumatic fractures (pp 1093–1096, 1099–1131)

Knowledge Objectives

1. Describe the anatomy and physiology of the musculoskeletal system. (pp 1087–1091)
2. Name the four mechanisms of injury. (pp 1092–1093)
3. Describe the different types of musculoskeletal injuries, including fractures, dislocations, amputations, sprains, and strains. (pp 1092–1098)
4. Recognize the characteristics of specific types of musculoskeletal injuries. (pp 1092–1099, 1115–1132)
5. Differentiate between open and closed fractures. (p 1093)
6. Explain how to assess the severity of an injury. (pp 1098–1099)
7. Describe the emergency medical care of the patient with an orthopaedic injury. (pp 1103–1132)
8. Describe the emergency medical care of the patient with a swollen, painful, deformed extremity (fracture). (pp 1103–1130)
9. Discuss the need for, general rules of, and possible complications of splinting. (pp 1104–1105)
10. Explain the reasons for splinting fractures, dislocations, and sprains at the scene versus transporting the patient immediately. (pp 1104–1105)
11. Describe the emergency medical care of the patient with an amputation. (p 1132)

Skills Objectives

1. Demonstrate the care of musculoskeletal injuries. (pp 1103–1104, Skill Drill 31-1)
2. Demonstrate how to apply a rigid splint. (p 1106, Skill Drill 31-2)
3. Demonstrate how to apply a zippered air splint. (pp 1107–1108, Skill Drill 31-3)
4. Demonstrate how to apply an unzippered air splint. (p 1108, Skill Drill 31-4)
5. Demonstrate how to apply a vacuum splint. (p 1109, Skill Drill 31-5)
6. Demonstrate how to apply a Hare traction splint. (pp 1111–1113, Skill Drill 31-6)
7. Demonstrate how to apply a Sager traction splint. (pp 1113–1114, Skill Drill 31-7)
8. Demonstrate how to splint the clavicle, the scapula, the shoulder, the humerus, the elbow, and the forearm. (pp 1115–1121)
9. Demonstrate how to splint the hand and wrist. (p 1123, Skill Drill 31-8)
10. Demonstrate how to care for a patient with an amputation. (p 1132)

Introduction

The human body is a well-designed system in which form, upright posture, and movement are provided by the musculoskeletal system. This system also protects the vital internal organs of the body. The term musculoskeletal refers to the bones and voluntary muscles of the body. However, the bones and muscles are susceptible to external forces that can cause injury. Also at risk are the tendons, cartilage, and the ligaments.

Musculoskeletal injuries are among the most common reasons why patients seek medical attention. Complaints related to the musculoskeletal system result in almost 60 million visits to physicians annually in the United States. Approximately one in seven Americans will experience some type of musculoskeletal impairment, leading to millions of missed days of work or school and costing hundreds of billions of dollars yearly. An estimated 70% to 80% of all patients with multiple system trauma have one or more musculoskeletal injuries.

Musculoskeletal system injuries are often easily identified because of pain, swelling, and deformity. Although these injuries are rarely fatal, they often result in short- or long-term disability. By providing prompt assessment and treatment, such as splinting, EMTs may help reduce the disability period for patients. Despite the sometimes dramatic appearance of these injuries, do not focus solely on a musculoskeletal injury without first determining that no life-threatening injuries exist. Never forget the ABCs!

As an EMT, you must be familiar with the basic anatomy of the musculoskeletal system. Although muscles are technically soft tissue, they are discussed in this chapter because of their close relationship with the skeleton. Therefore, the chapter begins with a review of the musculoskeletal anatomy. Various types and causes of musculoskeletal injuries in general are identified, and the assessment and treatment process for each is explained, followed by a detailed discussion of splinting. The chapter then focuses on specific musculoskeletal injuries, beginning at the clavicle and ending at the feet.

Anatomy and Physiology of the Musculoskeletal System

Muscles

The muscular system includes three types of muscles: skeletal, smooth, and cardiac. Skeletal muscle, also called striated muscle because of its characteristic stripes, attaches to the bones and usually crosses at least one joint. This type of muscle is also called voluntary muscle because it is under direct voluntary control of the brain, responding to commands to move specific body parts **Figure 31-1**. Usually, movement is the result of several muscles contracting and relaxing simultaneously. Skeletal muscle makes up the largest portion of the body’s muscle mass. Its primary functions are movement and posture. Cardiac muscle contributes to the cardiovascular system, and smooth muscle is a component of other body systems, including the digestive system and the cardiovascular system.

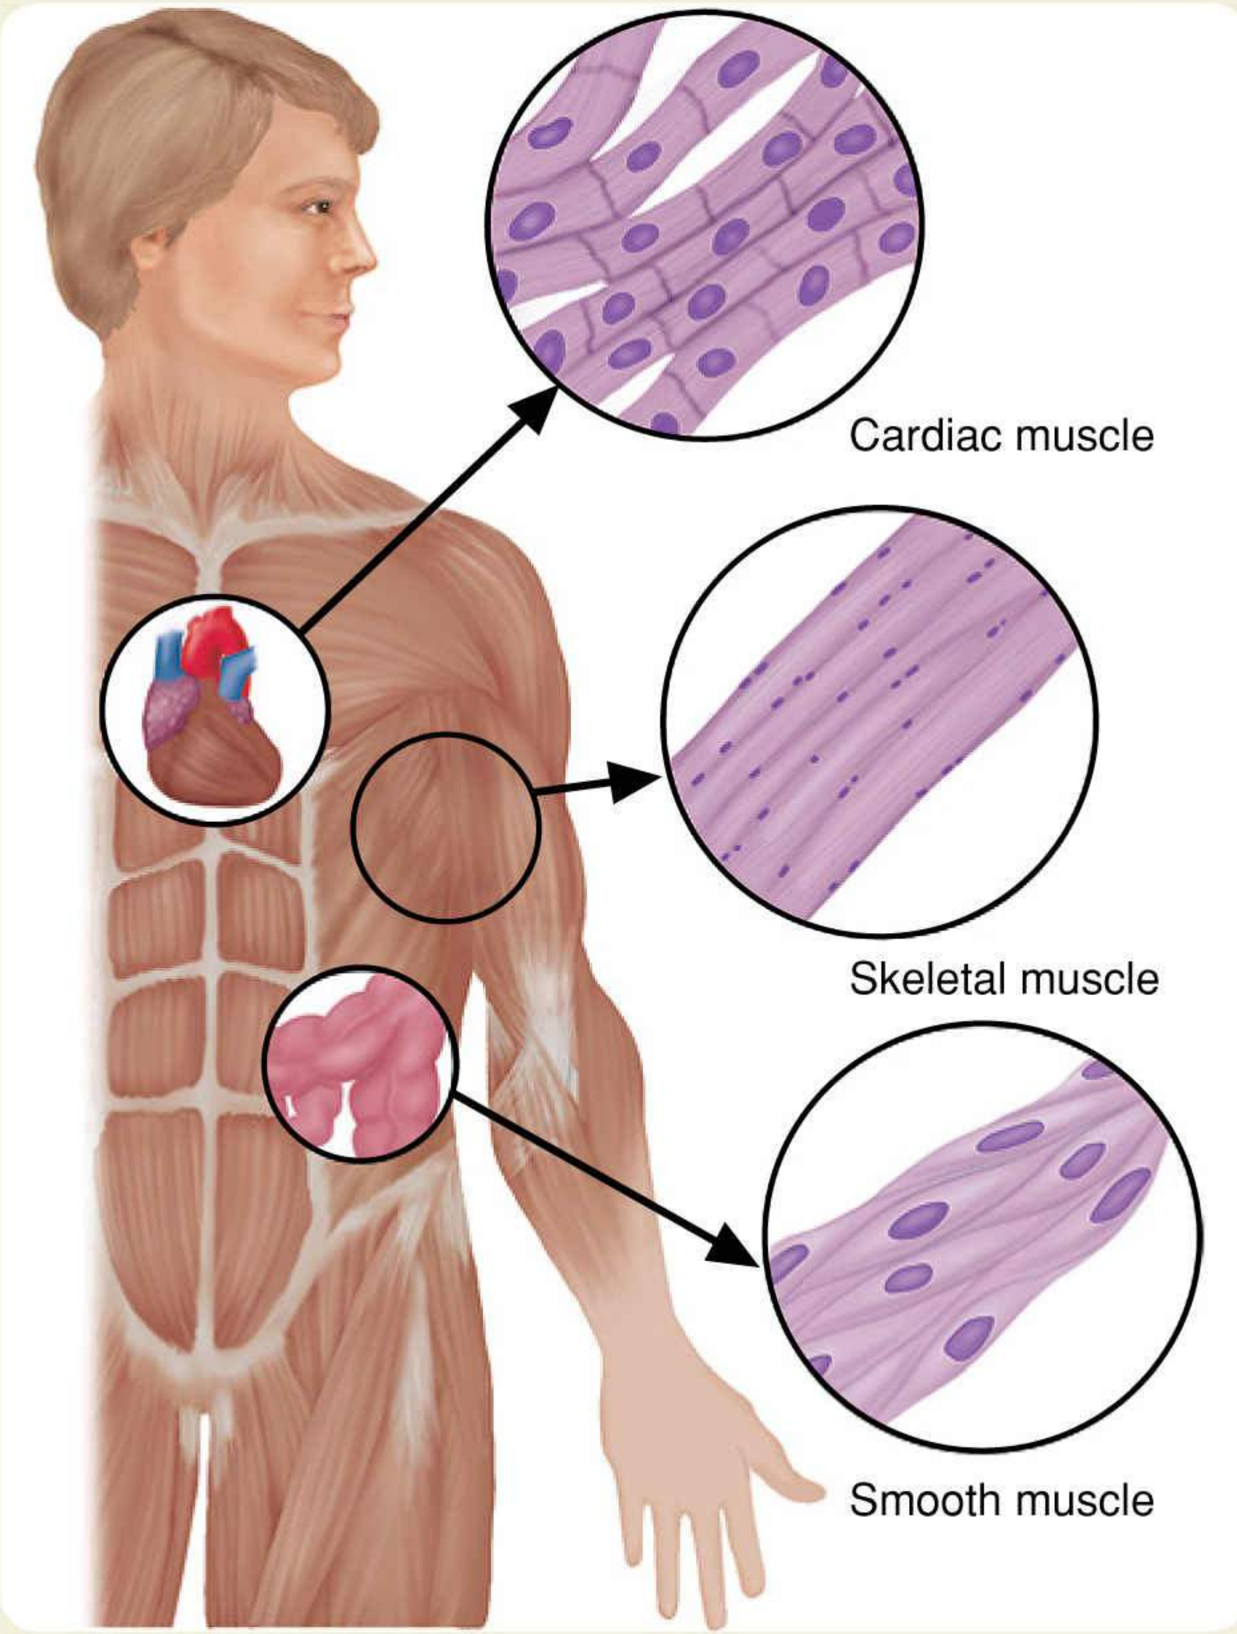


Figure 31-1 The major muscle type of concern for musculoskeletal injuries is skeletal muscle.

All skeletal muscles are supplied with arteries, veins, and nerves. Blood from the arteries brings oxygen, glucose, and nutrients to the muscles **Figure 31-2**. Waste products, including carbon dioxide and lactic acid, are carried away in the veins. Disease or trauma can result in the loss of a muscle's nervous supply; this, in turn, can lead to weakness and eventually atrophy, or a decrease in the size of the muscle and its inherent ability to function. Skeletal muscle tissue is directly attached to the bone by tough, ropelike structures known as tendons, which are extensions of the **fascia** (fibrous tissue) that covers all skeletal muscle. Fascia surrounds and supports the muscles and neurovascular structures.

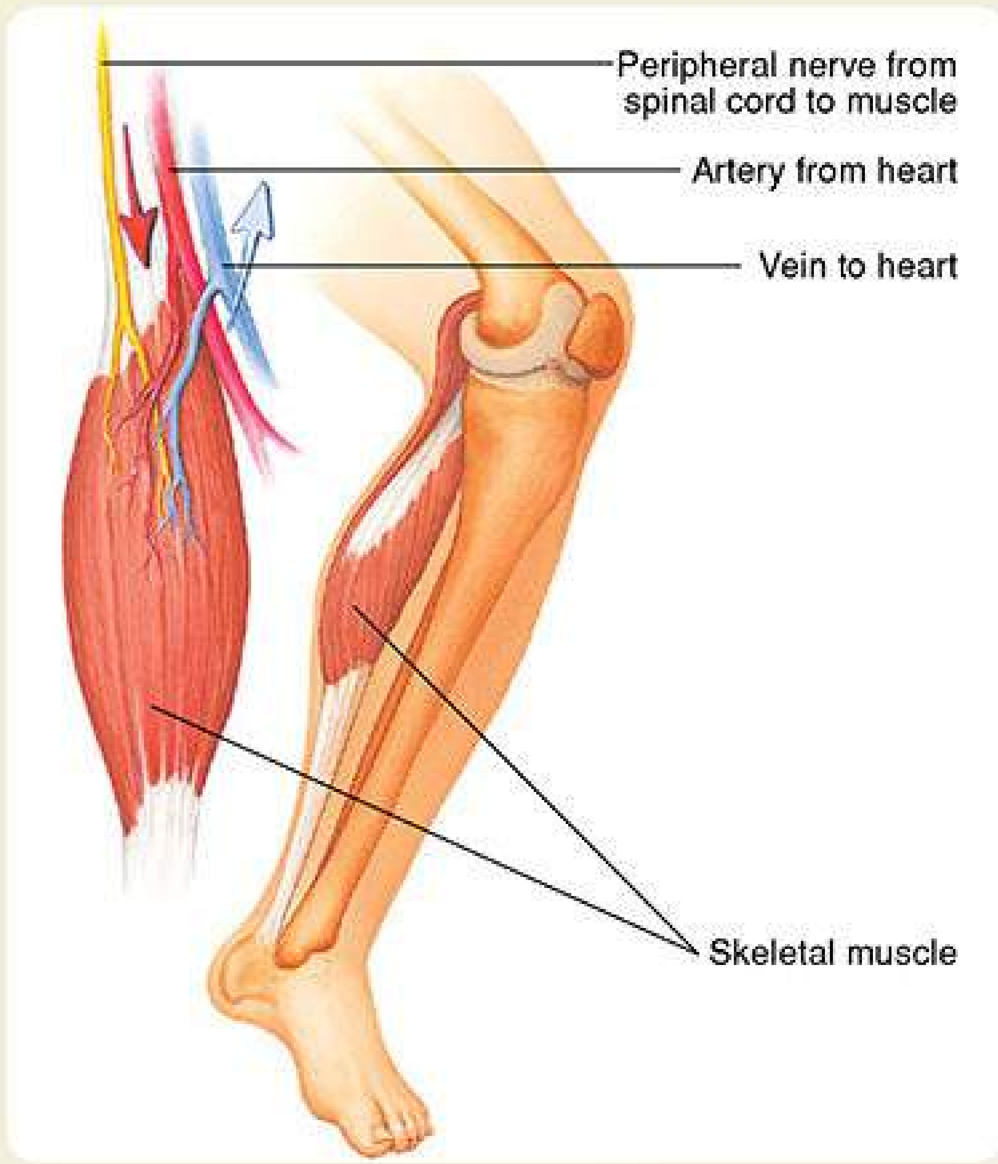

Figure 31-2 Skeletal muscles are supplied with arteries, veins, and nerves that bring oxygen and nutrients, carry away waste products, and supply nervous stimuli.

YOU are the Provider — PART 1

At 1620 hours, you are dispatched to a soccer field for a player with a possible broken leg. You and your partner proceed to the scene, with a response time of about 5 minutes. En route, dispatch advises you that the patient is conscious, alert, and breathing. The weather is overcast, the temperature is 88°F (31°C), and the traffic is moderate.

1. Under which circumstances can orthopaedic injuries pose a threat to a patient's life?
2. Given the information you have, can you rule out a critical injury?

Smooth muscle, also called involuntary muscle because it is not under voluntary control of the brain, performs much of the automatic work of the body. This type of muscle is found in the walls of most tubular structures of the body, such as the gastrointestinal tract and the blood vessels. Smooth muscle contracts and relaxes to control the movement of the contents within these structures **Figure 31-3**.

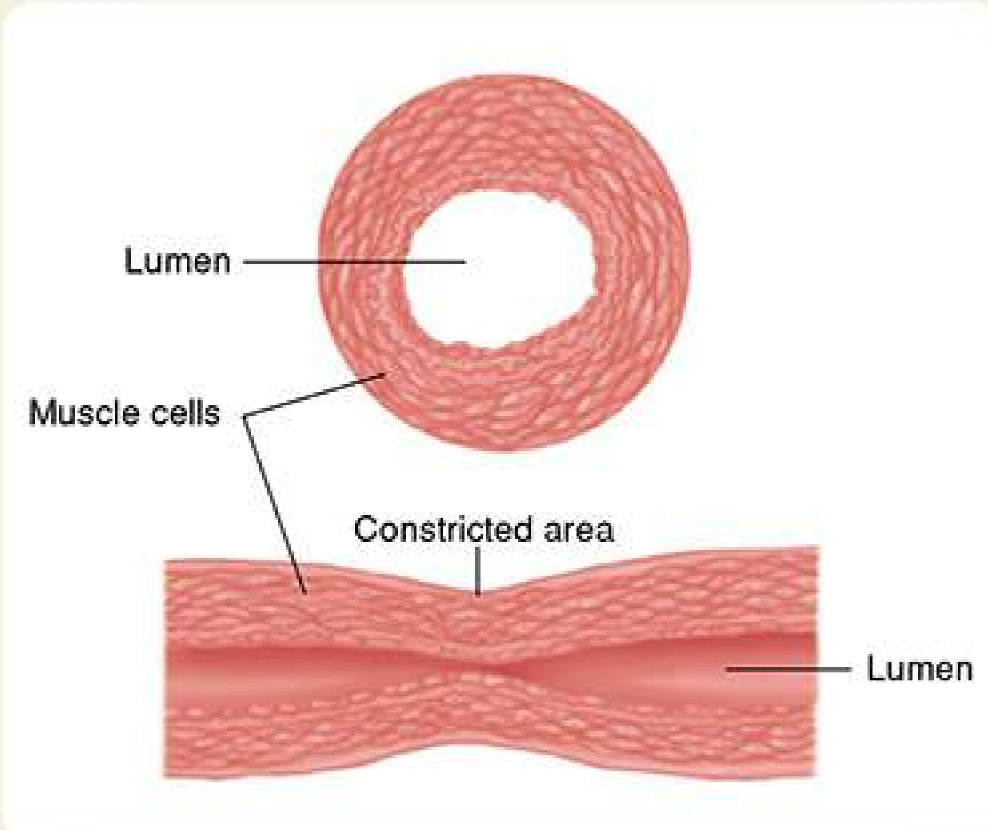

Figure 31-3 Smooth muscle is found in the walls of most tubular structures in the body. These muscles contract and relax to control the movement of the contents within these structures.

The heart neither looks nor acts like skeletal or smooth muscle. It is composed largely of cardiac muscle, a specially adapted involuntary muscle with its own regulatory system. The remainder of this chapter is concerned exclusively with skeletal muscle.

The Skeleton

The skeleton, which gives us our recognizable human form, protects our vital internal organs, and allows us to move, is made up of approximately 206 bones **Figure 31-4**. The bones in the skeleton also produce blood cells (in the bone marrow) and serve as a reservoir for important minerals and electrolytes.

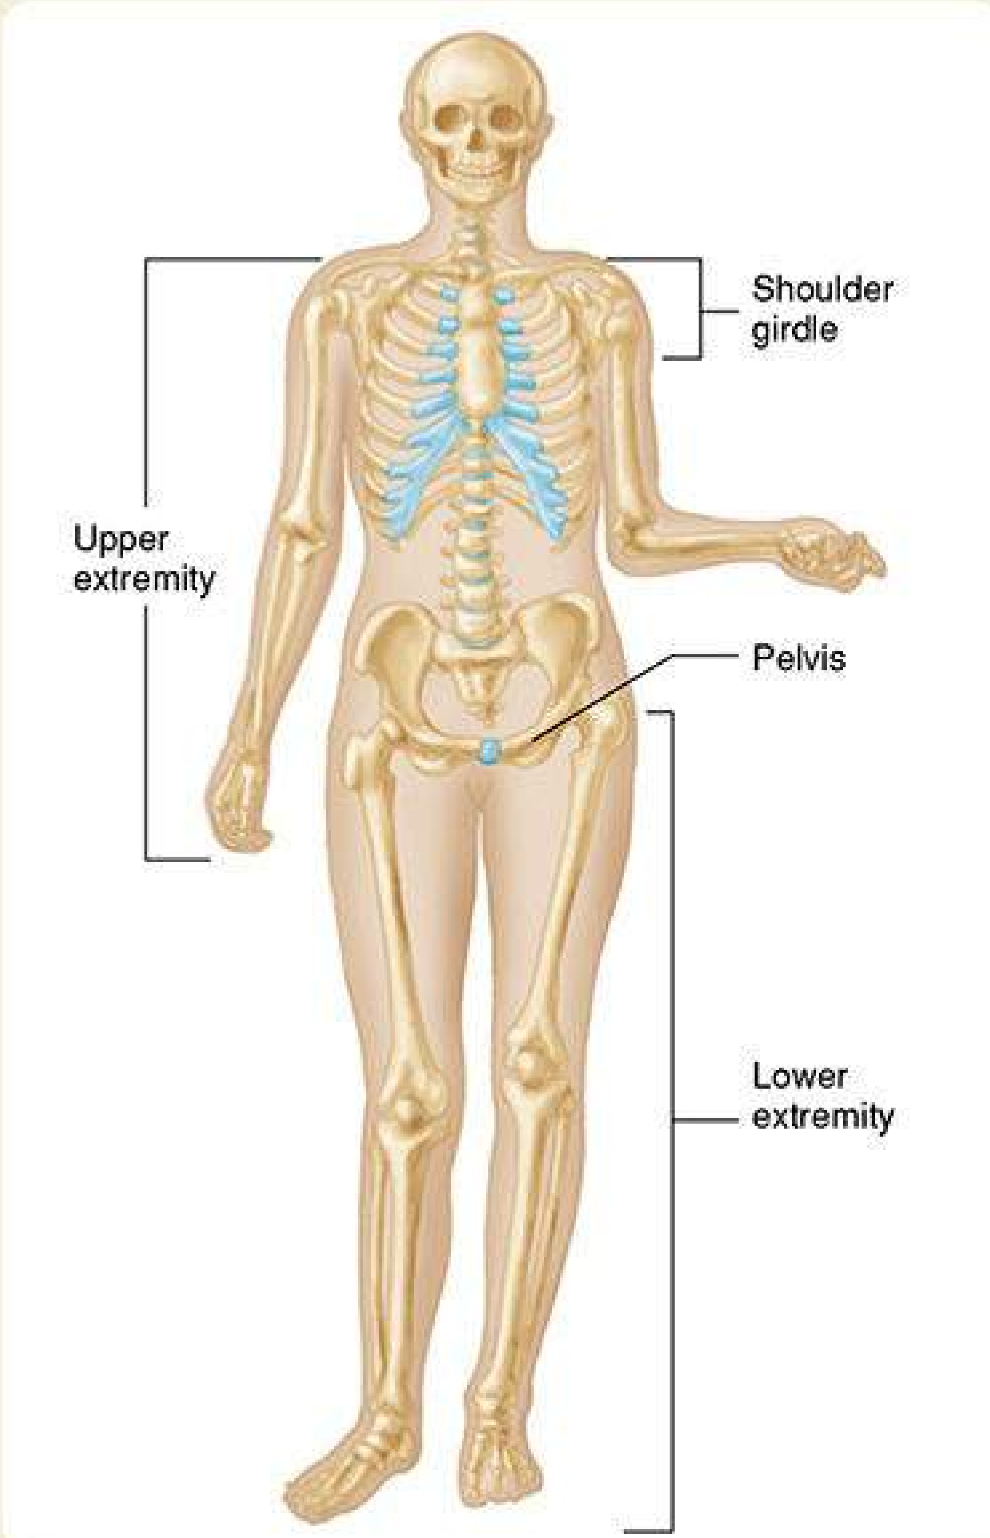

Figure 31-4 The human skeleton, consisting of approximately 206 bones, gives us our form and protects our vital organs.

The skull is a solid, vaultlike structure that surrounds and protects the brain. The thoracic cage protects the heart, lungs, and great vessels; the lower ribs protect the liver and spleen. The bony spinal canal encases and protects the spinal cord.

The pectoral girdle, also referred to as the shoulder girdle, consists of two scapulae and two clavicles **Figure 31-5**. The scapula (shoulder blade) is a flat, triangular bone held to the rib cage by powerful muscles that buffer it against injury. The clavicle (collarbone) is a slender, S-shaped bone attached by ligaments to the sternum on one end and to the acromion process on the other. The clavicle acts as a strut to keep the shoulder propped up; however, because it is slender and very exposed, this bone is vulnerable to injury.

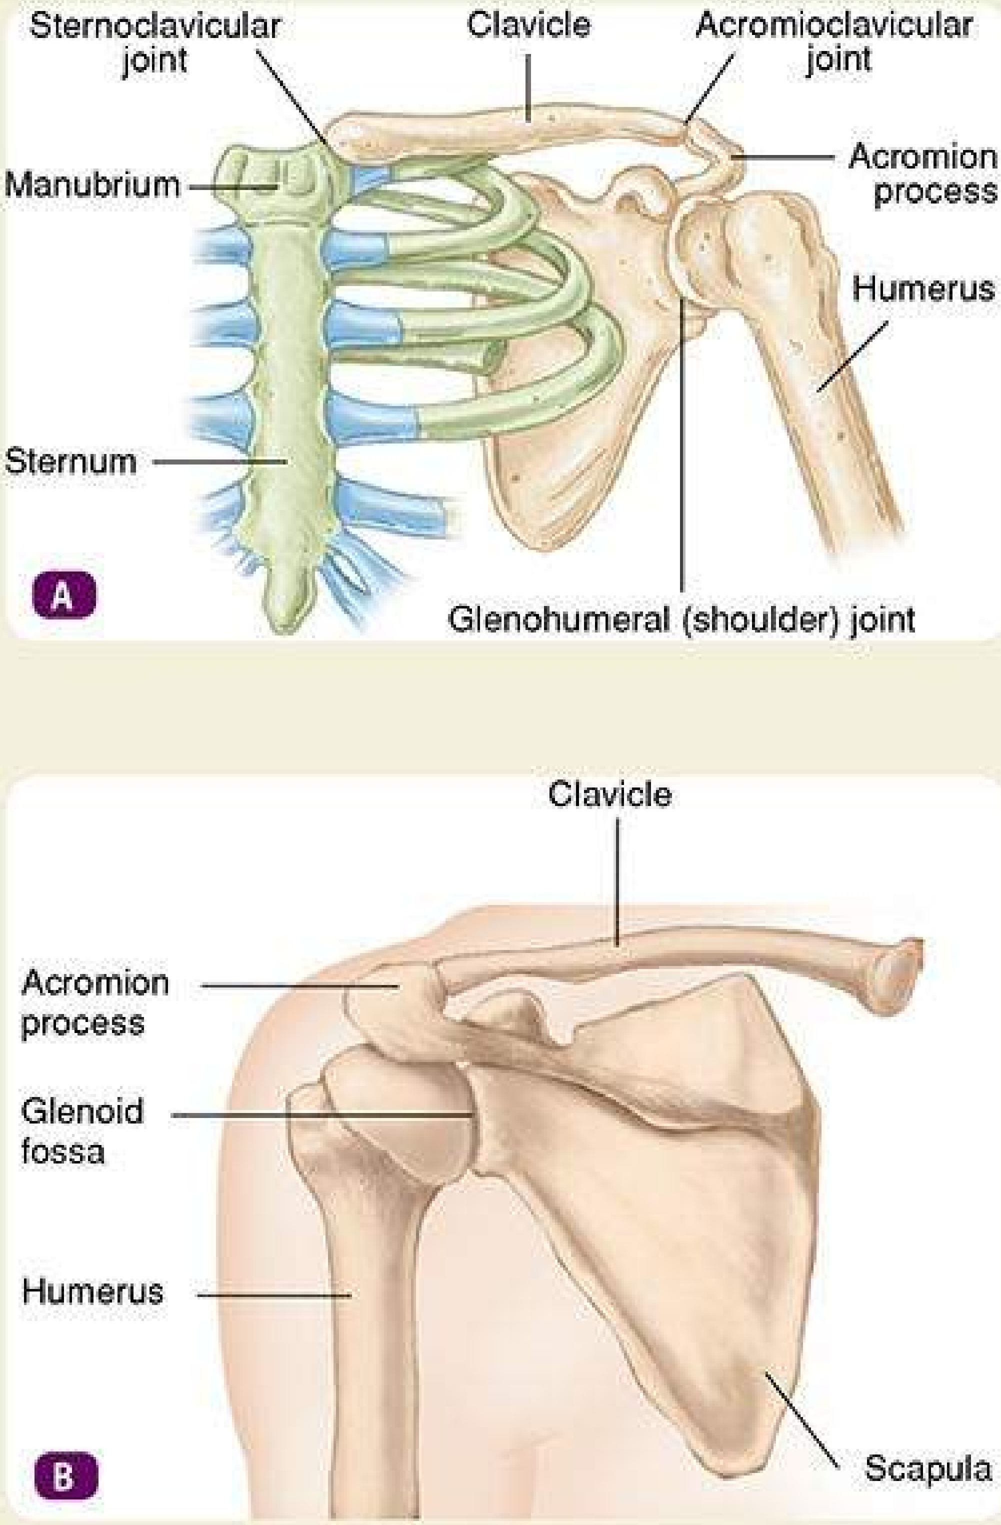

Figure 31-5 The pectoral girdle. **A.** Anterior view, including the clavicle. **B.** Posterior view, including the scapula.

A, B: © Jones & Bartlett Learning.

The upper extremity extends from the shoulder to the fingertips. The arm is composed of the upper arm (humerus), elbow, and forearm (radius and ulna) **Figure 31-6**. The upper extremity joins the shoulder girdle at the glenohumeral joint. The upper extremity begins with the humerus. The humerus connects with the bones of the forearm at the elbow—the radius and ulna—to form the hinged elbow joint.

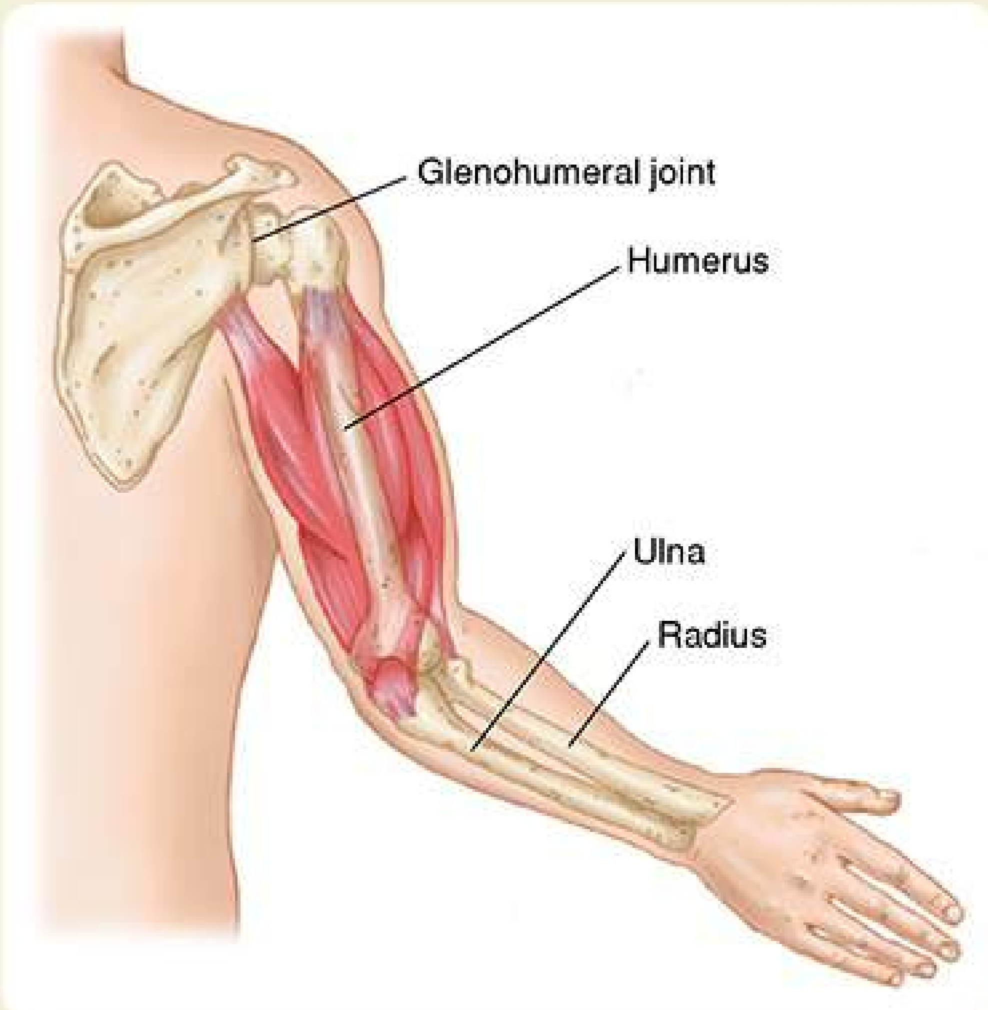

Figure 31-6 The anatomy of the arm.

The radius and ulna make up the forearm. The radius, the larger of the two forearm bones, lies on the thumb side of the forearm. The ulna is narrow and is on the little finger side of the forearm. Because the radius and the ulna are parallel, when one is broken, the other is often broken as well.

The hand contains three sets of bones: wrist bones (carpals), hand bones (metacarpals), and finger bones (phalanges) **Figure 31-7**. The carpals are vulnerable to fracture when a person falls on an outstretched hand. Phalanges are more apt to be injured by a crush injury, such as being slammed in a door.

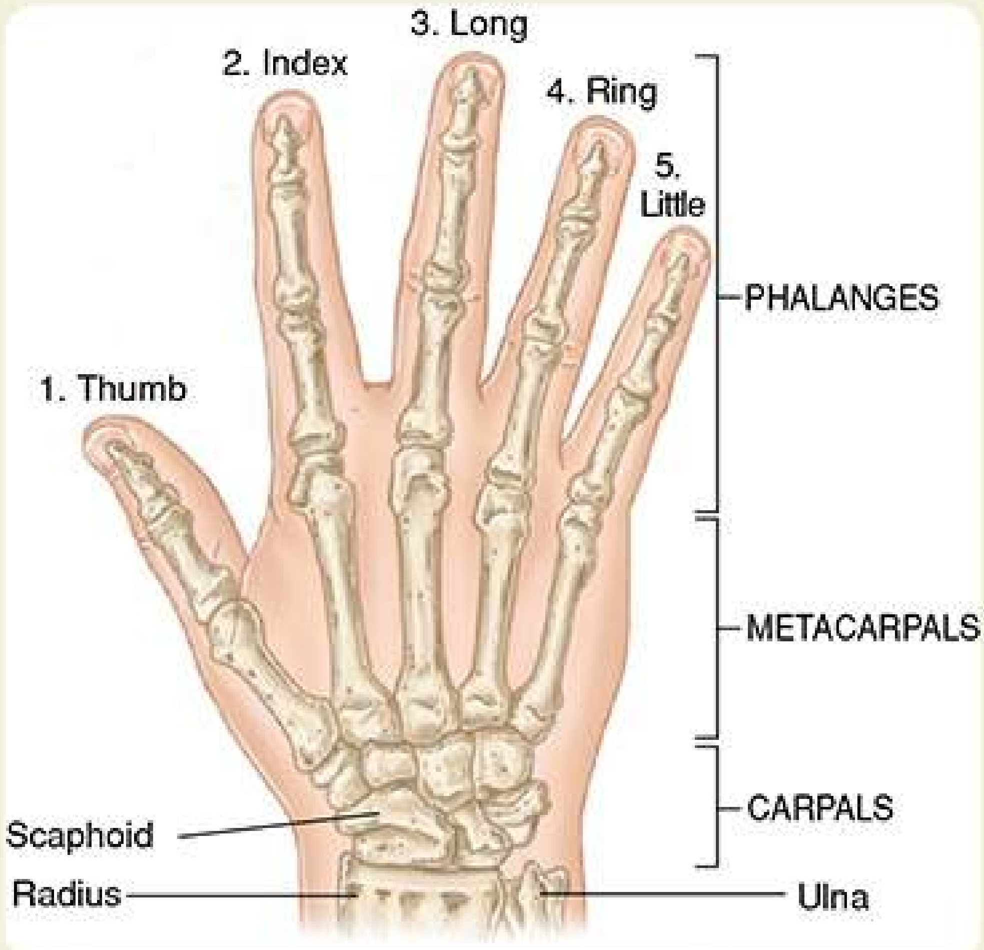

Figure 31-7 The anatomy of the wrist and hand.

The pelvis supports the body weight and protects the structures within the pelvis: the bladder, rectum, and female reproductive organs. The pelvic girdle is actually three separate bones—the ischium, ilium, and pubis—fused together to form the innominate (or hip) bone. The two iliac bones are joined posteriorly by tough ligaments to the sacrum at the sacroiliac joints; the two pubic bones are connected anteriorly by equally tough ligaments to one another at the pubic symphysis. These joints allow very little motion, so the pelvic ring is strong and stable.

The lower extremity consists of the bones of the thigh, leg, and foot **Figure 31-8**. The femur (thighbone) is a long, powerful bone that connects in the ball-and-socket joint of the pelvis and in the hinge joint of the knee. The femoral *head* is the ball-shaped part that fits into the acetabulum. It is connected to the shaft (diaphysis), or long tubular portion of the femur, by the femoral neck. The femoral neck is a common site for fractures, generally referred to as hip fractures, especially in the older population. The greater trochanter and lesser trochanter are the names given to lateral and medial bony protuberances below the femoral neck and just above the shaft of the femur.

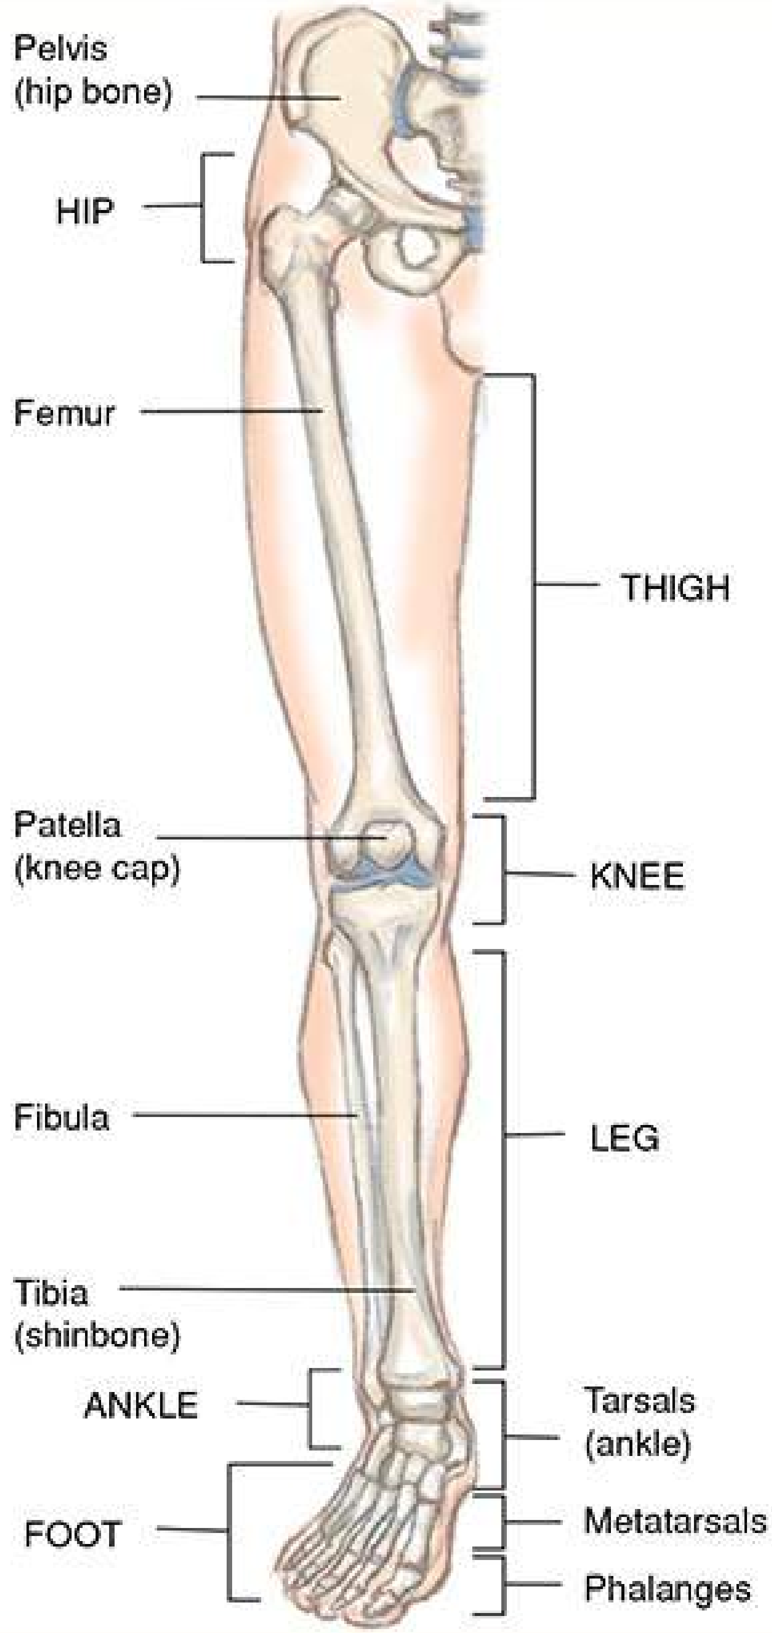

Figure 31-8 The bones of the thigh, leg, and foot.

The lower leg consists of two bones, the tibia and the fibula. The **tibia** (shinbone) is the larger of the two leg bones that are responsible for supporting the major weight-bearing surface of the knee and ankle. The tibia connects to the patella (knee cap) via the patellar tendon just below the knee joint and runs down the front of the lower leg. The tibia is vulnerable to direct blows and can be felt just beneath the skin. The much smaller **fibula** runs behind and beside the tibia. The fibula is an important anchor for ligaments surrounding the knee joint, and it forms the lateral side of the ankle joint.

The foot consists of three classes of bones: ankle bones (tarsals), foot bones (metatarsals), and toe bones (phalanges) **Figure 31-9**. The largest of the tarsal bones is the heel bone, or **calcaneus**, which is subject to injury with axial loading injuries, such as when a person jumps from a height and lands on the feet.

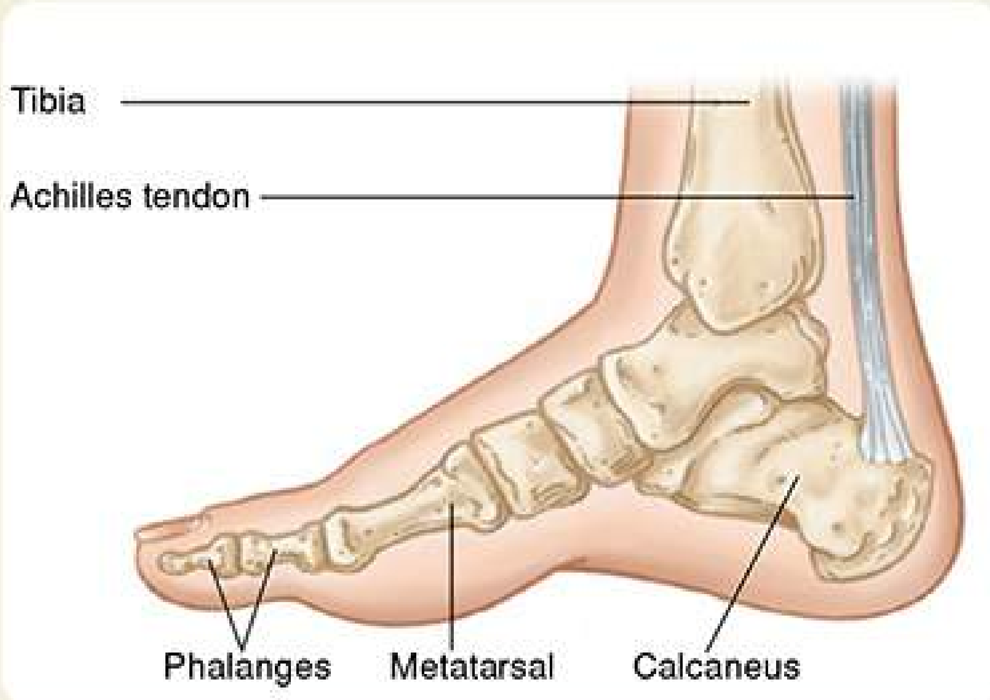

Figure 31-9 The bones of the foot and ankle.

The bones of the skeleton provide a framework to which the muscles and tendons are attached. Bone is a living tissue that contains nerves and receives oxygen and nutrients from the arterial system. Therefore, when a bone breaks, a patient typically experiences severe pain and bleeding. Bone marrow, located in the center of each bone, constantly produces red blood cells to provide oxygen and nourishment to the body and remove waste. White blood cells and platelets are also produced in the marrow cavity.

A **joint** is formed wherever two bones come into contact. The sternoclavicular joint, for example, is where the sternum and the clavicle come together. Joints are held together in a tough fibrous structure known as a capsule, which is supported and strengthened in certain key areas by bands of fibrous tissue called **ligaments**. In moving joints, the ends of the bones are covered with a thin layer of cartilage known as **articular cartilage**. This cartilage is a pearly white substance that allows the ends of the bones to glide easily. Joints are bathed and lubricated by synovial (joint) fluid.

Some joints, such as the shoulder, allow motion to occur in a circular manner. Other joints, such as the knee and elbow, act as hinges. Still other joints, including the sacroiliac joint in the lower back and the sternoclavicular joints, allow only a minimum amount of motion. Certain joints, such as the sutures in the skull (present until about 18 months of age), fuse together during growth to create a solid, immobile, bony structure **Figure 31-10**.

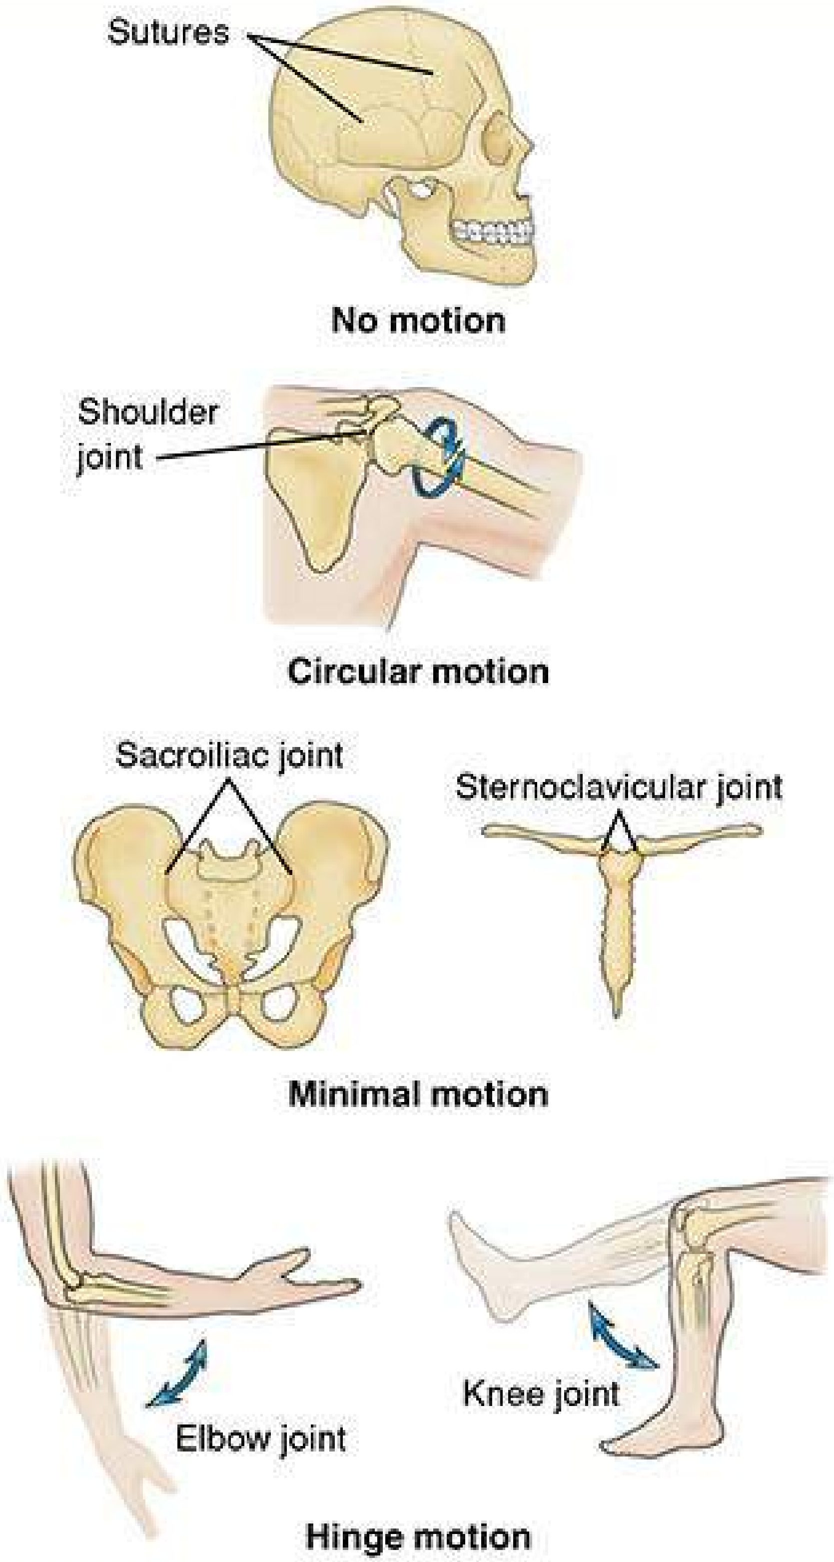

Figure 31-10 Joints have many functions. Some joints allow for motion to occur in a circular manner; others act as hinges. Still others allow only a minimum amount of motion or none at all.

Musculoskeletal Injuries

Injury to bones and joints is often associated with injury to the surrounding soft tissues, especially to the adjacent nerves and blood vessels. The entire area is known as the **zone of injury** Figure 31-11. Depending on the amount of kinetic energy the tissues absorb from forces acting on the body, the zone may extend to a distant point. For this reason, do not be distracted by a patient's obvious injury; you must first complete a primary assessment to check for life-threatening injuries. This is especially true in assessing damage from high-energy trauma, which is discussed next.

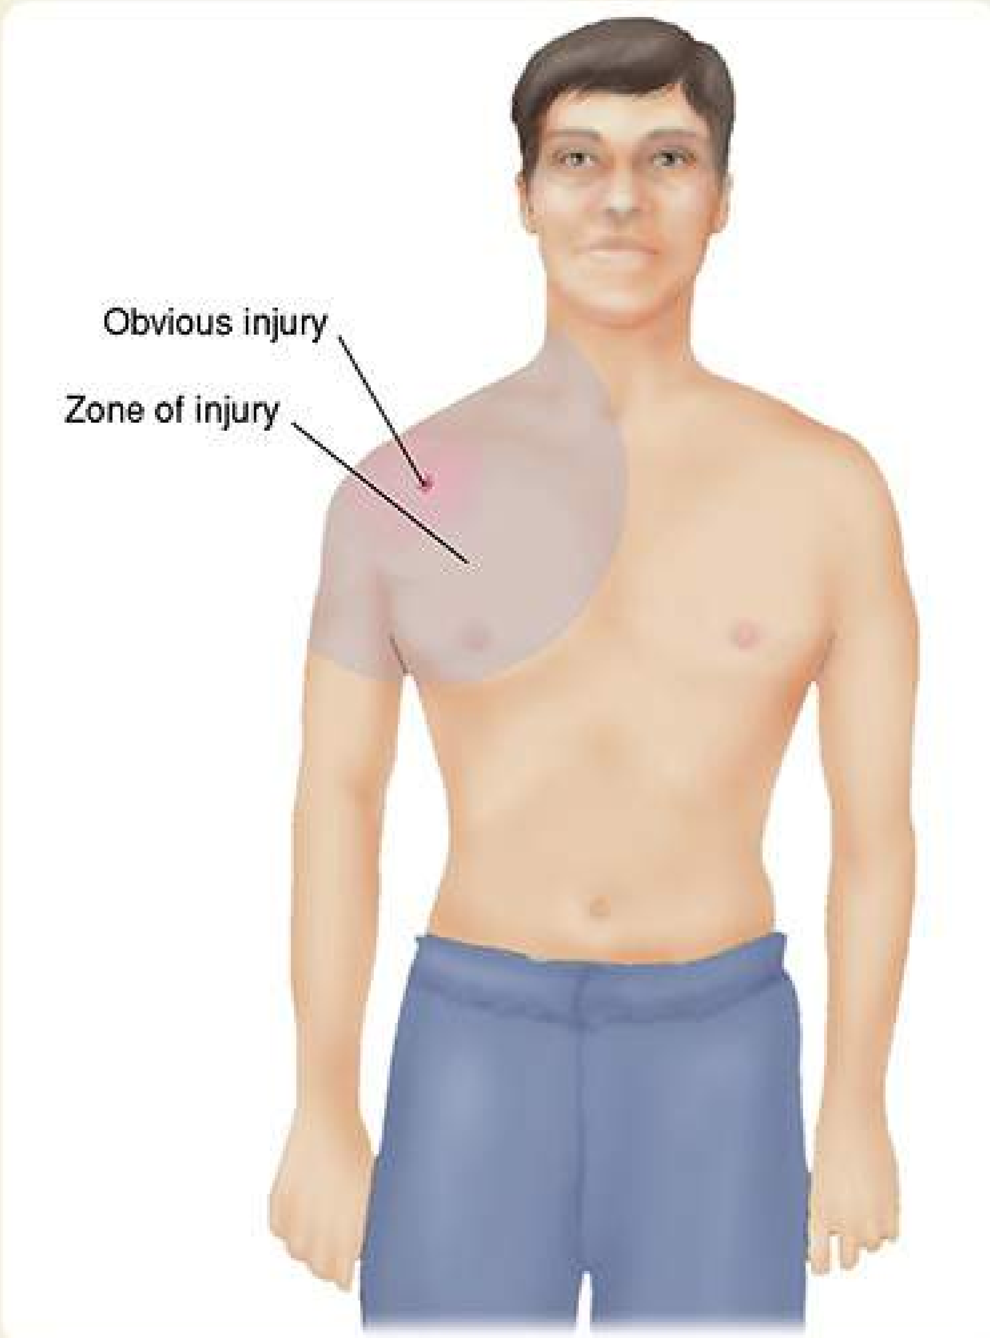

Figure 31-11 The zone of injury is the area of soft tissue, including the adjacent nerves and blood vessels, that surround the obvious injury of a bone or joint.

Mechanism of Injury

Significant force is generally required to cause fractures and dislocations. This force may be applied to the limb in any of the following ways **Figure 31-12**:

- Direct blows

- Indirect forces
- Twisting forces
- High-energy injuries

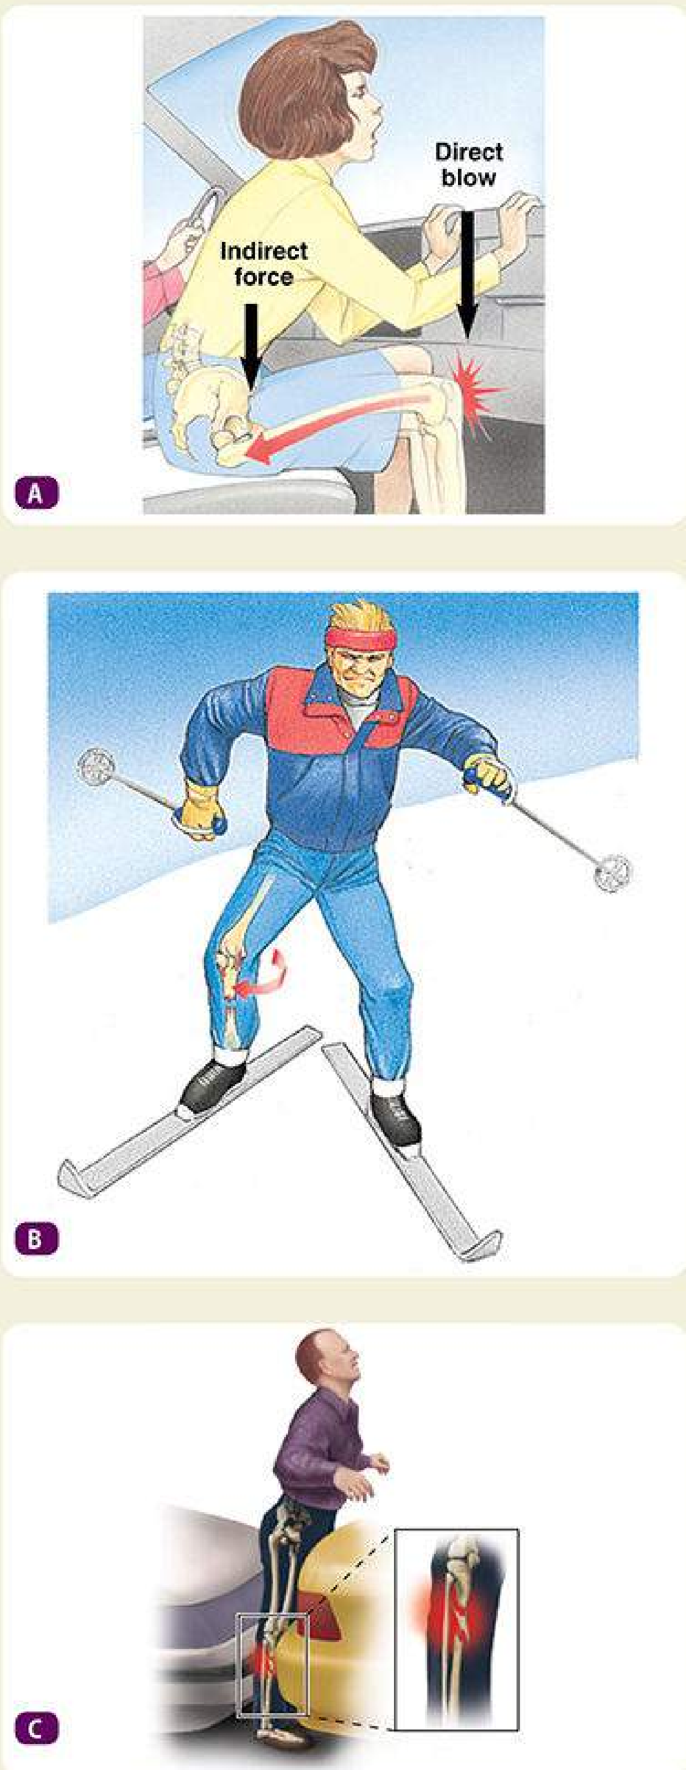

Figure 31-12 Significant force is required to cause fractures or dislocations. Among these are **(A)** direct blows and indirect forces, **(B)** twisting forces, and **(C)** high-energy crush injuries.

A direct blow fractures the bone at the point of impact. An example is the patella (knee cap) that fractures when it strikes the dashboard in a motor vehicle crash.

Indirect force may cause a fracture or dislocation at a distant point, as when a person falls and lands on an outstretched hand. The direct impact may cause a wrist fracture, but the indirect force can also cause dislocation of the elbow or a fracture of the forearm, humerus, or even clavicle. Therefore, when you are caring for patients who have fallen, immediately identify the point of contact and the mechanism of injury (MOI) so that you decrease the chance of overlooking any associated injuries.

Twisting forces are a common cause of musculoskeletal injury, especially to the anterior cruciate ligament (ACL) or the medial cruciate ligament (MCL) in the knee. Skiing injuries often happen because of twisting. A ski becomes caught, and the skier falls, applying a twisting force to the lower extremity.

High-energy injuries, such as those that result from motor vehicle crashes, falls from heights, gunshot wounds, and other extreme forces, produce severe damage to the skeleton, surrounding soft tissues, and vital internal organs. A patient may have multiple injuries to many body parts, including more than one fracture or dislocation in a single limb.

A significant MOI is not always necessary to fracture a bone. A slight force can easily fracture a bone that is weakened by a tumor, infection, or osteoporosis, a generalized bone disease that is common among postmenopausal women. In geriatric patients with osteoporosis, minor falls or simple twisting injuries can cause a fracture, most often of the wrist, spine, or hip. You should suspect the presence of a fracture in any older patient who reports pain and has sustained even a mild injury.

Fractures

A **fracture** is a broken bone. More precisely, it is a break in the continuity of the bone, often occurring as a result of an external force **Figure 31-13**. The break can occur anywhere on the surface of the bone and in many different types of patterns. Contrary to a common misconception, there is no difference between a broken bone and a fractured bone. A potential complication of fractures is compartment syndrome (discussed later in the chapter), which refers to elevated pressure within a fascial compartment.

Figure 31-13 A fracture can occur anywhere on the surface of a bone and may or may not break the skin.

Fractures are classified as either closed or open. In assessing and treating patients with possible fractures or dislocations, your first priority is to determine whether the overlying skin is damaged. If it is not, the patient has a **closed fracture**. However, making this determination is not always as easy as it sounds. With an **open fracture**, there is an external wound, caused either by the same blow that fractured the bone or by the broken bone ends lacerating the skin. The wound may vary in size from a very small puncture to a gaping tear that exposes bone and soft tissue. Regardless of the extent and severity of the damage to the skin, you should treat any injury that breaks the skin as a possible open fracture. Complications of open fractures include increased blood loss and a higher likelihood of infection. Be sure to wear gloves if there are any open wounds.

Fractures are also described by whether the bone is moved from its normal position. A **nondisplaced fracture** (also known as a hairline fracture) is a simple crack of the bone that may be difficult to distinguish from a sprain or simple contusion. Radiograph examinations are required for physicians to diagnose a nondisplaced fracture. A **displaced fracture** produces actual deformity, or distortion, of the limb by shortening, rotating, or angulating it. Often, the deformity is very obvious and can be associated with crepitus. However, in some cases the deformity is minimal. Be sure to look for differences between the injured limb and the opposite uninjured limb in any patient with a suspected fracture of an extremity **Figure 31-14**.

Figure 31-14 Always compare the injured limb with the uninjured limb when checking for deformity.

Medical personnel often use the following special terms to describe particular types of fractures Figure 31-15:

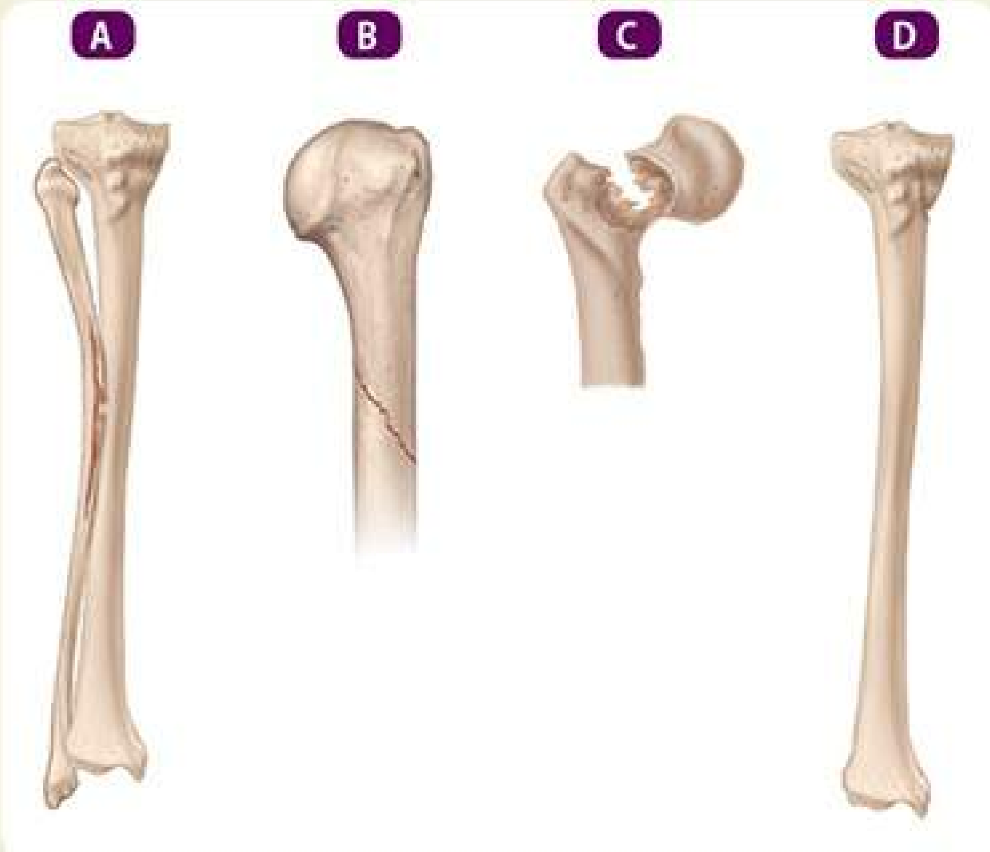

Figure 31-15 Special terms to describe fractures. **A.** Greenstick fracture. **B.** Oblique fracture. **C.** Pathologic fracture. **D.** Incomplete fracture.

A, B, C, D: © Jones & Bartlett Learning.

- **Comminuted.** A fracture in which the bone is broken into more than two fragments.
- **Epiphyseal.** A fracture that occurs in a growth section of a child's bone and may lead to growth abnormalities.
- **Greenstick.** An incomplete fracture that passes only partway through the shaft of a bone but may still cause substantial angulation; occurs in children.
- **Incomplete.** A fracture that does not run completely through the bone; a nondisplaced partial crack.
- **Oblique.** A fracture in which the bone is broken at an angle across the bone. This is usually the result of a sharp, angled blow to the bone.
- **Pathologic.** A fracture of weakened or diseased bone, seen in patients with osteoporosis, infection, or cancer; often produced by minimal force.
- **Spiral.** A fracture caused by a twisting or spinning force, causing a long, spiral-shaped break in the bone. This is sometimes the result of abuse in young children.
- **Transverse.** A fracture that occurs straight across the bone. This is usually the result of a direct blow injury.

Suspect a fracture if one or more of the following signs is present in any patient who has a history of injury and reports pain.

Deformity

The limb may appear to be shortened, rotated, or angulated at a point where there is no joint **Figure 31-16**. Always use the opposite, uninjured limb as a mirror image for comparison.

Figure 31-16 Obvious deformity, shortening, rotation, or angulation should increase your index of suspicion for a fracture.

Tenderness

Point tenderness on palpation in the zone of injury is the most reliable indicator of an underlying fracture, although it does not tell you the type of fracture **Figure 31-17**.

Guarding

An inability to use the extremity is the patient's way of immobilizing it to minimize pain. The muscles around the fracture contract in an attempt to prevent any movement of the broken bone. Guarding does not occur with all fractures; some patients may continue to use the injured part for a time. Occasionally, non-displaced fractures are less painful, and there is minimal soft-tissue damage.

Figure 31-17 Point tenderness is the sensitive spot at the site of injury that can be located by palpation along the bone with the tip of your finger.

Swelling

Rapid swelling usually indicates bleeding from a fracture and is typically followed by substantial pain. Often, if the swelling is severe, it may mask deformity of the limb **Figure 31-18**. Generalized swelling from fluid buildup may occur several hours after an injury.

Figure 31-18 Swelling that occurs in association with a fracture can often mask deformity of the limb.

Bruising

Fractures are almost always associated with **ecchymosis** (discoloration) of the surrounding soft tissues **Figure 31-19**. Bruising may be present after almost any injury and may take hours to develop; it is not specific to bone or joint injuries. The discoloration associated with acute injuries is usually redness, as you may have seen with someone who has been punched. Within hours or days, blue, purple, and black discoloration will appear, followed by yellow and green.

Figure 31-19 Fractures almost always have associated bruising into the surrounding soft tissue.

© fotokostic/iStockphoto.

Crepitus

A grating or grinding sensation known as **crepitus** can be felt and sometimes even heard when fractured bone ends rub together.

False Motion

Also called free movement, **false motion** is a point in the limb where there is no joint. It is a positive indication of a fracture.

Exposed Fragments

In open fractures, bone ends may protrude through the skin or be visible within the wound **Figure 31-20**. *Never* attempt to push the end of a protruding bone back into place. This will increase the risk for infection.

Figure 31-20 Bone ends may protrude through the skin or be visible within the wound of an open fracture.

Pain

Pain, along with tenderness, bruising, and bleeding, commonly occurs in association with fractures. Remember to use the OPQRST mnemonic to assess pain: Onset; Provocation/palliation; Quality; Region/Radiation; Severity; and Time (duration).

Locked Joint

A joint that is locked into position is difficult and painful to move. Keep in mind that crepitus and false motion appear only when a limb is moved or manipulated and are associated with injuries that are extremely painful. Do not manipulate the limb excessively in an effort to elicit these signs. This sign is more commonly the result of a soft-tissue injury within the joint (typically the knee or elbow), but the presence of a locked joint should alert you to the possibility of an underlying fracture.

Dislocations

A **dislocation** is a disruption of a joint in which the bone ends are no longer in contact. The supporting ligaments are often torn, usually completely, allowing the bone ends to separate from each other **Figure 31-21**. A fracture-dislocation is a combination injury at the joint in which the joint is dislocated and there is a fracture of the end of one or more of the bones.

A dislocated joint may sometimes spontaneously **reduce**, or return to its normal position before your assessment. In this situation, you will be able to confirm the dislocation only by taking a patient history. Often, however, the joint surfaces remain completely separated from one another. A dislocation that does not spontaneously reduce is a serious problem. The ends of the bone can be locked in a displaced position, making any attempt at motion of the joint very difficult and very painful. Commonly dislocated joints include the fingers, shoulder, elbow, hip, and knee.

Figure 31-21 A dislocation is a disruption of a joint in which the bone ends are no longer in contact. **A.** The clinical appearance of an elbow dislocation. **B.** Radiograph appearance of the same elbow.

A: © E.M. Singletary, M.D. Used with permission.; B: © Medical Body Scans/Science Source.

The signs and symptoms of a dislocated joint are similar to those of a fracture **Figure 31-22**:

- Marked deformity
- Swelling
- Pain that is aggravated by any attempt at movement
- Tenderness on palpation
- Virtually complete loss of normal joint motion (locked joint)
- Numbness or impaired circulation to the limb or digit

Sprains

A **sprain** occurs when a joint is twisted or stretched beyond its normal range of motion. As a result, the supporting capsule and ligaments are stretched or torn, resulting in injury to the ligaments, articular capsule, synovial membrane, and tendons crossing the joint. A sprain should be considered a partial dislocation.

Figure 31-22 Joint dislocations, such as this finger, are characterized by deformity, swelling, pain with any movement, tenderness, locking, and impaired circulation.

Sprains can range from mild to severe, depending on the amount of damage done to the supporting ligaments. The most severe sprains involve actual tearing of the ligament and may allow joint dislocation. Mild sprains are caused by ligament stretching rather than tearing. A sprain can occur in any joint, but sprains most often occur in the knee, shoulder, and ankle. Most sprains occur after a person misjudges a step or landing. Evasive moves, like those done during a sporting event, commonly cause sprains in athletes. Some patients might report hearing a “snap” when the injury occurred.

After the injury, the joint alignment generally returns to a fairly normal position, so the joint is not significantly displaced. In contrast with fractures and dislocations, sprains usually do not involve deformity, and joint mobility is usually limited by pain, not by joint incongruity. The following signs and symptoms often indicate that the patient may have a sprain **Figure 31-23**:

- The patient is unwilling to use the limb (guarding).

- Swelling and ecchymosis are present at the injured joint as a result of torn blood vessels.
- Pain prevents the patient from moving or using the limb normally.
- Instability of the joint is indicated by increased motion, especially at the knee; however, this may be masked by severe swelling and guarding.

Figure 31-23 Sprains most often occur in the knee or ankle and are characterized by swelling, bruising, point tenderness, pain, and joint instability.

A fracture can look like a sprain, and vice versa. You will frequently not be able to distinguish a nondisplaced fracture from a sprain. Therefore, it is important to document the MOI, because certain sprains and fractures occur more consistently with certain mechanisms. Your approach should always be to determine the MOI. The basic principles of prehospital management for sprains, dislocations, and fractures are essentially the same and are discussed later in the chapter.

▶ Strain

A **strain** (pulled muscle) is a stretching or tearing of the muscle and/or tendon, causing pain, swelling, and bruising of the soft tissues in the area. It occurs because of an abnormal contraction or from excessive stretching. Strains may range from minute separation to complete rupture. Unlike a sprain, no ligament or joint damage typically occurs.

Often no deformity is present and only minor swelling is noted at the site of the injury. Some patients may report a “snap” when a muscle tears. Some may report increased sharp pain with passive movement of the injured extremity. Patients may report severe weakness of the muscle. Most patients also have extreme point tenderness. The general treatment of strains is similar to the prehospital management for sprains, dislocations, and fractures.

▶ Amputations

An **amputation** is an injury in which an extremity is completely severed from the body. This injury can damage every aspect of the musculoskeletal system—from bone to ligament to muscle. Amputations can occur as a result of trauma or a surgical intervention.

▶ Complications

Orthopaedic injuries can lead to numerous complications—not just those involving the skeletal system, but also systemic changes or illness. It is essential that you do not focus all of your attention on the skeletal injury. Keep in mind that there is a patient attached to the injured extremity! For example, pregnant women who sustain pelvic fractures tend to have higher mortality rates. Therefore, it is imperative to treat not only the fracture, but also the other needs of the woman and fetus.

The likelihood of a complication is often related to the strength of the force that caused the injury, the injury's location, and the patient's overall health. Any injury to a bony structure is likely to be accompanied by bleeding. In general, the greater the force that caused the injury, the greater the hemorrhage will be. Following a fracture, the sharp ends of the bone may damage muscles, blood vessels, arteries, and nerves, or the ends may penetrate the skin and produce an open fracture. A significant loss of tissue may occur at the fracture site if the muscle is severely damaged or if the penetration of the bone into the skin causes a large deformity.

To prevent contamination following an open fracture, brush away any obvious debris on the skin surrounding an open fracture before applying a dressing. Do not enter or probe the open fracture site in an attempt to retrieve debris because this may lead to further contamination.

Long-term disability is one of the most devastating consequences of an orthopaedic injury. In many cases, a severely injured limb can be repaired and made to look almost normal. Unfortunately, many patients cannot return to work for long periods because of the extensive rehabilitation required and because of chronic pain. As an EMT, you have a critical role in mitigating the risk of long-term disability. You can help reduce the risk or duration of long-term disability by preventing further injury, reducing the risk of wound infection, minimizing pain by the use of cold and analgesia, and transporting patients with orthopaedic injuries to an appropriate medical facility.

Assessing the Severity of Injury

You must become skilled at quickly and accurately assessing the severity of an injury. The Golden Period (the time from injury to definitive care) is critical not only for life, but also for preserving limb viability. In an extremity with anything less than complete circulation, prolonged hypoperfusion can cause significant damage. For this reason, any suspected open fracture or vascular injury is considered a critical emergency. In a patient who has multisystem trauma, any additional bleeding can increase problems with underlying injuries or overall perfusion.

Remember that most injuries are not critical; you can identify critical injuries by using the musculoskeletal injury grading system shown in Table 31-1 as a guideline.

YOU are the Provider — PART 2

When you arrive at the scene, you find the patient, a 21-year-old woman, sitting on the ground with an ice pack over her left tibia. She is conscious and alert and tells you that another player fell against her leg.

Recording Time: 0 Minutes	
Appearance	Anxious; in obvious pain
Level of consciousness	Conscious and alert
Airway	Open; clear of secretions and foreign bodies
Breathing	Increased rate; adequate depth
Circulation	Radial pulses, increased rate; strong and regular

The patient denies having any other injuries and tells you that she heard a "snap" when the other player fell against her leg. She is in severe pain.

3. What initial treatment should you provide to this patient?
4. What are some indicators of a fractured bone?

Table 31-1 Musculoskeletal Injury Grading System

Minor Injuries

- Minor sprains
- Fractures or dislocations of digits

Moderate Injuries

- Open fractures of digits
- Nondisplaced long bone fractures
- Nondisplaced pelvic fractures
- Major sprains of a major joint

Serious Injuries

- Displaced long bone fractures
- Multiple hand and foot fractures
- Open long bone fractures
- Displaced pelvic fractures
- Dislocations of major joints
- Multiple digit amputations
- Laceration of major nerves or blood vessels

Severe, Life-Threatening Injuries (Survival is Probable)

- Multiple closed fractures
- Limb amputations
- Fractures of both long bones of the legs (bilateral femur fractures)

Critical Injuries (Survival is Uncertain)

- Multiple open fractures of the limbs
- Suspected pelvic fractures with hemodynamic instability

Patient Assessment

As an EMT, your assessments, attempts to splint, and efforts to stabilize the patient's condition are very important. However, always look at the big picture, evaluating the overall complexity of the situation to determine and treat any life threats. For example, overlooking an obstructed airway to splint a lower leg fracture could be deadly for the patient. Always carefully assess the MOI to try to determine the amount of kinetic energy that an injured limb has absorbed, and maintain a high index of suspicion for associated injuries.

It is not important to distinguish among fractures, dislocations, sprains, and contusions. In most cases, your assessment will be reported as an "extremity injury." However, you must be able to distinguish mild injuries from severe injuries because some severe injuries may compromise neurovascular function, which could threaten long-term function.

Scene Size-up Information

Information from dispatch may indicate the MOI, the number of patients involved, and any first aid procedures used prior to your arrival. This will be useful information for you to think about as you travel to the scene. Remember, the information given by the dispatcher is only as accurate as the patient's or bystander's report. In addition, the situation may change prior to your arrival at the incident. Dispatch information can still be used to help you consider whether spinal immobilization will be needed, the equipment you may need, and whether hazards might be present.

As you arrive at the scene, try to identify the forces associated with the MOI. Could they have produced injuries other than the musculoskeletal injuries reported by dispatch? Consider the possibility of hidden bleeding; internal injuries that you cannot see and closed fractures of the femur are examples. Standard precautions may be as simple as gloves. With a severe MOI or other risk factors, a mask and gown may be necessary. Eye protection may also be indicated. Evaluate the need for law enforcement support, advanced life support, or additional ambulances, and request them early based on your initial scene assessment.

When you assess a patient who has experienced a significant MOI, look for indicators of the MOI and be alert for both primary and secondary injuries. Primary injuries occur as a result of the MOI, whereas secondary injuries are the result of what happens after the initial injury. For example, being hit by a motor vehicle will often result in a primary pelvic injury and often a secondary head injury when the patient rolls onto the hood of the car. As you put together information from dispatch and your observations of the scene, consider what injuries the MOI would lead you to expect. For example, when you approach a rear-end motor vehicle crash, you should suspect head, neck, and chest injuries.

Primary Assessment

The primary assessment should focus on identifying and managing life threats. Treating the patient according to his or her level of consciousness and ABCs is always the priority. Threats to airway, breathing, and circulation are considered life threatening and must be treated immediately to prevent mortality. Significant bleeding, internal or external, is an immediate life threat. If the patient has obvious life-threatening external hemorrhage, it should be addressed first (even before airway and breathing), and then begin treating the patient for shock as quickly as possible. For example, if you are unable to control arterial bleeding from extremities by using direct pressure, apply a **tourniquet** (if possible). Arterial bleeding from a compound fracture should be treated prior to giving oxygen.

When evaluating the patient's level of consciousness and orientation, check for responsiveness using the AVPU scale, and assess mental status by asking the patient about his or her chief complaint. If the patient is alert, this should help direct you to any apparent life threats. An unresponsive patient may have an underlying life-threatening condition. You should administer high-flow oxygen via a nonrebreathing mask (or a bag-valve mask (BVM), if indicated) to all patients whose level of consciousness is less than alert and oriented, and provide rapid transport to the emergency department (ED).

Perform a primary assessment of the patient and ask about the MOI. Was it a direct blow, indirect force, twisting force, or high-energy injury? In many situations, the musculoskeletal complaints will be simple and usually not life threatening; however, some situations, such as those with a significant MOI, will include multiple problems that include musculoskeletal injuries. The initial interaction with your patient will provide you with a starting point and help you to distinguish the simple from the complex injuries. If there was significant trauma and multiple body systems were affected, the musculoskeletal injuries may be a lower priority. Scene time should not be wasted on prolonged musculoskeletal assessment or splinting fractures that are otherwise not life threatening. The expression "splinting to death" is used to describe such a situation; you are so involved in splinting fractures that the patient dies from other injuries.

Words of Wisdom

Medical emergences can result in falls and fractures. For example, a cardiac event or stroke can cause a fall and fractured hip in an older person.

Fractures and sprains usually do not create airway and breathing problems. Other problems, such as injuries to the head, intoxication, or other related illnesses and injuries, may cause inadequate breathing. Evaluating the chief complaint and MOI will help you to identify whether the patient has an open airway and whether breathing is present and adequate. In a conscious patient, this is as simple as noting whether the patient can speak normally. In an unconscious patient, it is as simple as opening the airway using the appropriate technique to check for breathing. Remember, very little else matters if the patient's airway and breathing are inadequate.

Words of Wisdom

If a spinal injury is suspected after evaluating the MOI and signs and symptoms, take the appropriate precautions and prepare for immobilization per local protocols.

Your circulatory assessment should focus on determining whether the patient has a pulse, has adequate perfusion, or is bleeding. If your patient is conscious, he or she will have a pulse. If the patient is unconscious, make sure there is a pulse by palpating the carotid artery. Hypoperfusion (shock) and bleeding problems will most likely be your primary concern. If the skin is pale, cool, or clammy and capillary refill time is slow, treat your patient for shock immediately. Maintain a normal body temperature, because trauma patients can rapidly become hypothermic even in warm environments. If musculoskeletal injuries in the extremities are suspected, they must be at least initially stabilized, if not splinted, prior to moving. Eliminating this cause of shock may need to be done later in your assessment.

If the patient has an airway or breathing problem, or significant bleeding, provide rapid transport to the hospital after quickly treating these life threats. A patient who has a significant MOI but whose condition appears otherwise stable should also be transported promptly to the closest appropriate hospital. Patients with bilateral fractures of the long bones (humerus, femur, or tibia) have been subjected to a high amount of kinetic energy, which should dramatically increase your index of suspicion for serious unseen injuries. When a decision for rapid transport is made, you can use a long backboard as a splinting device to splint the whole body rather than splinting each extremity individually. If you take time to splint the patient's arms and legs individually, you may delay the prompt surgical intervention that may be needed for other injuries when a significant MOI has occurred. Individual splints should be applied en route if the ABCs are stable and time permits.

Patients with a simple MOI, such as twisting of an ankle or dislocating a shoulder, may be further assessed and their condition stabilized on scene prior to transport if no other problems exist.

Handling Injured Extremities During Assessment and Transport

Recall that fractures can break through the skin and cause external bleeding. This may occur during the initial injury or during manipulation of the extremity while preparing for splinting or transport. Careful handling of the extremity minimizes this risk. If external bleeding is present, bandage the extremity quickly to control bleeding. The dressings that cover the wound and bone should be kept clean to reduce the potential for bone infection. The bandage should be secure enough to control bleeding without restricting circulation distal to the injury. Monitor bandage tightness by assessing the circulation, sensation, and movement distal to the bandage. Swelling from fractures and internal bleeding may cause bandages to become too tight. If bleeding cannot be controlled, quickly apply a tourniquet.

Also handle fractures carefully while preparing for transport. Careful handling is necessary to limit pain and prevent sharp bone ends from breaking through the skin or damaging nerves and blood vessels in the extremity.

History Taking

After the life threats have been managed during the primary assessment, investigate the chief complaint. Obtain a medical history and be alert for injury-specific signs and symptoms and for any pertinent negatives, such as no pain or loss of sensation.

Obtain a SAMPLE history for all trauma patients. How much and in what detail you explore this history depends on the seriousness of the patient's condition and how quickly you need to transport the patient to the hospital. For patients with simple fractures, dislocations, or sprains, it is easier to obtain a SAMPLE history. At the scene you may have access to family members and others who have information about the patient's history. Make an attempt to obtain this history without delaying time to definitive care.

OPQRST can be of limited use in cases of severe injury and is usually too lengthy when matters of airway, breathing, circulation, and rapid transport require immediate attention. However, OPQRST may be useful when the MOI is unclear, the patient's condition is stable, or details of the injury are uncertain. This more detailed questioning for simple trauma may help you and the hospital staff to better understand the specific injury.

Secondary Assessment

If significant trauma has likely affected multiple systems, start with a secondary assessment of the entire body to be sure that you have found all of the problems and injuries. Begin with the head and work systematically toward the feet, checking the head, chest, abdomen, extremities, and back. The goal is to identify hidden and potentially life-threatening injuries. This secondary assessment will also help you to prepare for packaging and rapid transport. Knowing if an arm or leg is broken will be important when log rolling and securing the patient onto a backboard.

Use the DCAP-BTLS approach to assess the musculoskeletal system. Identify any extremity deformities that likely represent significant musculoskeletal injury, and stabilize them appropriately. Contusions and abrasions may overlie more subtle injuries and should prompt you to carefully evaluate the stability and neurovascular status of the limb. The presence of puncture wounds or other signs of penetrating injury should alert you to the possibility of an open fracture. Associated burns must be identified and treated appropriately. Palpate for tenderness, which, like contusions or abrasions, may be the only significant sign of an underlying musculoskeletal injury.

When lacerations are present in an extremity, an open fracture must be considered, bleeding controlled, and dressings applied. Careful inspection for swelling with comparison with the opposite limb may also reveal otherwise occult musculoskeletal injury. You may find a hematoma in the zone of injury during the assessment.

If your assessment reveals no external signs of injury, ask the patient to move each limb carefully, stopping immediately if a movement causes pain. Skip this step in your evaluation if the patient reports neck or back pain; even slight motion could cause permanent damage to the spinal cord.

When nonsignificant trauma has occurred and you suspect that your patient has a simple strain, sprain, dislocation, or fracture, take the time to focus your secondary assessment on that particular injury. Look for DCAP-BTLS. Be sure to assess the entire zone of injury by removing clothing from the area and looking and palpating for injuries. In musculoskeletal injuries, this zone generally extends from the joint above (proximal) to the joint below (distal), front and back.

Remember to evaluate the circulation, motor function, and abnormal sensations distal to the injury. Many important blood vessels and nerves lie close to the bone, especially around the major joints. Therefore, any injury or deformity of the bone may be associated with vessel or nerve injury. For this reason, you must assess neurovascular function every 5 to 10 minutes during the assessment, depending on the patient's condition, until the patient is at the hospital. Always recheck the neurovascular function before and after you splint or otherwise manipulate the limb. Manipulation can cause a bone fragment to press against or impale a nerve or vessel. Failure to restore circulation in this situation can lead to death of the limb. Always give priority to patients with impaired circulation resulting from bone fragments.

Words of Wisdom

If the patient has two or more injured extremities, treat the patient as a significant trauma patient and provide rapid transport to the hospital. The likelihood of other more severe injuries is greater when two or more bones have been broken.

Because many of the steps require patient cooperation, you will not be able to assess sensory and motor functions in an unconscious patient, but you can evaluate the limb for deformity, swelling, ecchymosis, false motion, and crepitus.

Examination of the injured limb should include the 6 Ps of musculoskeletal assessment—pain, paralysis, paresthesia (numbness or tingling), pulselessness, pallor, and pressure. Assess neurovascular status as described in Chapter 9, *Patient Assessment*.

Words of Wisdom

Extremity injuries that impair circulation or nerve function in distal tissues are urgent conditions. Patients with these injuries need careful assessment, prompt transport, and frequent reassessment of distal functions. It is also crucial to report this information in your initial radio contact with the hospital to allow personnel to prepare for a condition in which prompt surgery may be necessary to save the limb.

Determine a baseline set of vital signs, including pulse rate, rhythm, and quality; respiratory rate, rhythm, and quality; blood pressure; skin condition; and pupil size and reaction to light. These need to be obtained as soon as possible. Your patient may appear to be tolerating the injury well until you reassess these vital signs and they indicate otherwise. Trending these vital signs helps you to understand whether your patient's condition is improving or worsening over time, particularly during long transports. Shock or hypoperfusion is common in musculoskeletal injuries; therefore, this baseline information is very important in assessing your patient's condition.

Reassessment

Repeat the primary assessment to ensure your interventions are working as they should. Perform a reassessment every 5 minutes for an unstable patient and every 15 minutes for a stable patient.

Because trauma patients often have multiple injuries, you must assess their overall condition, stabilize the ABCs, and control any serious bleeding before further treating the injured area. In a critically injured patient, secure the patient to a backboard to immobilize the spine, pelvis, and extremities and provide prompt transport to a trauma center. In this situation, a secondary assessment with extensive evaluation and splinting of limb injuries in the field is a waste of valuable time. Perform the primary assessment and transport, reassessing the patient en route to the ED.

If the patient has no life-threatening injuries, you may take extra time at the scene to stabilize the patient's overall condition and more completely evaluate the injury. If possible, gently and carefully remove the patient's clothing to look for open fractures or dislocations, severe deformity, swelling, and/or ecchymosis.

When you have finished assessing the extremity, apply a secure splint to stabilize the injury prior to transport. The joint above and below the site of injury should be included in the splint. To minimize the potential for complications, the splint should be well padded. A comfortable and secure splint will reduce pain, reduce shock, and minimize compromised circulation. A good rule is to check the patient's circulation, motor function, and sensation before and after splinting. Splint application will be discussed later in the chapter.

The main goal in providing care for musculoskeletal injuries is stabilization in the most comfortable position that allows for maintenance of good circulation distal to the injury. This should be done whether you are preparing the patient for rapid transport or you have as much time as you need to assess and treat the patient.

Your radio report to the hospital should include a description of the problems found during your assessment. In particular, you should report problems with the patient's ABCs, open fractures, and compromised circulation that occurred before or after splinting. Many times the hospital staff can arrange for specialists or consider antibiotics early if they are aware of problems. How much information you include in your radio report will depend on your local protocols. Additional details, such as the mandated reporting of situations involving elder or child abuse, can be given during your verbal report at the hospital when you transfer care to the nursing staff or physician.

It is important to document the presence or absence of circulation, motor function, and sensation distal to the injury before you move an extremity, after manipulation or splinting of the injury, and on arrival at the hospital. Hospital staff may refer to your notes to clarify confusing situations or communication problems. Your careful documentation becomes part of the patient's permanent medical record and may protect you from legal action that the patient may pursue later. Do not rely on your memory for details from situations; your memory is unreliable. Always document your findings.

Emergency Medical Care

Your first steps in providing care for any patient are the primary assessment and stabilizing the patient's ABCs. If needed, perform a secondary assessment of either the entire body or the specific area of injury. Always follow standard precautions and be alert for signs and symptoms of internal bleeding. Internal bleeding should be suspected whenever the MOI suggests that severe forces have affected the body.

Follow the steps in **Skill Drill 31-1** when caring for patients with musculoskeletal injuries:

Skill Drill 31-1 Caring for Musculoskeletal Injuries

Step 1

Cover open wounds with a dry, sterile dressing, and apply pressure to control bleeding. Assess distal pulse and motor and sensory function. If bleeding cannot be controlled, quickly apply a tourniquet.

Step 2

Apply a splint, and elevate the extremity about 6 in. (15 cm) (slightly above the level of the heart). Assess distal pulse and motor and sensory function.

Step 3

Apply cold packs if there is swelling, but do not place them directly on the skin.

Step 4

Position the patient for transport, and secure the injured area.

1. Remove any jewelry. Completely cover open wounds with a dry, sterile dressing, and apply direct pressure to control bleeding. Assess distal pulse and motor and sensory function. If bleeding cannot be controlled, quickly apply a tourniquet. Once you have applied a sterile dressing, treat an open fracture in the same way as a closed fracture **Step 1**.
2. Apply the appropriate splint, and elevate the extremity. It is essential to splint the joint above and below the injury to ensure adequate stabilization. Patients with lower extremity injuries should lie supine with the limb elevated about 6 inches (15 cm) to minimize swelling. For any patient, be sure to position the injured limb slightly above the level of the heart. Never allow the injured limb to flop about or dangle from the edge of the backboard. Always assess pulse and motor and sensory functions before and after the application of splints. Assess the pulse by palpation, evaluate motor function by asking the patient to open his or her hand or flex his or her foot, and assess sensation and capillary

refill on the flesh near the tip of the index finger. Finally, assess the skin color and condition, and evaluate sensory function by touch **Step 2**.

3. If swelling is present, apply cold packs to the area; however, avoid placing cold packs directly on the skin or other exposed tissues **Step 3**.
4. Prepare the patient for transport. A patient with an isolated upper extremity injury will most likely be more comfortable in a semiseated position rather than in a supine position; however, assuming there is no risk of spinal injury, either position is acceptable. Ensure that the extremity is elevated above the level of the heart and secured so that it does not dangle from the edge of the backboard or stretcher **Step 4**.
5. Transport your patient to the most appropriate facility, and consider the use of advanced life support backup for pain management.
6. Inform hospital personnel about all wounds that have been dressed and splinted and any associated injuries treated by the EMS unit.

Splinting

A **splint** is a flexible or rigid device that is used to protect and maintain the position of an injured extremity **Figure 31-24**. Unless the patient's life is in immediate danger, you should splint all fractures, dislocations, and sprains before moving the patient. By preventing movement of fracture fragments, bone ends, a dislocated joint, or damaged soft tissues, splinting reduces pain and makes it easier to transfer and transport the patient. In addition, splinting will help to prevent the following:

Figure 31-24 Splinting reduces pain and prevents additional damage to the injured extremity.

- Further damage to muscles, the spinal cord, peripheral nerves, and blood vessels from broken bone ends
- Laceration of the skin by broken bone ends. One of the primary indications for splinting is to prevent a closed fracture from becoming an open fracture (conversion).
- Restriction of distal blood flow resulting from pressure of the bone ends on blood vessels
- Excessive bleeding of the tissues at the injury site caused by broken bone ends
- Increased pain from movement of bone ends

- Paralysis of extremities resulting from a damaged spine

A splint is simply a device to prevent motion of the injured part. It can be made from any material on occasions when you need to improvise. However, you should have an adequate supply of standard commercial splints on hand.

When no splinting materials are available, the arm can be bound to the chest wall, and an injured leg can be bound to the uninjured leg to provide temporary stability. The three basic types of splints are rigid, formable, and traction splints.

General Principles of Splinting

The following principles of splinting apply to most situations:

1. Remove clothing from the area of any suspected fracture or dislocation so that you can inspect the extremity for DCAP-BTLS.

Words of Wisdom

Straightening or splinting an injured limb can compromise distal functions, as can the initial injury. Record the status of distal circulation and nervous function (neurovascular status) before and after straightening or splinting. At a minimum, your written record should describe these functions before splinting and confirm that they were normal immediately after splinting and on hospital arrival. For all but the shortest transports, also indicate the results of reassessments while en route.

2. Note and record the patient's neurovascular status distal to the site of the injury, including pulse, sensation, and movement. Continue to monitor the neurovascular status until the patient reaches the hospital.
3. Cover open wounds with a dry, sterile dressing before splinting. Be sure to follow standard precautions. Do not intentionally replace protruding bones. Notify the receiving hospital of all open wounds.
4. Do not move the patient before splinting an extremity unless there is an immediate danger to the patient or you.
5. In a suspected fracture of the shaft of any bone, be sure to stabilize the joints above and below the fracture.
6. With injuries in and around the joint, be sure to stabilize the bones above and below the injured joint.
7. Pad all rigid splints to prevent local pressure and patient discomfort.
8. While applying the splint, maintain manual stabilization to minimize movement of the limb and to support the injury site.
9. If fracture of a long bone shaft has resulted in severe deformity, use constant, gentle manual traction to align the limb so that it can be splinted. This is especially important if the distal part of the extremity is cyanotic or pulseless.
10. If you encounter resistance to limb alignment, splint the limb in its deformed position.
11. Immobilize all suspected spinal injuries in a neutral in-line position on a backboard.
12. If the patient has signs of shock (hypoperfusion), align the limb in the normal anatomic position, and provide transport (total body immobilization).
13. When in doubt, splint.

Rigid Splints

Rigid (nonformable) splints are made from firm material and are applied to the sides, front, and/or back of an injured extremity to prevent motion at the injury site. Common examples of rigid splints include padded board splints, molded plastic and metal splints, padded wire ladder splints, and folded cardboard splints. As always, be sure to follow standard precautions. It takes two EMTs to apply a rigid splint. Follow the steps in Skill Drill 31-2:

YOU are the Provider — PART 3

A nurse present at the scene assists by stabilizing the leg above the ankle and below the knee while you expose the injury. The patient has an obvious deformity in the midshaft area of her tibia/fibula; however, there are no open wounds. As you further assess the injury, your partner obtains the patient's vital signs.

Recording Time: 5 Minutes	
Respirations	22 breaths/min; adequate depth
Pulse	112 beats/min; strong and regular

Skin	Pink, warm, and moist
Blood pressure	130/78 mm Hg
Oxygen saturation (Spo_2)	98% (on ambient air)

5. How should you proceed with your assessment of this patient's injury?
6. How should you treat an injured extremity in which distal perfusion is absent?

1. Gently support the limb at the site of injury as your partner prepares and begins to position the equipment. Apply steady, in-line traction if necessary. Maintain this support until the splint is completely applied **Step 1**. Assess distal pulse and motor and sensory function.
2. Place the rigid splint under or alongside the limb.
3. Place padding between the limb and the splint to make sure there is even pressure and even contact. Look for bony prominences, and pad them **Step 2**.
4. Apply bindings to hold the splint securely to the limb **Step 3**.
5. Check and record the distal nervous and circulatory (neurovascular) function **Step 4**.

There are two situations in which you must splint the limb in the position of deformity—when the deformity is severe, as is the case with many dislocations, and when you encounter resistance or extreme pain when applying gentle traction to the fracture of a shaft of a long bone. In either situation, apply padded board splints to each side of the limb and secure them with soft roller bandages **Figure 31-25**. Most dislocations should be splinted as found, but follow local protocols. Attempts to realign or reduce dislocations may lead to more damage.

Skill Drill 31-2 Applying a Rigid Splint

Step 1

Provide gentle support and in-line traction for the limb. Assess distal pulse and motor and sensory function.

Step 2

Place the splint alongside or under the limb. Pad between the limb and the splint as needed to ensure even pressure and contact.

Step 3

Secure the splint to the limb with bindings.

Step 4

Assess and record distal neurovascular function.

Formable Splints

The most commonly used formable (soft) splint is the precontoured, inflatable, clear plastic air splint. These splints are available in a variety of sizes and shapes, with or without a zipper that runs the length of the splint. Always inflate the splint after applying it. The air splint is comfortable, provides uniform contact, and has the added advantage of applying firm pressure to a bleeding wound. Air splints are used to stabilize injuries below the elbow or below the knee.

Figure 31-25 If you encounter resistance or extreme pain when applying traction to a long bone, apply padded board splints to each side of the limb, and secure them with soft roller bandages, stabilizing the limb in its deformed position.

Air splints have some drawbacks, particularly in cold weather areas. The zipper can stick, clog with dirt, or freeze. Significant weather changes affect the air pressure in the splint, which decreases as the environment grows colder and increases as the environment grows warmer. The same thing happens when there are changes in altitude, which can be a problem with helicopter transport of patients. Therefore, you should carefully monitor the splint and let air out if the splint becomes overinflated.

The method of applying an air splint depends on whether it has a zipper. With either type, you must first cover open wounds with a dry, sterile dressing, making sure that you use standard precautions. For a splint that has a zipper, follow the steps in **Skill Drill 31-3**:

1. Assess distal pulse and motor and sensory function.
2. Hold the injured limb slightly off the ground, applying gentle traction and supporting the site of injury. Have your partner place the open, deflated splint around the limb **Step 1**.
3. Zip up the splint, and inflate it by pump or by mouth. When this is done, test the pressure in the splint. With proper inflation, you should be able to compress the walls of the splint together with a firm pinch between the thumb and index finger near the edge of the splint.

Skill Drill 31-3 Applying a Zippered Air Splint

Step 1

Assess distal pulse and motor and sensory function. Support the injured limb, and apply gentle traction as your partner applies the open, deflated splint.

Step 2

Zip up the splint, inflate it by pump or by mouth, and test the pressure. Check and record distal neurovascular function.

4. Check and record pulse and motor and sensory functions, and monitor them periodically until the patient reaches the hospital **Step 2**.

If you use an unzippered or partially zippered type of air splint, follow the steps in **Skill Drill 31-4**:

1. Assess distal pulse and motor and sensory function.
2. Your partner supports the patient’s injured limb until splinting is accomplished.
3. Place your arm through the splint. Extend your hand beyond the splint, and grasp the hand or foot of the injured limb **Step 1**.
4. Apply gentle traction to the hand or foot while sliding the splint onto the injured limb. The hand or foot of the injured limb should always be included in the splint **Step 2**.
5. Your partner inflates the splint by pump or by mouth **Step 3**.
6. Test the pressure in the splint. This is something that you must do with either type of air splint.
7. Check and record pulse and motor and sensory functions, and monitor them en route.

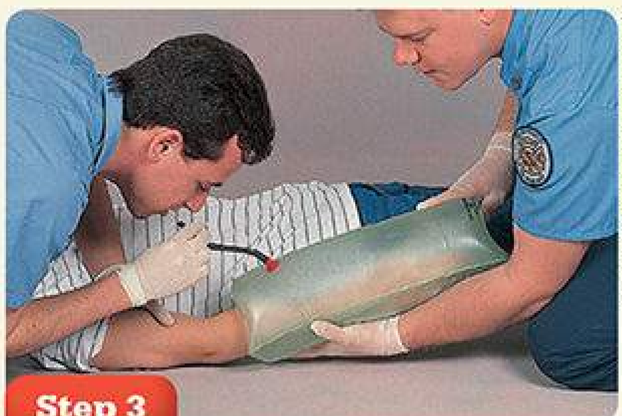
Skill Drill 31-4 Applying an Unzippered Air Splint

Step 1

Assess distal pulse and motor and sensory function. Your partner supports the injured limb. Place your arm through the splint to grasp the patient's hand or foot.

Step 2

Apply gentle traction while sliding the splint onto the injured limb.



Step 3

Your partner inflates the splint by pump or by mouth. Assess distal pulse and motor and sensory function.

Other formable splints include vacuum splints, pillow splints, structural aluminum malleable (SAM) splints, a sling and swathe, and pelvic binders for pelvic fractures. Just like an air splint, a vacuum splint can be easily shaped to fit around a deformed limb. Instead of pumping air in, however, you can use a hand pump to pull the air out through a valve. Follow the steps in **Skill Drill 31-5** to apply a vacuum splint:

1. Assess distal pulse and motor and sensory function.
2. Your partner supports and stabilizes the injured limb, applying traction if needed **Step 1**.
3. Gently place the injured limb onto the vacuum splint, and wrap the splint around the limb **Step 2**.
4. Draw the air out of the splint through the suction valve, and then seal the valve. Once the valve is sealed, the vacuum splint becomes rigid, conforming to the shape of the deformed limb and stabilizing it **Step 3**.
5. Check distal circulation and nervous functions, and monitor them en route.

Skill Drill 31-5 Applying a Vacuum Splint

Step 3

Draw the air out of the splint through the suction valve, and then seal the valve. Assess distal pulse and motor and sensory function.

Traction Splints

Application of in-line **traction** is the act of pulling on a body structure in the direction of its normal alignment. It is the most effective way to realign a fracture of the shaft of a long bone so that the limb can be splinted more effectively. Traction splints are used primarily to secure fractures of the shaft of the femur, which are characterized by pain, swelling, and deformity of the midthigh.

Excessive traction can be harmful to an injured limb. When applied correctly, however, traction stabilizes the bone fragments and improves the overall alignment of the limb. Do not attempt to force the bone fragments back into alignment. In the field, the goals of in-line traction are as follows:

1. Stabilize the fracture fragments to prevent excessive movement.
2. Align the limb sufficiently to allow it to be placed in a splint.

3. Avoid potential neurovascular compromise.

Several different types of lower extremity traction splints are commercially available, such as the Hare traction splint, the Sager splint, the Reel splint, and the Kendrick splint Figure 31-26. Each has its own unique method of application; therefore, it is important to practice using each method frequently. Consult with your agency on which traction splint you will use in the field, and make sure that you are comfortable applying this device to a patient.

Traction splints are not suitable for use on the upper extremity because the major nerves and blood vessels in the patient's axilla cannot tolerate counter-traction forces.

Figure 31-26 The Kendrick traction splint.

Courtesy of Kendrick EMS. Used with permission.

Do not use traction splints for any of the following conditions:

- Injuries of the upper extremity
- Injuries close to or involving the knee
- Injuries of the pelvis
- Partial amputations or avulsions with bone separation
- Lower leg, foot, or ankle injuries

Proper application of a traction splint requires a minimum of two EMTs. Before you apply a traction splint, be sure to control any external bleeding. The amount of traction that is required varies but often does not exceed 15 pounds (7 kg). Use the least amount of force necessary. Grasp the foot or hand at the end of the injured limb firmly; once you start pulling, do not stop until the limb is fully splinted. Releasing manual traction before the limb is secured will allow the muscles to contract, allowing the bone fragments to cause more damage to surrounding tissue. Always apply the direction of traction along the long axis of the limb. Imagine where the uninjured limb would lie, and pull gently along the line of that imaginary limb until the injured limb is in approximately that position **Figure 31-27**. Grasping the foot or hand and the initial pull of traction usually causes the patient some discomfort as the bone fragments move. A second EMT should support the injured limb directly under the site of the fracture. This initial discomfort quickly subsides, and you can then apply further gentle traction. However, if the patient strongly resists the traction or if it causes more pain that persists, stop and splint the limb in the deformed position.

Figure 31-27 To apply traction, imagine the position where the uninjured limb would lie, and then gently pull along that line until the injured limb is in that position. Do not release traction once you have applied it.

To apply a Hare traction splint, follow the steps in **Skill Drill 31-6**:

1. Cut open the patient's pant leg, or otherwise expose the injured lower extremity. Follow standard precautions as needed. Be sure to assess and record the pulse and motor function and sensation distal to the injury.
2. Place the splint beside the patient's uninjured leg, and adjust it to the proper length, with the ring at the ischial tuberosity and the splint extending 12 inches (30 cm) beyond the foot. Open and adjust the four Velcro support straps, which should be positioned at the midthigh, above the knee, below the knee, and above the ankle **Step 1**.
3. Manually support and stabilize the injured limb so that no motion will occur at the fracture site while your partner fastens the appropriate-sized ankle hitch about the patient's ankle and foot. Normally, the patient's shoe is removed for this procedure **Step 2**.
4. Support the leg at the site of the suspected injury while your partner manually applies gentle longitudinal traction to the ankle hitch and foot. Use only enough force to align (reposition) the limb so that it will fit into the splint; do not attempt to align the fracture fragments anatomically **Step 3**.

Skill Drill 31-6 Applying a Hare Traction Splint

Step 1

Expose the injured limb and check pulse, motor, and sensory function. Place the splint beside the uninjured limb, adjust the splint to proper length, and prepare the straps.

Step 2

Support the injured limb as your partner fastens the ankle hitch about the foot and ankle.

Step 3

Continue to support the limb as your partner applies gentle in-line traction to the ankle hitch and foot.

Step 4

Slide the splint into position under the injured limb.

Step 5

Pad the groin and fasten the ischial strap.

Step 6

Connect the loops of the ankle hitch to the end of the splint as your partner continues to maintain traction. Carefully tighten the ratchet to the point that the splint holds adequate traction.

Step 7

Secure and check support straps. Assess pulse and motor and sensory functions.

Step 8

Secure the patient and splint to the backboard in a way that will prevent movement of the splint during patient movement and transport.

5. Slide the splint into position under the patient's injured limb, making certain that the ring is seated well on the ischial tuberosity **Step 4**.
6. Pad the groin area, and gently apply the ischial strap **Step 5**.
7. While your partner continues to maintain traction, connect the loops of the ankle hitch to the end of the splint. Then apply gentle traction to the connecting strap between the ankle hitch and the splint, just strongly enough to maintain limb alignment. Use caution. This splint comes with a ratchet mechanism to tighten the strap. Overtightening can overstretch the limb and further injure the patient. Adequate traction has been applied when the leg is the same length as the other leg or the patient feels relief **Step 6**.
8. Once proper traction has been applied, fasten the support straps so that the limb is securely held in the splint. Check all proximal and distal support straps to make sure they are secure **Step 7**.
9. At this point, reassess distal pulses and motor function and sensation.
10. Place the patient securely on a backboard for transport to the ED. You may need to load the patient feetfirst into the ambulance so that you do not shut the door against the splint **Step 8**.

Because the traction splint stabilizes the limb by producing countertraction on the ischium and in the groin, pad these areas well. Avoid excessive pressure on the external genitalia. Always use commercially available padded ankle hitches rather than pieces of rope, cord, or tape. Such improvised hitches can sometimes be painful and can potentially obstruct circulation in the foot.

The Sager splint is lightweight and easy to store and applies a measurable amount of traction. Best of all, you can apply it by yourself when necessary. As with any splint, in addition to knowing the precise sequence of steps to apply the splint properly, you must practice the splinting technique frequently to maintain the necessary skills. Follow the steps below to apply a Sager splint **Skill Drill 31-7**:

1. Expose the injured extremity. Using standard precautions as needed, assess and record the pulse, motor function, and sensation distal to the injury.

Skill Drill 31-7 Applying a Sager Traction Splint

Step 1

After exposing the injured area, check the patient's pulse and motor and sensory functions. Adjust the thigh strap so that it lies anteriorly when secured.

Step 2

Estimate the proper length of the splint by placing it next to the uninjured limb. Fit the ankle pads to the ankle.

Step 3

Place the splint at the inner thigh, apply the thigh strap at the upper thigh, and secure snugly.

Step 4

Tighten the ankle harness just above the malleoli. Secure the cable ring against the bottom of the foot.

Step 5

Extend the splint's inner shaft to apply traction of about 10% of body weight.

Step 6

Secure the splint with elasticized cravat bandages.

Step 7

Secure the patient to a backboard. Check pulse and motor and sensory functions.

2. Before applying the splint, adjust the thigh strap so that it will lie anteriorly when secured in place **Step 1**.
3. Estimate the proper splint length by placing it alongside the uninjured limb, so that the wheel is at the level of the heel.
4. Arrange the ankle pads to fit the size of the patient's ankle **Step 2**.
5. Place the splint along the inner aspect of the limb, and slide the thigh strap around the upper thigh so that the perineal cushion is snug against the groin and the ischial tuberosity. Tighten the thigh strap snugly **Step 3**.
6. Secure the ankle harness tightly around the patient's ankle just above the malleoli.
7. Pull the cable ring snugly up against the bottom of the foot **Step 4**.
8. Pull out the inner shaft of the splint to apply traction of approximately 10% of body weight, using a maximum of 15 pounds (7 kg) **Step 5**.
9. Secure the limb to the splint using elasticized cravat bandages **Step 6**.
10. Secure the patient to a backboard.
11. Check pulse and motor and sensory functions **Step 7**.

Pelvic Binder

Pelvic binders are used to splint the bony pelvis to reduce hemorrhage from bone ends, venous disruption, and pain **Figure 31-29**. A pelvic binder is meant to provide temporary stabilization until definitive immobilization can be achieved. Generally, pelvic binders are lightweight, made of soft material, easily applied by one EMT, and should allow access to the abdomen, perineum, anus, and groin for examination and diagnostic testing. Because there are various manufacturers of pelvic binder devices, you should be familiar with the manufacturer's instructions for your specific device.

Words of Wisdom

Reel Splint

The Reel splint is a traction splint that is also used by the US military. Many devices used in combat eventually appear in the ambulance and are used by EMTs in the field. This splint is designed to be used on a lower extremity **Figure 31-28**.

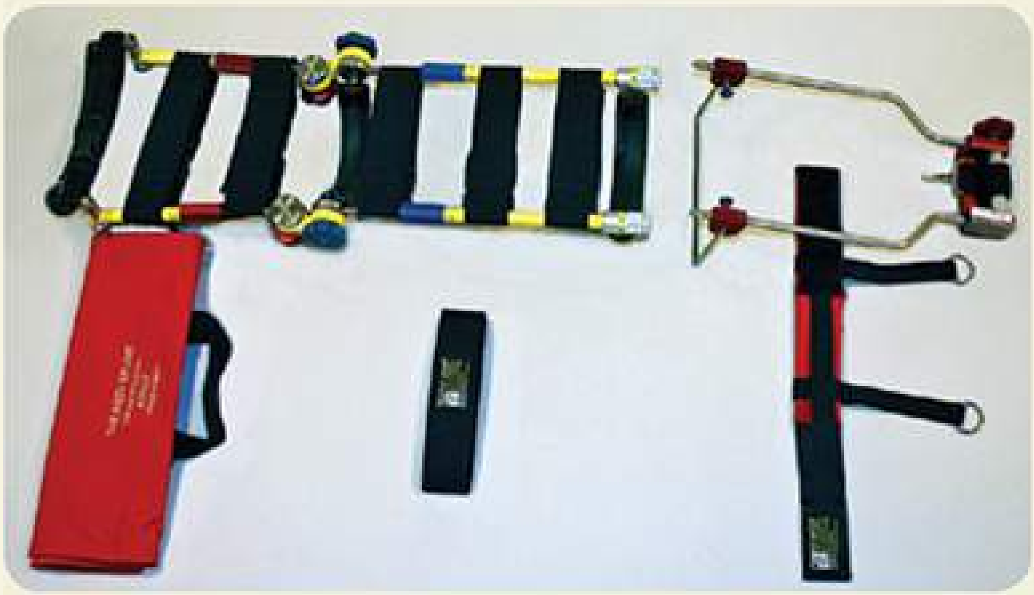

Figure 31-28 The Reel splint is also used by the US military.

Figure 31-29 Pelvic binders are meant to provide temporary stabilization until definitive immobilization can be achieved. *Note:* on a real patient, the clothing would be cut away prior to application of the splint.

Hazards of Improper Splinting

You must be aware of the hazards associated with the improper application of splints, including the following:

- Compression of nerves, tissues, and blood vessels
- Delay in transport of a patient with a life-threatening injury
- Reduction of distal circulation
- Aggravation of the injury
- Injury to tissue, nerves, blood vessels, or muscles as a result of excessive movement of the bone or joint

Transportation

Once an injured limb is adequately splinted, the patient is ready to be transferred to a backboard or stretcher and transported.

Very few, if any, musculoskeletal injuries justify the use of excessive speed during transport. The limb will be stable once a dressing and splint have been applied. However, a patient with a pulseless limb must be given a higher priority. Still, if the hospital is only a few minutes away, speeding to the ED will make no difference to the patient's time to definitive treatment. If the treatment facility is an hour or more away, a patient with a pulseless limb should be transported by helicopter or immediate ground transportation. If circulation in the distal limb is impaired, always notify medical control so that proper steps can be taken quickly once the patient arrives in the ED.

Specific Musculoskeletal Injuries

Injuries of the Clavicle and Scapula

The clavicle, or collarbone, is one of the most commonly fractured bones in the body. Fractures of the clavicle occur commonly in children when they fall on an outstretched hand. They can also occur with crush injuries of the chest. A patient with a fracture of the clavicle will report pain in the shoulder and will usually hold the arm across the front of his or her body **Figure 31-30**. A young child often reports pain throughout the entire arm and is unwilling to use any part of that limb. These complaints may make it difficult to localize the point of injury, but, generally, swelling and point tenderness occur over the clavicle. Because the clavicle is subcutaneous (just beneath the skin), the skin will occasionally "tent" over the fracture fragment. The clavicle lies directly over major arteries, veins, and nerves; therefore, fracture of the clavicle may lead to neurovascular compromise.

Figure 31-30 A patient with a fracture of the clavicle will usually hold the arm across the front of his or her body.

Words of Wisdom

Point tenderness and severe pain with or without gross instability are the most reliable indicators of an underlying fracture.

Fractures of the scapula, or shoulder blade, occur much less frequently because this bone is well protected by many large muscles. Fractures of the scapula are almost always the result of a forceful, direct blow to the back, directly over the scapula, which may also injure the thoracic cage, lungs, and heart. For this reason, you must carefully assess the patient for signs of breathing problems. Provide supplemental oxygen and prompt transport for patients who are having difficulty breathing. Remember, it is the associated chest injuries, not the fractured scapula itself, that pose the greatest threat of long-term disability.

Abrasions, contusions, and significant swelling may also occur, and the patient will often limit use of the arm because of pain at the fracture site. The scapula also has bony projections that may be fractured with a lesser degree of force.

Figure 31-31 With acromioclavicular separations, the distal end of the clavicle usually sticks out.

© Mike Devlin/Science Source.

The joint between the outer end of the clavicle and the acromion process of the scapula is called the **acromioclavicular (AC) joint**. This joint is frequently separated during sports, such as football or hockey, when a player falls and lands on the point of the shoulder, driving the scapula away from the outer end of the clavicle. This dislocation is often called an AC separation. The distal end of the clavicle will often stick out, and the patient will report pain, including point tenderness over the AC joint **Figure 31-31**.

Fractures of the clavicle and scapula and AC separations can all be splinted effectively with a sling and swathe. A **sling** is any bandage or material that helps support the weight of an injured upper extremity, relieving the downward pull of gravity on the injured site. To be effective, a sling must apply gentle upward support to the olecranon process of the ulna. The knot of the sling should be tied to one side of the neck so that it does not press uncomfortably on the cervical spine **Figure 31-32A**.

To fully stabilize the shoulder region, a **swathe**, a bandage that passes completely around the chest, must be used to bind the arm to the chest wall. The swathe should be tight enough to prevent the arm from swinging freely, but not so tight as to compress the chest and compromise breathing. Leave the patient's fingers exposed so that you can assess neurovascular function at regular intervals **Figure 31-32B**

Commercially available shoulder stabilizers or slings will provide adequate splinting for injuries of the shoulder region, as will triangular bandage slings.

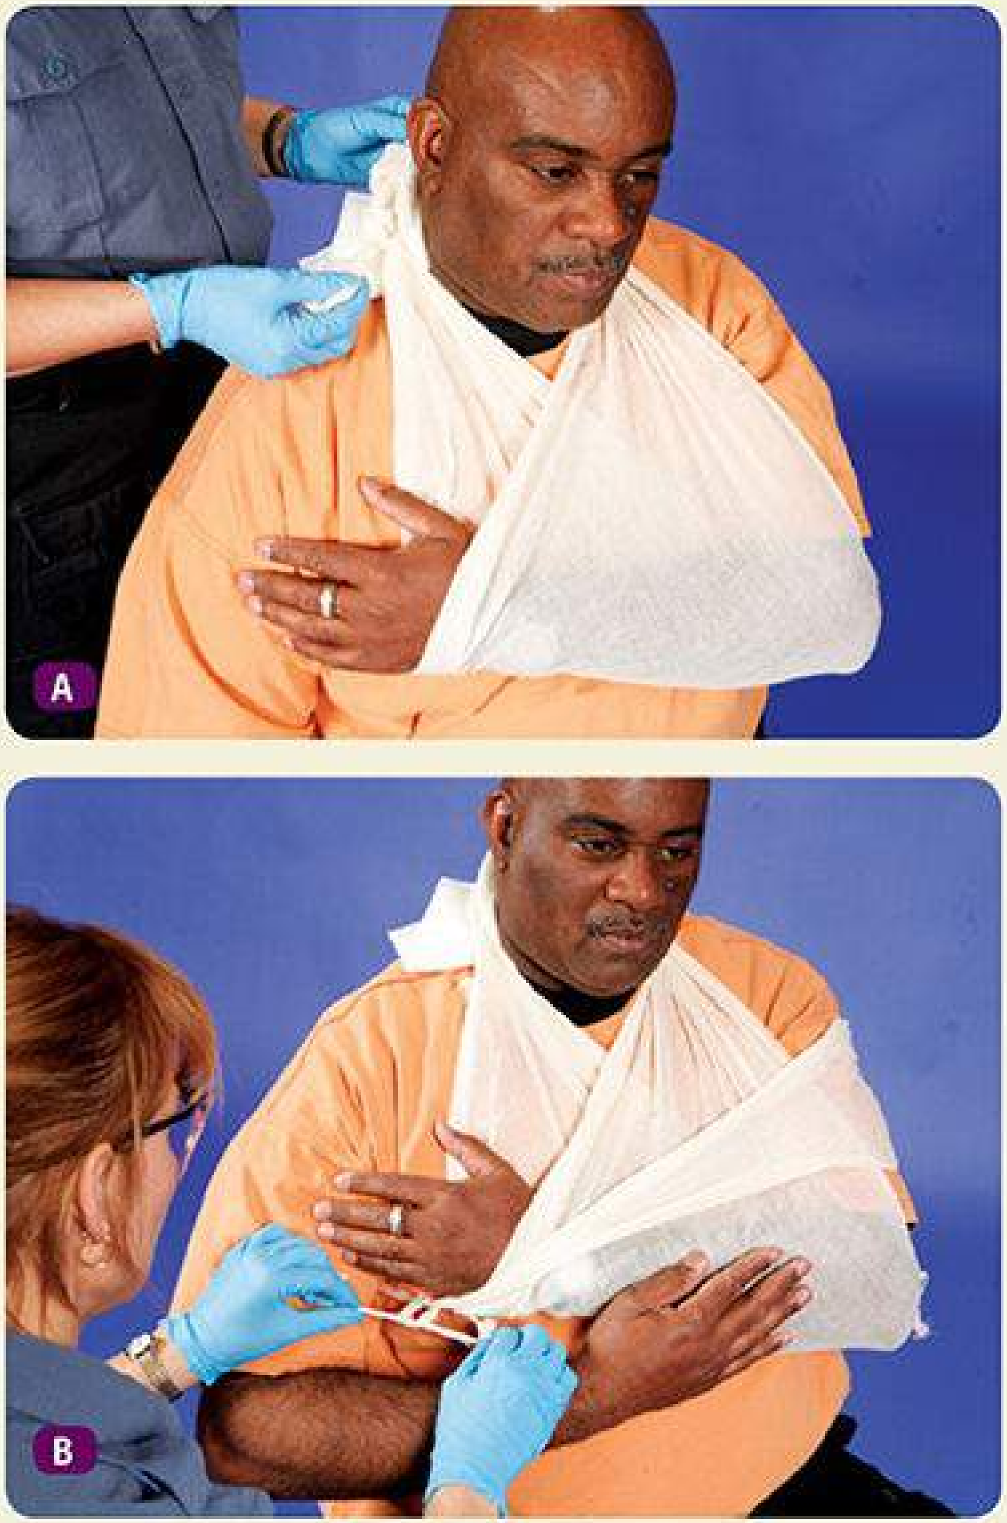

Figure 31-32 **A.** Apply a sling so that the knot is tied to one side of the neck. **B.** Bind the arm to the chest wall with a swathe so that the arm cannot swing freely. Leave the patient's fingers exposed so that you can assess distal circulation.

Dislocation of the Shoulder

The glenohumeral joint (shoulder joint) is where the head of the humerus, the supporting bone of the upper arm, meets the **glenoid fossa** of the scapula. The glenoid fossa joins with the humeral head to form the glenohumeral joint. In shoulder dislocations, the humeral head most commonly dislocates anteriorly, coming to lie in front of the scapula as a result of forced abduction (away from the midline) and external rotation of the arm **Figure 31-33**.

Shoulder dislocations are extremely painful. The patient will guard the shoulder and try to protect it by holding the dislocated arm in a fixed position away from the chest wall **Figure 31-34**. The shoulder joint will usually be locked, and the shoulder will appear squared off or flattened. The humeral head will protrude anteriorly underneath the pectoralis major on the anterior chest wall. As a result, the axillary nerve may be compressed, causing a numb patch on the outer aspect of the shoulder. Be sure to document this finding. Some patients may also report some numbness in the hand because of either nervous or circulatory compromise.

Figure 31-33 Most shoulder dislocations are anterior. Note the absence of the normal rounded appearance of the shoulder.

Figure 31-34 A patient with a dislocated shoulder will guard the shoulder, trying to protect it by holding the arm in a fixed position away from the chest wall.

Stabilizing an anterior shoulder dislocation is difficult because any attempt to bring the arm in toward the chest will produce pain. You must splint the joint in whatever position is most comfortable for the patient. If necessary, place a pillow or rolled blankets or towels between the arm and chest to fill up the space between them **Figure 31-35**. Once the arm has been stabilized in this way, the elbow can usually be flexed to 90 degrees without causing further pain. At this point, you can apply a sling to the forearm and wrist to support the weight of the arm. Finally, secure the arm in the sling to the pillow and chest with a swathe. Transport the patient in a seated or semiseated position.

Figure 31-35 Splint the shoulder joint in a position of comfort, and place a pillow or towel between the arm and the chest wall to stabilize the arm, after which the elbow can be flexed to 90°. Apply a sling, and secure the arm to the chest with a swathe.

Dislocation of the shoulder disrupts the supporting ligaments of the anterior aspect of the shoulder. Often, these ligaments fail to heal properly, so dislocation recurs, each time causing further neurovascular compromise and joint injury. In certain cases, surgical repair may be required. Some patients are able to reduce (set) their own dislocated shoulders. Generally, however, this maneuver must be done in a hospital setting and only after radiograph films have been obtained.

Words of Wisdom

When you assess a patient with a possible shoulder dislocation, position yourself behind the patient and compare the shoulders. The dislocated side is often lower than the uninjured side.

Posterior dislocation is less common than anterior shoulder dislocation. Football players, especially linemen, are susceptible to this injury. The arm will often be locked in adduction (toward the midline), so it cannot be rotated. Reducing the dislocation usually requires medical supervision.

Fracture of the Humerus

Fractures of the humerus occur either proximally, in the midshaft, or distally at the elbow Table 31-2. Fractures of the proximal humerus resulting from falls are common among older people. Fractures of the midshaft occur more often in young patients, usually as the result of a violent injury.

With any severely angulated fracture, consider applying traction to realign the fracture fragments before splinting them. Check your local protocols for indications and techniques for applying traction to a severely angulated fracture. Support the site of the fracture with one hand, and with the other hand, grasp the two humeral condyles (its lateral and medial protrusions) just above the elbow. Pull gently in line with the normal axis of the limb Figure 31-36. Once you achieve gross realignment of the limb, splint the arm with a sling and swathe, supplemented by a padded board splint on the lateral aspect of the arm Figure 31-37. If the patient reports significant pain or resists gentle traction, splint the fracture in the deformed position with a padded wire ladder or a padded board splint, using pillows to support the injured limb. Note that compartment syndrome, discussed later in this chapter, can develop in the forearm in children with these fractures.

Figure 31-36 To align a severe deformity associated with a humeral shaft fracture, apply gentle pressure to the humeral condyles, as shown in this uninjured arm.

Figure 31-37 Splint a humeral shaft fracture with a sling and swathe supplemented by a padded board splint on the lateral aspect of the arm.

Elbow Injuries

Fractures and dislocations often occur around the elbow, and the different types of injuries are difficult to distinguish without radiographic examinations. However, they all produce similar limb deformities and require the same emergency care. Injuries to nerves and blood vessels are quite common in this region. Such injuries can be caused or worsened by inappropriate emergency care, particularly by excessive manipulation of the injured joint.

Fracture of the Distal Humerus

This type of fracture, also known as a supracondylar or intercondylar fracture, is common in children. Frequently, the fracture fragments rotate significantly, producing deformity and causing injuries to nearby vessels and nerves. Swelling occurs rapidly and is often severe.

Dislocation of the Elbow

This type of injury typically occurs in athletes and rarely in young children. It can occur in toddlers when they are lifted or pulled by the arm (sometimes called “nursemaid’s elbow”), although it is not technically a joint dislocation. The ulna and radius are most often displaced posteriorly relative to the humerus. The ulna, the bone on the little finger side of the forearm, and the radius, the bone on the thumb side of the forearm, both join the distal humerus. The posterior displacement makes the olecranon process of the ulna much more prominent Figure 31-38. The joint is usually locked, with the forearm moderately flexed on the arm; this position makes any attempt at motion extremely painful. As with a fracture of the distal humerus, there is swelling and significant potential for vessel or nerve injury.

Table 31-2 Characteristics and Treatment of Fractures of the Humerus

Type	Characteristics	Treatment
Proximal humeral fractures	▪ Significant swelling, but no significant deformity of the upper arm ▪ Neurovascular compromise uncommon ▪ If neurologic compromise present, any or all of the brachial plexus may be affected, depending on the degree of displacement ▪ Concurrent soft-tissue injuries possible ▪ Possible rotator cuff injury (If radiograph films show no fracture, a tear of the rotator cuff is possible, especially if the patient cannot rotate the arm)	▪ Stabilize in a sling and swathe or a shoulder stabilizer. ▪ Use the chest wall as a splint, and secure the injured arm to the chest wall. ▪ Place a short, padded board splint on the lateral side of the arm under the sling and swathe for additional support.
Midshaft fractures	▪ Gross angulation of the arm ▪ Marked instability and crepitus of fracture fragments ▪ Possible neurovascular compromise ▪ Possible entrapment of the radial nerve (The patient cannot extend or dorsiflex the wrist or fingers and may report numbness on the dorsum of the hand; classic "wrist drop.")	▪ Stabilize with a sling and swathe or a shoulder stabilizer. ▪ Use the chest wall as a splint, and secure the injured arm to the chest wall. ▪ Place a short, padded board splint on the lateral side of the arm under the sling and swathe for additional support.
Distal humeral fractures	▪ Significant swelling at the elbow ▪ Possible neurovascular compromise ▪ Possible injury to the ulnar or median nerve (Document nerve status before and after any attempt to reduce or stabilize the fracture.)	▪ Stabilize in a splint, in addition to a sling and swathe or a shoulder stabilizer.

Figure 31-38 Posterior dislocation of the elbow makes the olecranon process of the ulna much more prominent.

Elbow Joint Sprain

This diagnosis is often mistakenly applied to an occult, nondisplaced fracture, since it can be difficult to distinguish between sprains and fractures.

Fracture of the Olecranon Process of the Ulna

This fracture can result from direct or indirect forces and is often associated with lacerations and abrasions. The patient will be unable to actively extend the elbow.

Fractures of the Radial Head

Often missed during diagnosis, this fracture generally occurs as a result of a fall on an outstretched arm or a direct blow to the lateral aspect of the elbow. Attempts to rotate the forearm will cause discomfort.

Care of Elbow Injuries

All elbow injuries are potentially serious and require careful management. Always assess distal neurovascular functions periodically in patients with elbow injuries. If you find strong pulses and good capillary refill, splint the elbow injury in the position in which you found it, adding a wrist sling if this seems helpful. Two padded board splints, one applied to each side of the limb and secured with soft roller bandages, usually are enough to stabilize the arm **Figure 31-39A**. Make sure the board extends from the shoulder joint to the wrist joint, stabilizing the entire bone above and below the injured joint. Alternatively, you can mold a padded wire ladder splint or a SAM splint to the shape of the limb **Figure 31-39B**. If necessary, you may add further support to the limb with a pillow.

YOU are the Provider — PART 4

As the nurse continues to manually stabilize the patient's leg, you retrieve the splinting supplies from the ambulance, and your partner reassesses her vital signs.

Recording Time: 13 Minutes	
Level of consciousness	Conscious and alert
Respirations	22 breaths/min; adequate depth
Pulse	110 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	134/80 mm Hg
Spo_2	99% (on ambient air)

7. How should you splint this patient's injury?
8. What are some methods for providing pain relief from orthopaedic trauma?

A cold, pale hand or a weak or absent pulse and poor capillary refill indicate that the blood vessels have likely been injured. Further care of this patient must be dictated by a physician. Notify medical control immediately. If you are within 10 to 15 minutes of the hospital, splint the limb in the position in which you found it, and provide prompt transport. Otherwise, medical control may direct you to try to realign the limb to improve circulation in the hand.

If the limb is pulseless and significantly deformed at the elbow, apply gentle manual traction in line with the long axis of the limb to decrease the deformity. This maneuver may restore the pulse. Be careful, because excessive manipulation may only worsen the vascular problem. If no pulse returns after one attempt, splint the limb in the most comfortable position for the patient. If the pulse is restored by gentle longitudinal traction, splint the limb in whatever position allows the strongest pulse. Provide prompt transport for all patients with impaired distal circulation.

Figure 31-39 **A.** Two padded board splints provide adequate stabilization for an injured elbow. **B.** A structural aluminum malleable splint can be molded to the shape of the limb so that you can splint it in the position in which it was found.

Special Populations

Growth plate injuries in children are common, especially around the wrist, elbow, knee, and ankle. Injuries tend to occur through these cartilaginous growth centers because they are inherently weaker than the surrounding bone. Since longitudinal growth of the limb is dependent upon the function of the growth plate, it is extremely important to recognize the possibility of growth plate injuries, stabilize the injured limb, and transport the patient in a timely manner to an appropriate center with pediatric, pediatric orthopaedic, and pediatric surgical coverage. Proper functioning of the injured growth plate throughout the remainder of skeletal growth may depend on timely anatomic reduction of the fracture and close follow-up by an orthopaedist.

Any deformity close to a joint in children younger than 16 years should be assumed to be a growth plate injury. Treat and transport the patient appropriately.

Fractures of the Forearm

Fractures of the shaft of the radius and ulna are common in people of all age groups but are seen most often in children and older people. Usually, both bones break at the same time when the injury is the result of a fall on an outstretched hand **Figure 31-40**. An isolated fracture of the shaft of the ulna may occur as the result of a direct blow to it; this is known as a nightstick fracture.

Fractures of the distal radius, which are especially common in older patients with osteoporosis, are known as Colles fractures. The term silver fork deformity is used to describe the distinctive appearance of the patient's arm **Figure 31-41**. In children, this fracture may occur through the growth plate and can have long-term consequences.

To stabilize fractures of the forearm or wrist, you can use a padded board, air, vacuum, or pillow splint. If the shaft of the bone has been fractured, be sure to include the elbow joint in the splint. Splinting of the elbow joint is not essential with fractures near the wrist; however, the patient will be more comfortable if you add a sling or pillow for more support. If possible, elevate the injured extremity above the heart to help alleviate swelling.

Figure 31-40 Fractures of the forearm often occur in children as a result of a fall on an outstretched hand.

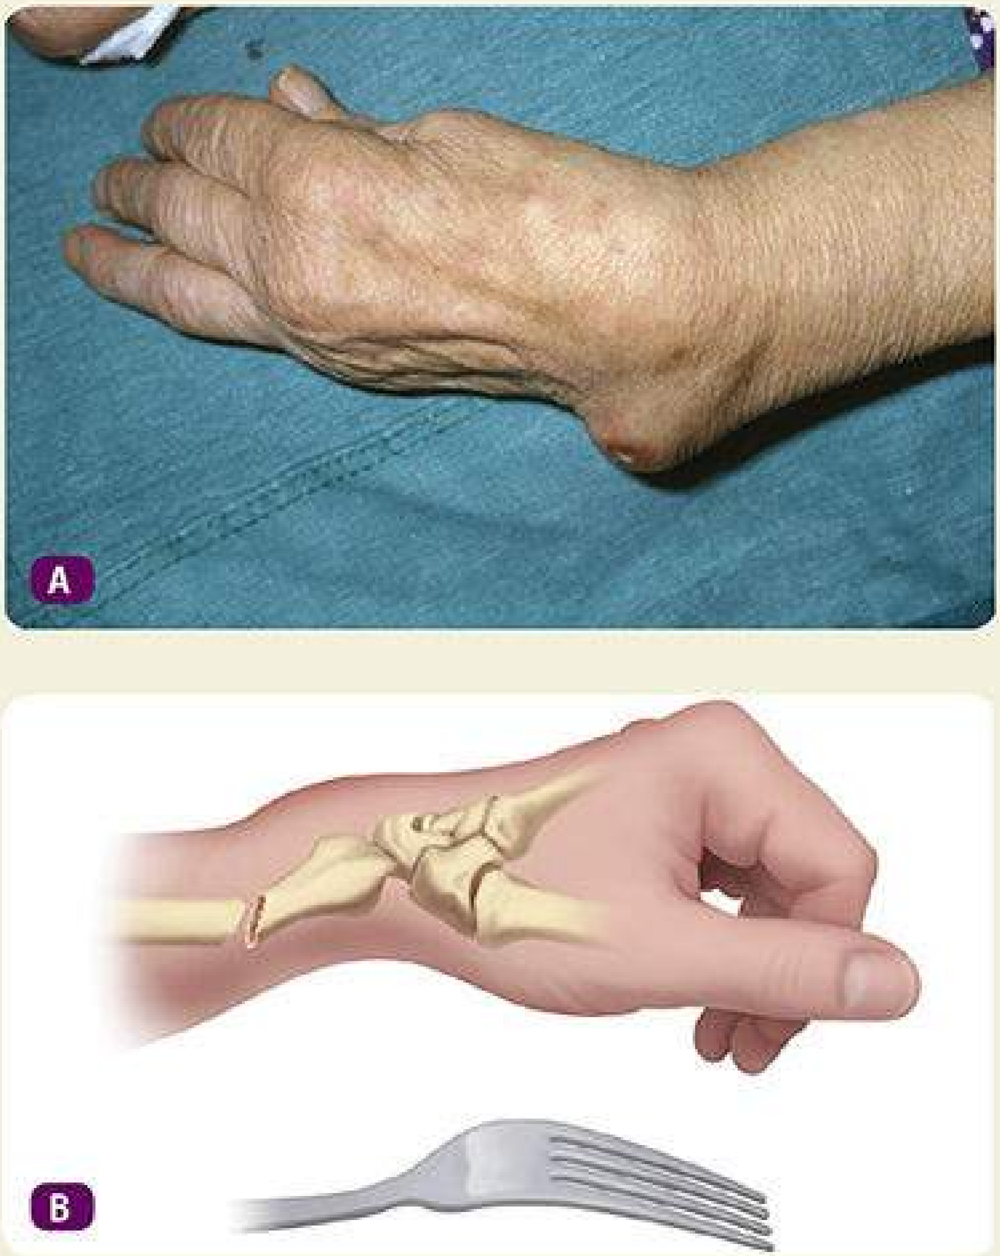

Figure 31-41 **A.** Fractures of the distal radius produce a characteristic silver fork deformity. **B.** An artist's illustration.

A: © Dr. M.A. Ansary/Science Source; B: © Jones & Bartlett Learning.

Injuries of the Wrist and Hand

Injuries of the wrist, ranging from dislocations to sprains, must be confirmed by radiograph examination. Dislocations are usually associated with a fracture, resulting in a fracture dislocation. Another common wrist injury is the isolated, nondisplaced fracture of a carpal bone, especially the scaphoid. Any questionable wrist sprain or fracture should be splinted and evaluated in the ED or an orthopaedic surgeon's office.

Special Populations

In the United States over 80,000 distal radial fractures a year occur in people older than 65 years.

Hand injuries vary widely, some with potentially serious consequences. Industrial, recreational, and home accidents often result in dislocations, fractures, lacerations, burns, and amputations. Because the fingers and hands are required to function in such intricate ways, any injury that is not treated properly may result in permanent disability, as well as deformity. For this reason, all injuries to the hand, including simple lacerations, should be evaluated by a physician. For example, do not attempt to "pop" a dislocated finger joint back in place **Figure 31-42**. Always take any amputated parts to the hospital with the patient. Be sure to wrap the amputated part in a dry or moist sterile dressing, depending on your local protocol, and place it in a dry plastic bag. Put the bag in a cooled container; do not soak the part in water or allow it to freeze.

Figure 31-42 Dislocation of the finger joint. Do not try to "pop" the joint back into place.

A bulky forearm dressing makes an effective splint for any hand or wrist injury. Follow the steps in **Skill Drill 31-8**:

1. Follow standard precautions.
2. Cover open wounds with a dry, sterile dressing.
3. Assess distal pulse and motor and sensory function.
4. Supporting the injured limb, form the injured hand into the **position of function**, with the wrist slightly bent down and all finger joints moderately flexed. This is the position that is used to hold a can most comfortably.

Skill Drill 31-8 Splinting the Hand and Wrist

Step 1

Support the injured limb and move the hand into the position of function. Place a soft roller bandage in the palm.

Step 2

Apply a padded board splint on the palmar side with fingers exposed.

Step 3

Secure the splint with a roller bandage.

5. Place a soft roller bandage into the palm of the hand **Step 1**.
6. Apply a padded board splint to the palmar side of the wrist, leaving the fingers exposed **Step 2**.
7. Secure the entire length of the splint with a soft roller bandage **Step 3**. Assess distal pulse and motor and sensory function.
8. Apply a sling and swathe, or prop the splinted hand and wrist on a pillow or on the patient's chest during transport to the hospital.

Fractures of the Pelvis

Fracture of the pelvis often results from direct compression in the form of a heavy blow that literally crushes the pelvis. The blow may be from a motor vehicle crash, a weapon, a falling object, or a fall from a height. Injuries to the pelvis can also be caused by indirect forces. For example, when the knee strikes the dashboard in a motor vehicle crash, the impact of the force is transmitted along the line of the femur (thighbone), which is the longest and largest bone in the body. The head of the femur is driven into the pelvis, causing it to fracture. However, not all pelvic fractures result from violent trauma. Even a simple fall can produce a fracture of the pelvis, especially in older people with osteoporosis.

Fractures of the pelvis may be accompanied by life-threatening loss of blood from the laceration of blood vessels affixed to the pelvis at certain key points. Up to several liters of blood may drain into the pelvic space and the **retroperitoneal space**, which lies between the abdominal cavity and the posterior abdominal wall. The result is significant hypotension, shock, and sometimes death. For this reason, you must take immediate steps to treat shock, even if there is only minimal swelling. Often, there are no visible signs of bleeding until severe blood loss has occurred. Be prepared to resuscitate the patient rapidly if this becomes necessary.

Because the pelvis is surrounded by heavy muscle, open fractures of the pelvis are uncommon. However, pelvis fracture fragments can lacerate the rectum and vagina, creating an open fracture that is often overlooked. Once the protective pelvic ring is broken, the structures it is designed to protect, including the urinary bladder, are more susceptible to injury. The bladder may be lacerated by pelvic bone fragments, or it may tear as a result of direct pressure on the bladder itself or tension on the urethra.

You should suspect a fracture of the pelvis in any patient who has sustained a high-velocity injury and reports discomfort in the lower back or abdomen. Because the area is covered by heavy muscle and other soft tissue, deformity or swelling may be very difficult to see. The most reliable sign of fracture of the pelvis is simple tenderness or instability on firm compression and palpation. Firm compression on the two iliac crests will produce pain at a fracture site in the pelvic ring. Assess for tenderness by taking the following steps **Figure 31-43**:

1. Place the palms of your hands over the lateral aspect of each iliac crest, and apply firm but gentle inward pressure on the pelvic ring.
2. With the patient lying supine, place a palm over the anterior aspect of each iliac crest, and apply firm downward pressure.
3. Use the palm of your hand to firmly but gently palpate the pubic symphysis, the firm cartilaginous joint between the two pubic bones. This area will be tender if there is injury to the anterior portion of the pelvic ring.

YOU are the Provider — PART 5

After properly splinting the patient's leg, you place her onto the stretcher, load her into the ambulance, and begin transport to the hospital. You reassess her condition and vital signs en route and note that her condition remains stable. You call your radio report in to the receiving facility; your estimated time of arrival is 8 minutes.

Recording Time: 23 Minutes	
Level of consciousness	Conscious and alert
Respirations	20 breaths/min; adequate depth
Pulse	115 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	128/76 mm Hg
Spo_2	98% (on ambient air)

During transport, the patient reports numbness and tingling in her left foot. Your reassessment reveals that her pedal pulse is weaker than it was before and that her foot looks pale and feels cool.

9. What is the most likely cause of the patient's complaint? What can you can do to remedy the situation?
10. What factors increase the risk of complications following orthopaedic trauma?

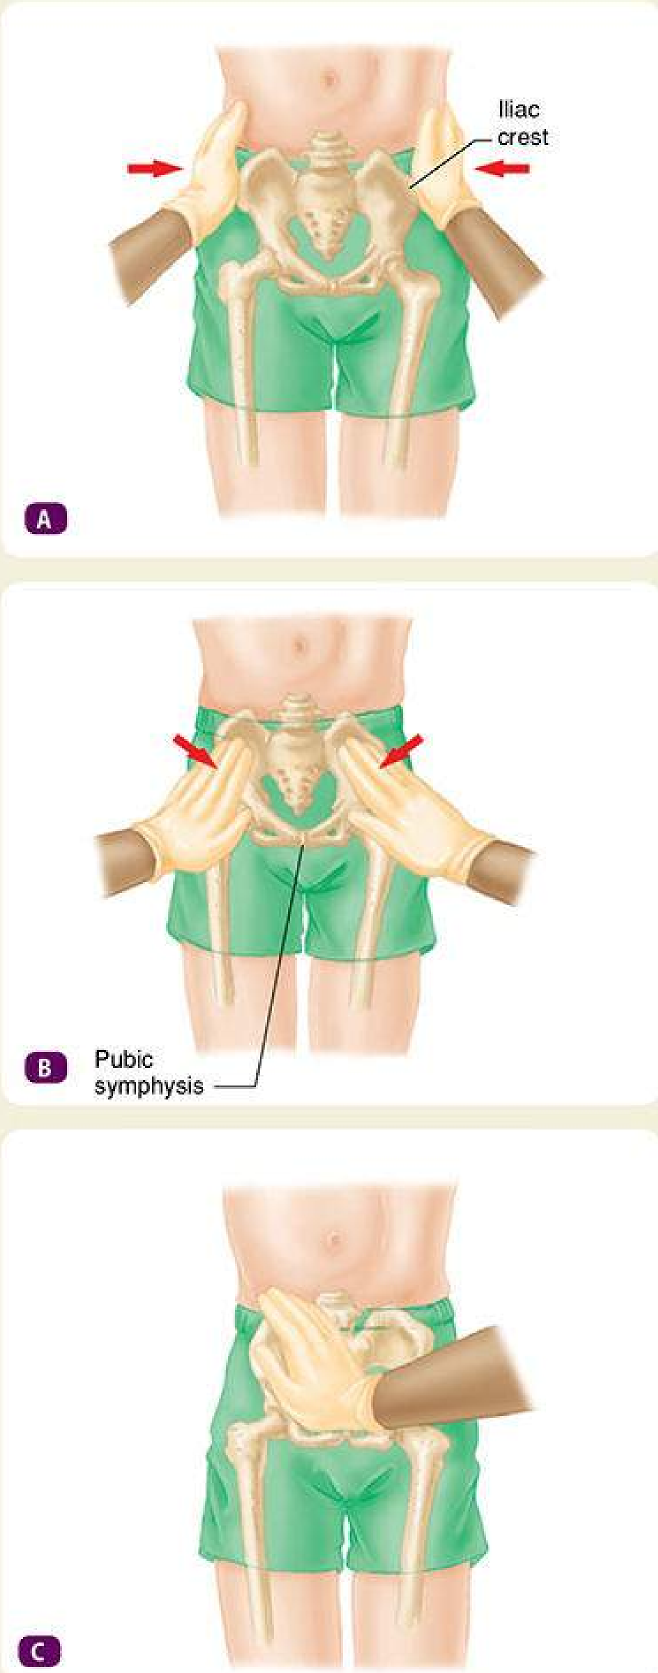

Figure 31-43 **A.** To assess for tenderness or instability in the pelvic region, place your hands over the lateral aspect of each iliac crest, and gently compress the pelvis. **B.** With the patient in a supine position, place your palms over the anterior aspect of each iliac crest, and apply firm but gentle downward pressure. **C.** Palpate the pubic symphysis with the palm of your hand.

If there has been injury to the bladder or the urethra, the patient will have lower abdominal tenderness and may have evidence of **hematuria** (blood in the urine) or blood at the urethral opening.

Perform the primary assessment, and carefully monitor the general condition of any patient whom you suspect has a pelvic fracture, because he or she is at high risk for hypovolemic shock. Patients in stable condition can be secured to a backboard or a scoop stretcher to stabilize isolated fractures of the pelvis.

Dislocation of the Hip

The hip joint is a very stable ball-and-socket joint that dislocates only after significant injury. Most dislocations of the hip are posterior. The femoral head is displaced posteriorly to lie in the muscles of the buttock. Posterior dislocation of the hip most commonly occurs as a result of a motor vehicle crash in which the knee meets with a direct force, such as the dashboard, and the entire femur is driven posteriorly, dislocating the hip joint **Figure 31-44**. Thus, you should suspect a hip dislocation in any patient who has been in a motor vehicle crash and has a contusion, laceration, or obvious fracture in the knee region. Very rarely does the femoral head dislocate anteriorly; in this circumstance, the legs are suddenly and forcibly spread wide apart and locked in this position.

Posterior dislocation of the hip is frequently complicated by injury to the sciatic nerve, which is located directly behind the hip joint. The **sciatic nerve** is the largest nerve in the lower extremity; it controls the activity of muscles in the posterior thigh and below the knee and the sensation in most of the leg and foot. When the head of the femur is forced out of the hip socket, it may compress or stretch the sciatic nerve, leading to partial or complete paralysis of the nerve. The result is decreased sensation in the leg and foot and frequently weakness in the foot muscles. Generally, only the dorsiflexors, the muscles that raise the toes or foot, are involved, causing the "foot drop" that is characteristic of damage to the peroneal portion of the sciatic nerve.

Patients with a posterior dislocation of the hip typically lie with the hip joint flexed (the knee joint drawn up toward the chest) and the thigh rotated inward toward the midline of the body over the top of the opposite thigh **Figure 31-45A**. With the less common anterior dislocation, the limb is in the opposite position, extended straight out, externally rotated, and pointing away from the midline of the body.

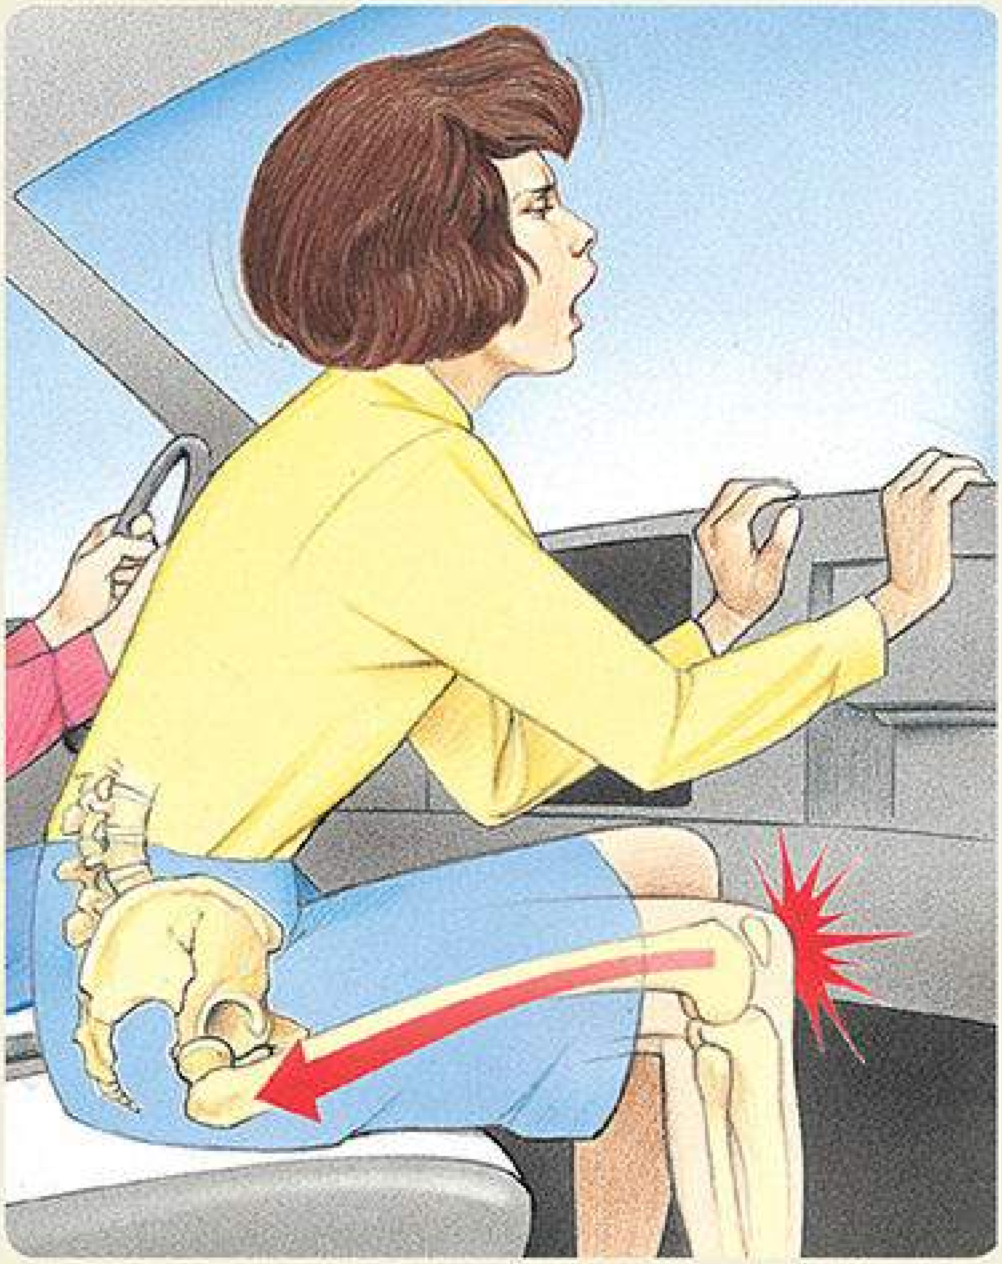

Figure 31-44 Posterior dislocation of the hip can occur as a result of the knee hitting the dashboard in a motor vehicle crash. The impact drives the femur posteriorly (see arrow), dislocating the joint.

Dislocation of the hip is associated with very distinctive signs. The patient will have severe pain in the hip and will strongly resist any attempt to move the joint. The lateral and posterior aspects of the hip region will be tender on palpation. With some thin patients, you can palpate the femoral head deep within the muscles of the buttock. Check for a sciatic nerve injury by carefully assessing sensation and motor function in the lower extremity. Occasionally, sciatic nerve function will be normal at first and then slowly diminish.

As with any other extremity injury, do not attempt to reduce the dislocated hip in the field unless medical control directs you to do so. Splint the dislocation in the position of the deformity, and place the patient supine on a backboard. Support the affected limb with pillows and rolled blankets, particularly under the flexed knee **Figure 31-45B**. Then secure the entire limb to the backboard with long straps so that the hip region will not move, and provide prompt transport.

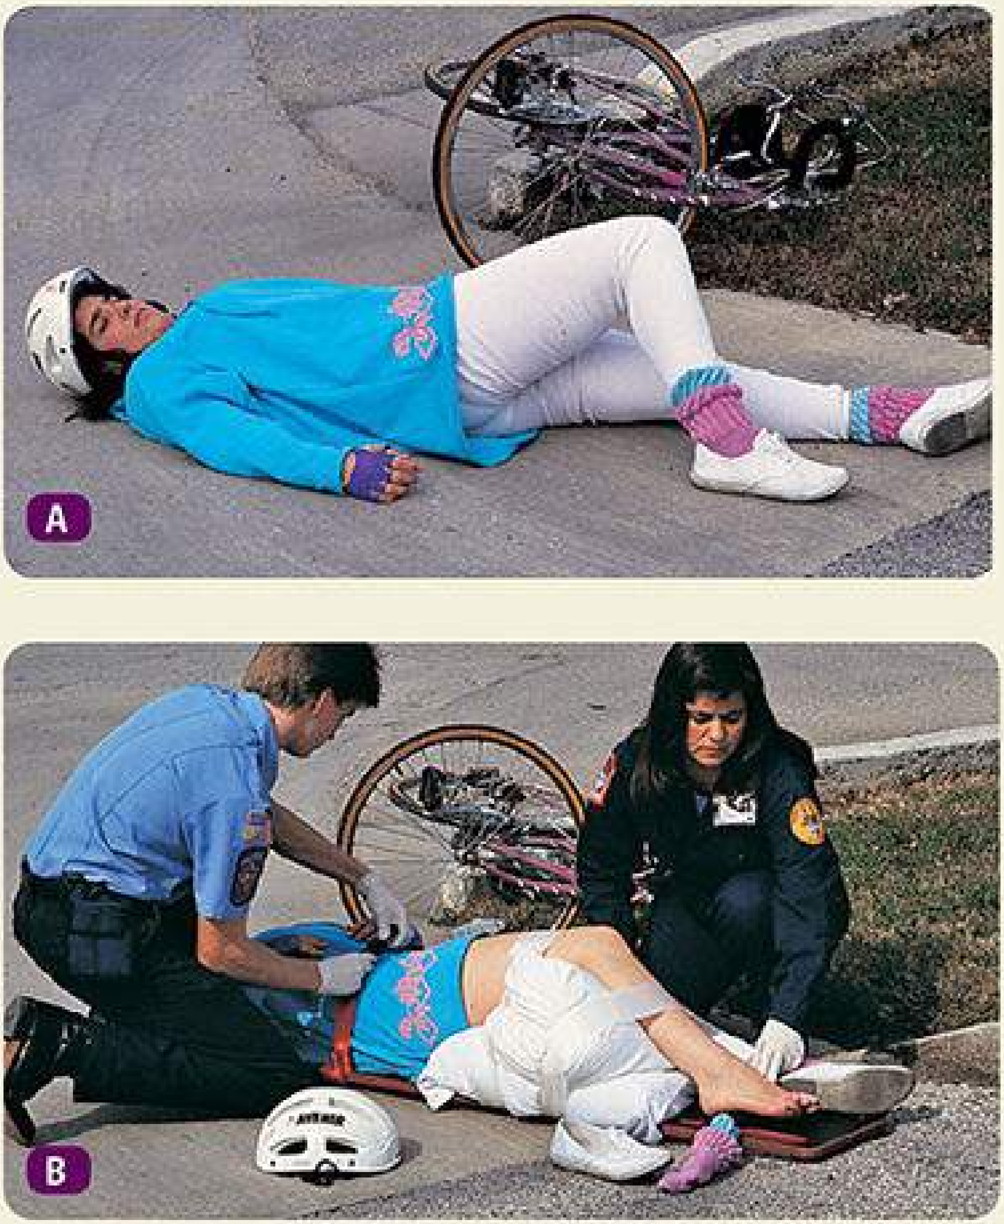

Figure 31-45 **A.** The usual position of a patient with a posterior dislocation of the hip. The hip joint is flexed, and the thigh is rotated inward and adducted across the midline of the body. **B.** Support the affected limb with pillows and blankets, particularly under the flexed knee. Secure the entire limb to a backboard with long straps to prevent movement during transport.

Fractures of the Proximal Femur

Fractures of the proximal (upper) end of the femur are common fractures, especially in older people and patients with osteoporosis. Although these fractures are usually called hip fractures, they rarely involve the hip joint. Instead, the break goes through the neck of the femur, the intertrochanteric (middle) region, or across the proximal shaft of the femur (subtrochanteric fractures). These three fracture types may also be a result of high-energy injuries in younger patients.

Patients with displaced fractures of the proximal femur display a very characteristic deformity. They lie with the leg externally rotated, and the injured leg is usually shorter than the opposite, uninjured limb. When the fracture is not displaced, this deformity is not present. With any kind of hip fracture, patients typically are unable to walk or move the leg because of pain in the hip region or in the groin or inner aspect of the thigh. The hip region is usually tender on palpation, and gentle rolling of the leg will cause pain but will not do further damage. On occasion, the pain is referred to the knee, and it is not uncommon for a geriatric patient with a hip fracture to report knee pain after a fall. Assess the pelvis for any soft-tissue injury and bandage appropriately. In addition, assess pulses and motor and sensory functions, looking for signs of vascular and nerve damage. Once your assessment is complete, splint the lower extremity of an older patient who has fallen and reports pain in either the hip or the knee, even if there is no deformity, and then transport the patient to the ED.

The age of the patient and the severity of the injury will dictate how you splint the fracture. A geriatric patient with an isolated hip fracture does not require a traction splint. You can effectively stabilize such a fracture by placing the patient on a backboard or scoop stretcher, using pillows or rolled blankets to support the injured limb in the deformed position. Then secure the injured limb carefully to the device with long straps.

All patients with hip fractures may have a significant amount of blood loss. Therefore, you should treat with high-flow oxygen, monitor vital signs frequently, and be alert for signs of shock.

Special Populations

As the population of older adults grows to approximately 20% of the general population, it is important that EMTs prepare for a future in which older patients may constitute the majority of emergency calls.

Femoral Shaft Fractures

Fractures of the femur can occur in any part of the shaft, from the hip region to the femoral condyles just above the knee joint. Following a fracture, the large muscles of the thigh spasm in an attempt to “splint” the unstable limb. The muscle spasm often produces significant deformity of the limb, with severe angulation or external rotation at the fracture site. Usually, the limb also shortens significantly. Fractures of the femoral shaft may be open, and fragments of bone may protrude through the skin. As with any other open fracture, never attempt to push the bone(s) back into the skin.

There is often a significant amount of blood loss, as much as 500 to 1,000 mL, after a fracture of the shaft of the femur. With open fractures, the amount of blood loss may be even greater. Thus, it is not unusual for hypovolemic shock to develop. Handle patients with these fractures with extreme care because any extra movement or fracture manipulation may increase the amount of blood loss.

Because of the severe deformity that occurs with these fractures, bone fragments may penetrate or press on important nerves and vessels and produce significant damage. For this reason, you must carefully and periodically assess the distal neurovascular function in patients who have sustained a fracture of the femoral shaft. Remove the clothing from the affected limb so that you can adequately inspect the injury site for any open wounds. Remember to follow standard precautions when any blood or body fluids are present. Monitor the patient’s vital signs closely, and continue to watch for the onset of hypovolemic shock. You must provide rapid transport in this situation.

Cover any open wound with a dry, sterile dressing. If the foot or leg below the level of the fracture shows signs of impaired circulation (is pale, cold, or pulseless), apply gentle longitudinal traction to the deformed limb in line with the long axis of the limb. Gradually turn the leg from the deformed position to restore the limb’s overall alignment. Often, this restores or improves circulation to the foot. If it does not, the patient may have sustained a serious vascular injury and may be in need of prompt medical attention.

A fracture of the femoral shaft is best stabilized with a traction splint, such as a Sager splint.

Injuries of Knee Ligaments

The knee is very vulnerable to injury; therefore, many different types of injuries occur in this region. Ligament injuries, for example, range from mild sprains to complete dislocation of the joint. The patella can also dislocate. In addition, all the bony elements of the knee (distal femur, upper tibia, and patella) can fracture.

The knee is especially susceptible to ligament injuries, which occur when abnormal bending or twisting forces are applied to the joint. Such injuries are often seen in both recreational and competitive athletes. The ligaments on the medial side of the knee are most frequently injured, typically when the foot is fixed to the ground and the lateral aspect of the knee is struck by a heavy object, such as when a football player is tackled from the side.

Usually, a patient with a knee ligament injury will report pain in the joint and be unable to use the extremity normally. When you examine the patient, you will generally find swelling, occasional ecchymosis, point tenderness at the injury site, and a joint effusion (excess fluid in the joint).

Splint all suspected knee ligament injuries. The splint should extend from the hip joint to the foot, stabilizing the bone above the injured joint (the femur) and the bone below it (the tibia). A variety of splints can be used, including a padded rigid long leg splint or two padded board splints securely applied to the medial and lateral aspects of the limb. A backboard, a pillow splint, or simply binding the injured limb to its uninjured mate is an acceptable—but less effective—splinting technique. The patient will usually be able to straighten the knee to allow you to apply the splint. However, if you encounter resistance or pain when trying to straighten the knee, splint it in the flexed position. Then continue to monitor the distal neurovascular function until the patient reaches the hospital.

Dislocation of the Knee

Dislocations of the knee are true emergencies that may threaten the limb. When the knee is dislocated, the ligaments that provide support to it may be damaged or torn. When this happens, the proximal end of the tibia completely displaces from its juncture with the lower end of the femur, usually producing a significant deformity. Although substantial ligament damage always occurs with a knee dislocation, the more urgent injury is often to the popliteal artery, which is frequently lacerated or compressed by the displaced tibia. When gross deformity, severe pain, and an inability to move the joint cause you to suspect a dislocation of the knee, always check the distal circulation carefully before taking any other step. If the distal pulses are absent, contact medical control immediately for further stabilization and transport instructions.

The direction of dislocation refers to the position of the tibia with respect to the femur. Posterior knee dislocations, which result from extreme hyperextension of the knee, are the most common, occurring in almost half of all cases. Commonly, the anterior and posterior cruciate ligaments are damaged, but there is also a high risk of injury to the popliteal artery.

Medial dislocations result from a direct blow to the lateral part of the leg. Because the deforming force causes the medial aspect of the knee to stretch apart, there is a high likelihood of injury to the medial ligaments. When the force is applied from the medial direction, a lateral dislocation occurs and the lateral part of the knee is stretched apart, injuring the lateral ligament. Lateral and medial dislocations happen far less commonly and are less likely to injure the popliteal artery.

Patients with a knee dislocation will typically report pain in the knee and report that the knee "gave out." If the knee did not spontaneously reduce, there may be evidence of significant deformity and decreased range of motion. Complications may include limb-threatening popliteal artery disruption, injuries to the nerves, and joint instability. Do not confuse this injury with a relatively minor patella dislocation, discussed below.

If adequate distal pulses are present, splint the knee in the position in which you found it, and transport the patient promptly. Do not attempt to manipulate or straighten any severe knee injury if there are good distal pulses. If the limb is straight, apply standard rigid long leg splints to at least two sides of the limb to stabilize it **Figure 31-46A**. If the knee is bent and the foot has a good pulse, splint the joint in the bent position, using parallel padded board splints secured at the hip and ankle joint to provide a stable A-frame **Figure 31-46B**. Secure the limb to a backboard or stretcher with pillows and straps to eliminate any motion during transport.

On rare occasions, and depending on local protocol, medical control may instruct you to realign a deformed, pulseless limb to reduce compression of the popliteal artery and, thus, restore distal circulation. Only make one attempt to do this. First, straighten the limb by applying gentle longitudinal traction in the axis of the limb. Once you apply manual traction, maintain it until the limb is fully splinted; otherwise, the limb will return to its deformed position. If traction significantly increases the patient's pain, do not continue. As you apply traction, monitor the posterior tibial pulse to see whether it returns. Splint the limb in the position in which you feel the strongest pulse. If you are unable to restore the distal pulse, splint the limb in the position that is most comfortable for the patient, and then provide prompt transport to the hospital. Notify medical control of the status of the distal pulse so that treatment can be arranged in advance.

Fractures About the Knee

Fractures about the knee may occur at the distal end of the femur, at the proximal end of the tibia, or in the patella. Because of local tenderness and swelling, it is easy to confuse a nondisplaced or minimally displaced fracture about the knee with a ligament injury. Likewise, a displaced fracture about the knee may produce significant deformity that makes it look like a dislocation. Manage these two types of injuries as follows:

- If there is an adequate distal pulse and no significant deformity, splint the limb with the knee straight.
- If there is an adequate pulse and significant deformity, splint the joint in the position of deformity.

- If the pulse is absent below the level of the injury, suspect possible vascular and nerve damage, and contact medical control immediately for further instructions.
- Never use a traction splint if you suspect a fractured knee.

Figure 31-46 **A.** When the injured knee is straight, apply padded board splints extending from the hip to the ankle. **B.** If the knee is flexed and the foot has good pulses, apply padded board splints with the knee in the flexed position.

Dislocation of the Patella

A dislocated patella most commonly occurs in teenagers and young adults who are engaged in athletic activities. Some patients have recurrent dislocations of the patella. As with recurrent dislocation of the shoulder, a minor twisting may be enough to produce the problem. Usually, the dislocated patella displaces to the lateral side. The displacement of the patella produces a significant deformity in which the knee is held in a moderately flexed position, and the patella is displaced to the lateral side of the knee Figure 31-47.

Splint the knee in the position in which you found it; most often, this is with the knee flexed to a moderate degree. To stabilize the knee, apply padded board splints to the medial and lateral aspects of the joint, extending from the hip to the ankle. Use pillows to support the limb on the stretcher.

Occasionally, as you apply the splint, the patella will return to its normal position spontaneously. When this occurs, stabilize the limb as for a knee ligament injury in a padded long leg splint, and transport the patient to the ED. Report the spontaneous reduction as soon as you arrive at the hospital so that the medical staff is aware of the severity of the injury.

Figure 31-47 Usually, the dislocated patella displaces to the lateral side, and the knee is held in a partially flexed position.

Injuries of the Tibia and Fibula

Fracture of the shaft of the tibia or the fibula may occur at any place between the knee joint and the ankle joint. Often both bones fracture at the same time. Even a single fracture may result in severe deformity, with significant angulation or rotation. Because the tibia is located just beneath the skin, open fractures of this bone are relatively common Figure 31-48.

Fractures of the tibia and fibula should be stabilized with a padded rigid long leg splint or an air splint that extends from the foot to the upper thigh. Once splinted, the affected leg should be secured to the opposite leg. Traction splints are not indicated for isolated tibial fractures. As with most other fractures of the shaft of long bones, you should correct severe deformity before splinting by applying gentle longitudinal traction. The goal is to restore a position that will take a standard splint; it is not necessary to replace the fracture fragments in their anatomic position.

Fractures of the tibia and fibula are sometimes associated with vascular injury as a result of the distorted position of the limb following injury. Realigning the limb frequently restores an adequate blood supply to the foot. If it does not, transport the patient promptly and notify medical control while you are en route.

Ankle Injuries

The ankle is a commonly injured joint. Ankle injuries occur in people of all ages and range in severity from a simple sprain, which heals after a few days of rest, to severe fracture-dislocations. As with other joints, it is sometimes difficult to tell a nondisplaced ankle fracture from a simple sprain without radiograph examination **Figure 31-49**. Therefore, any ankle injury that produces pain, swelling, localized tenderness, or the inability to bear weight must be evaluated by a physician. The most frequent mechanism of ankle injury is twisting, which stretches or tears the supporting ligaments. A more extensive twisting force may result in fracture of one or both malleoli. Dislocation of the ankle is usually associated with fractures of one or both malleoli.

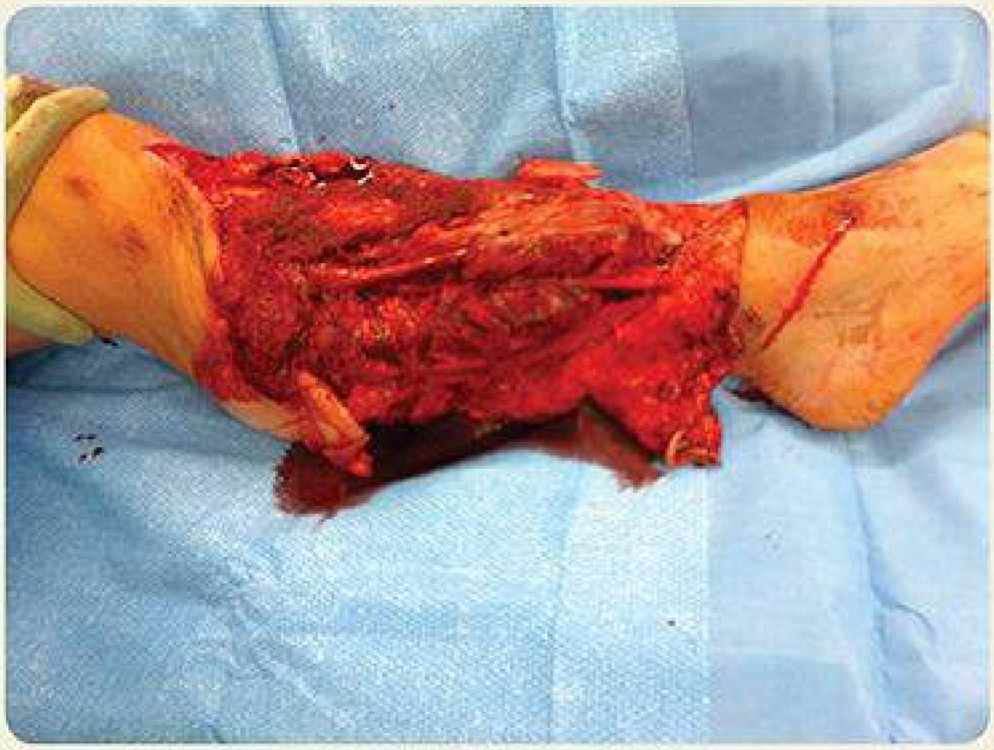

Figure 31-48 Because the tibia is so close to the skin, open fractures are relatively common.

You can manage the wide spectrum of injuries to the ankle in the same way, as follows:

1. Dress all open wounds.
2. Assess distal neurovascular function.
3. Correct any gross deformity by applying gentle longitudinal traction to the heel.
4. Before releasing traction, apply a splint.

You can use a padded rigid splint, an air splint, or a pillow splint. Make sure it includes the entire foot and extends up the leg to the level of the knee joint.

Foot Injuries

Injuries to the foot can result in the dislocation or fracture of one or more of the tarsals, metatarsals, or phalanges of the toes. Toe fractures are especially common.

Of the tarsal bones, the calcaneus, or heel bone, is the most frequently fractured. Injury often occurs when the patient falls or jumps from a height and lands directly on the heel. The force of injury compresses the calcaneus, producing immediate swelling and ecchymosis. If the force of impact is great enough, as from a fall from a roof or tree, there may also be other fractures.

Figure 31-49 Swelling about the ankle is characteristic of sprains and fractures.

Frequently, the force of injury is transmitted up the legs to the spine, producing a fracture of the lumbar spine **Figure 31-50**. When a patient who has jumped or fallen from a height reports heel pain, ask him or her about back pain and carefully check the spine for tenderness and deformity.

If you suspect that the foot is dislocated, immediately assess for pulses and motor and sensory functions. If pulses are present, stabilize the extremity using a commercially available splint or a pillow splint, leaving the toes exposed so that you can periodically assess neurovascular function. If pulses are absent, contact medical control and discuss reduction of dislocation if the local scope of practice permits.

Injuries of the foot are associated with significant swelling but rarely with gross deformity. Vascular injuries are uncommon. As in the hand, lacerations about the ankle and foot may damage important underlying nerves and tendons. Puncture wounds of the foot are common and may cause serious infection if not treated early. All of these injuries must be evaluated and treated by a physician.

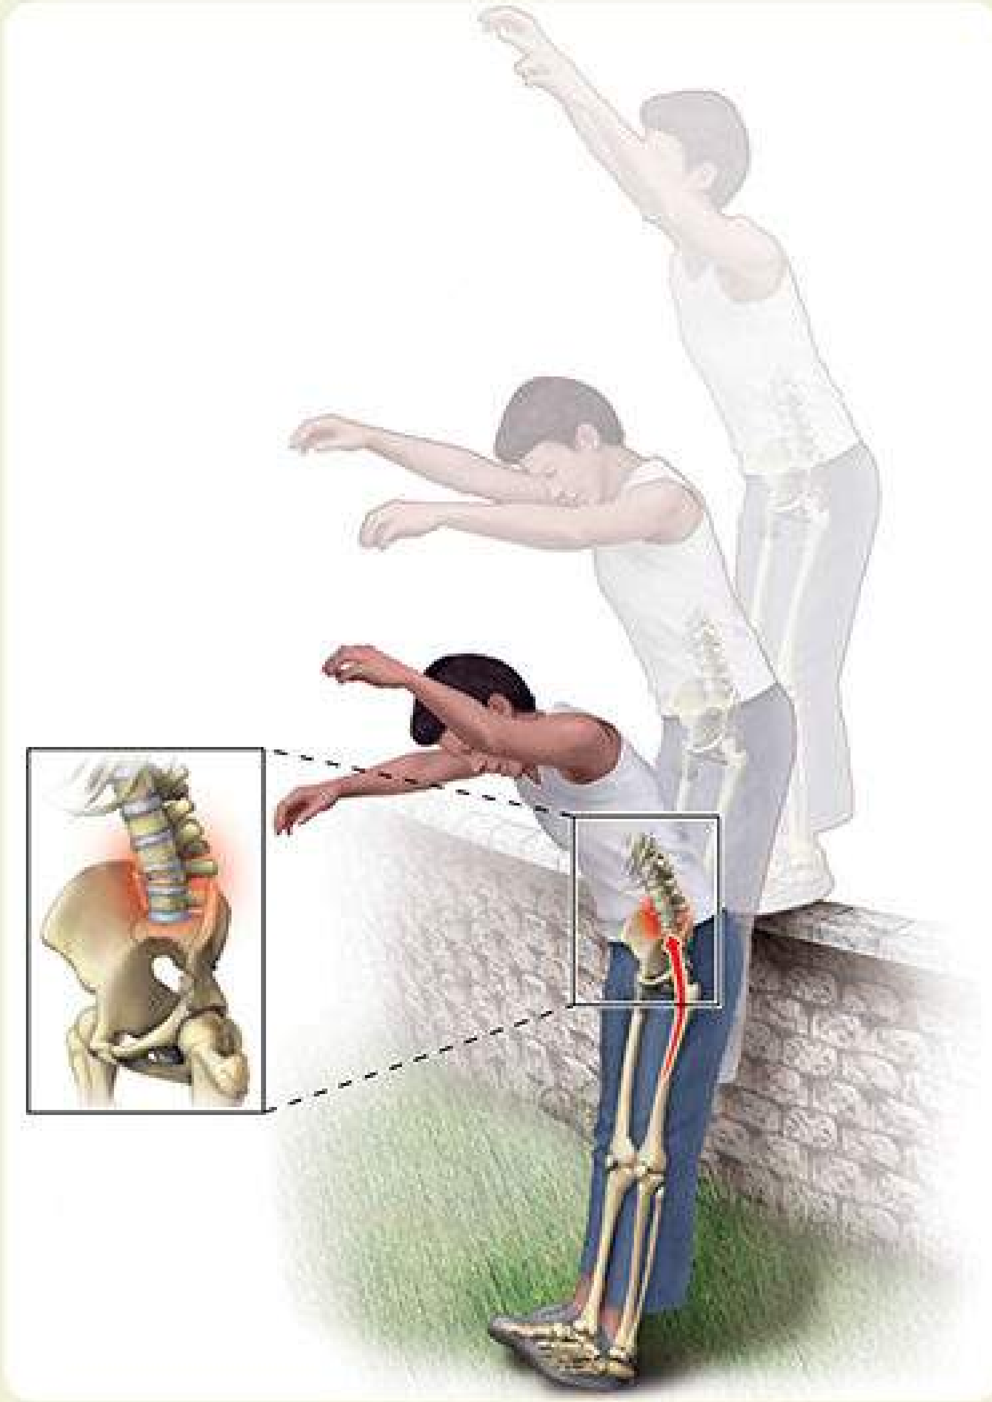

Figure 31-50 Frequently after a fall, the force of injury is transmitted up the legs to the spine, sometimes resulting in a fracture of the lumbar spine.

To splint the foot, apply a rigid padded board splint, an air splint, or a pillow splint, stabilizing the ankle joint and the foot Figure 31-51. Leave the toes exposed so that you can periodically assess neurovascular function.

When the patient is lying on the stretcher, elevate the foot approximately 6 inches (15 cm) to minimize swelling. All patients with lower extremity injuries should be transported in the supine position to allow for elevation of the limb. Never allow the foot and leg to dangle off the stretcher onto the floor or ground.

If a patient has fallen from a height and reports heel pain, use a backboard to immobilize any suspected spinal injury in addition to splinting the foot.

Sprains and Strains

Because it may be difficult to differentiate among the various types of injuries in the field, it is best to err on the side of caution and treat every severe sprain as if it is a fracture. Therefore, general treatment of sprains and strains is similar to that of fractures and includes RICES (Rest, Ice, Compression, Elevation, and Splinting as described in Chapter 26, *Soft-Tissue Injuries*). In addition, reduce or protect the limb from weight-bearing activity. Manage pain as soon as is practical.

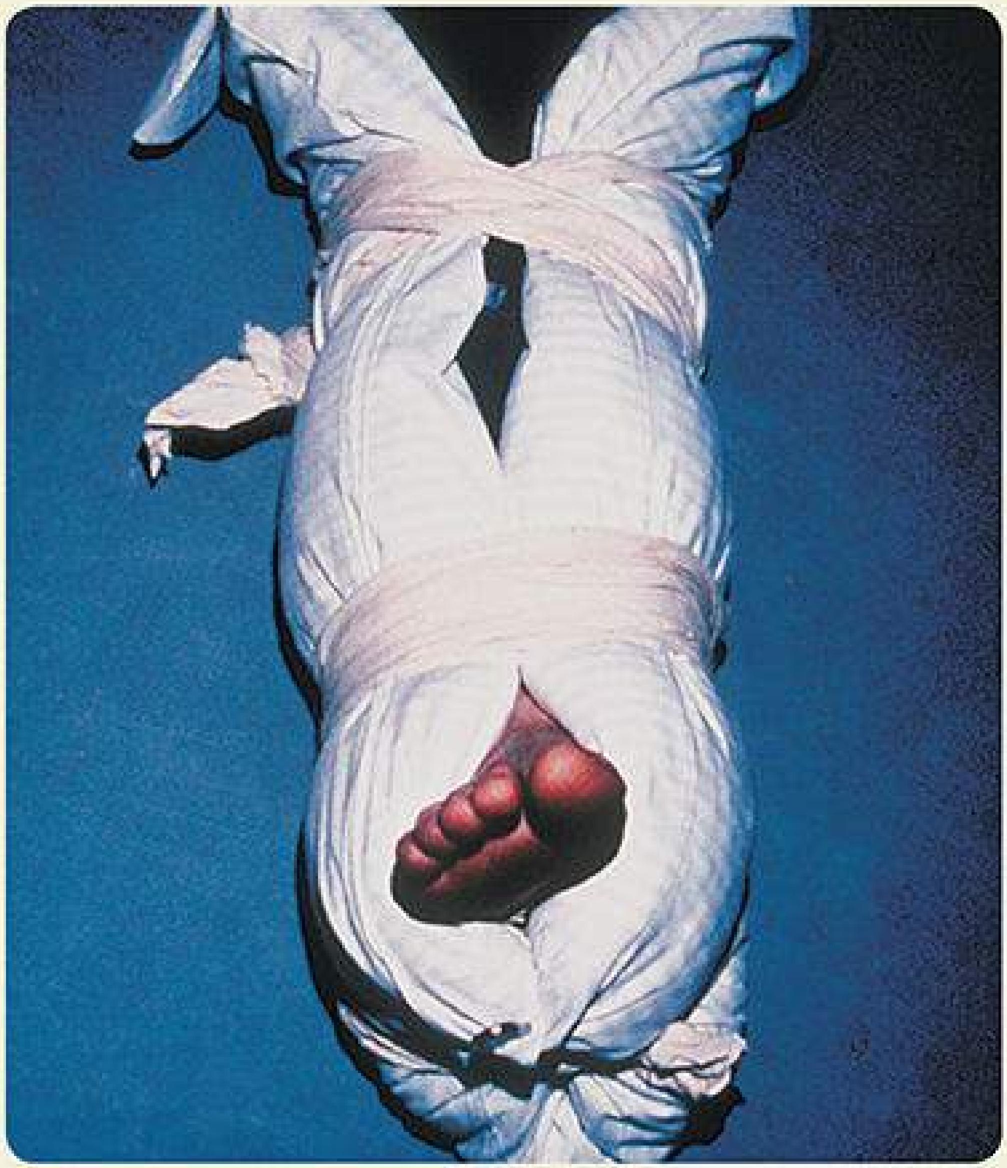

Figure 31-51 A pillow splint provides excellent stabilization of the foot.

Amputations

You must control bleeding and treat for shock when dealing with traumatic amputations. Complete traumatic amputations may occasionally not bleed much if the cut vessels go into spasm, reducing blood loss.

Surgeons today can occasionally reattach amputated parts **Figure 31-52**. However, correct prehospital care of the amputated part is vital to successful reattachment. With partial amputations, make sure to stabilize the part with bulky compression dressings and a splint to prevent further injury. Do not sever any partial amputations; this may complicate later reattachment. Hemorrhage from complete or incomplete amputations can be severe and life threatening. Control any bleeding from the stump. If bleeding is severe, quickly apply a tourniquet.

With a complete amputation, make sure to wrap the clean part in a sterile dressing and place it in a plastic bag. Follow your local protocols regarding how to preserve amputated parts. In some areas, dry sterile dressings are recommended for wrapping amputated parts; in other areas, dressings moistened with sterile saline are recommended. Put the bag in a cool container filled with ice. Lay the wrapped part on a bed of ice; do not pack it in ice. The goal is to keep the part cool without allowing it to freeze or develop frostbite. The amputated part should be transported with the patient to the appropriate resource hospital.

Compartment Syndrome

Be on the alert for **compartment syndrome**, which most commonly occurs with a fractured tibia in adults or forearm in children and can be overlooked, especially in patients with an altered level of consciousness. Compartment syndrome typically develops within 6 to 12 hours after injury, usually as a result of excessive bleeding, a severely crushed extremity, or the rapid return of blood to an ischemic limb. This syndrome is characterized by pain that is out of proportion to the injury, pain on passive stretch of muscles within the compartment, pallor (pale skin), decreased sensation, and decreased power (ranging from decreased strength and movement of the limb to complete paralysis). Compartment syndrome must be managed surgically.

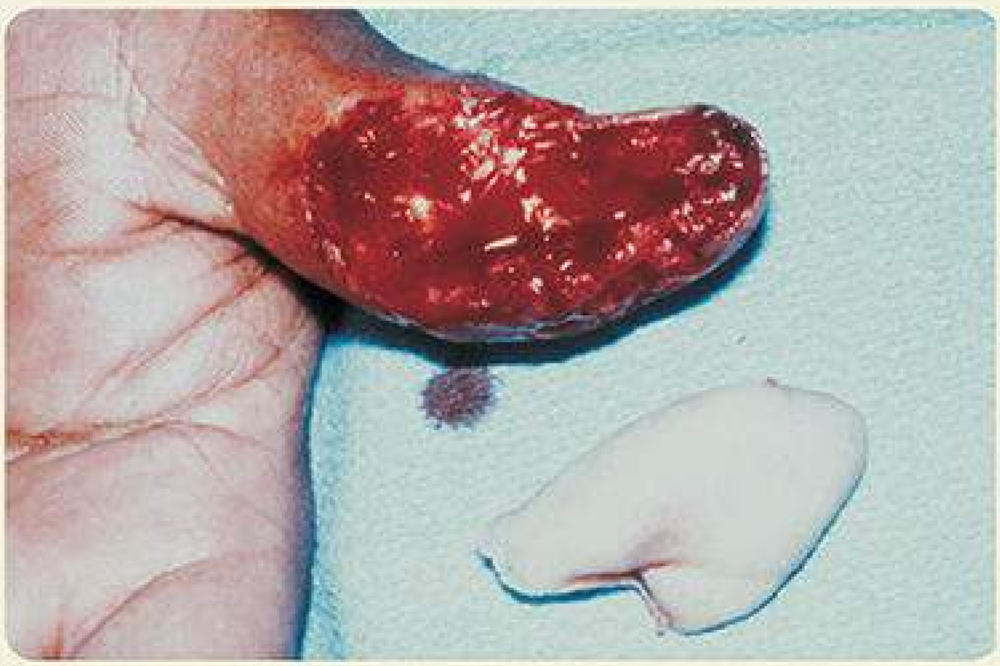

Figure 31-52 Amputated parts can occasionally be reattached, so make every attempt to find the part and transport it to the ED along with the patient.

If you have a patient with a fracture below the elbow or the knee, be on the lookout for extreme pain, decreased sensation or any tingling or numbness, pain on stretching of affected muscles, and decreased power. These are indicators that the pressure within a fascial compartment is elevated. If you suspect that a patient has compartment syndrome, splint the affected limb, keeping it at the level of the heart, and provide immediate transport, reassessing neurovascular status frequently during transport.

YOU are the Provider SUMMARY

1. Under which circumstances can orthopaedic injuries pose a threat to a patient's life?

Sprains, strains, and dislocations are rarely life threatening. Dislocations and isolated closed fractures can cause neurovascular damage and permanent disability if not treated promptly, but typically do not pose a threat to life. However, multiple closed long bone fractures, which can cause severe internal bleeding if bone fragments lacerate major blood vessels, can result in hypovolemic shock and death. Open fractures and extremity amputations (excluding fingers and toes) can also result in hypovolemic shock due to severe external bleeding. Amputation of a leg or arm can quickly lead to exsanguination (bleeding to death) if not promptly treated. Contamination of the wound could also lead to an infection of the underlying bone. Pelvic fractures are potentially life threatening because the pelvic cavity can accommodate a large volume of blood. Patients can die of pelvic fractures because hypovolemic shock occurs secondary to severe internal bleeding when a fractured bone fragment or dislocated bone lacerates or severs a major artery or vein or due to bleeding from fractured bone ends.

2. Given the information you have, can you rule out a critical injury?

No. As concise as the dispatch information can sometimes be, you will not know the extent of a patient's injury (or injuries) until you arrive at the scene and perform a patient assessment. In this case, all you know is that the patient is conscious and alert and breathing and has a possible leg fracture. While the dispatch information infers that this is an isolated injury secondary to a soccer-related incident, keep an open mind and avoid the preconceived notion that the leg injury is the only injury.

When you approach any patient, regardless of the nature of the call, you must perform a primary assessment in order to detect and correct immediate threats to airway, breathing, and circulation. Avoid tunnel vision when assessing and treating patients with orthopaedic trauma. A fractured leg may be the most obvious injury; however, it may not be the only injury. Furthermore, it may not be the most life-threatening injury.

3. What initial treatment should you provide to this patient?

Because the patient denies having any other injuries—for example, a neck injury, which may require spinal immobilization—your initial action, after taking standard precautions, should be to expose the injury site and then perform manual stabilization. With an injury in the tibia-fibula area, you or your partner should manually stabilize above the ankle and below the knee. Manual stabilization will help minimize the potential for further injury by preventing movement of the leg.

After you expose and manually stabilize the injury site, assess the patient for obvious signs of injury, such as swelling, deformity, bruising, and open wounds. The absence of deformity does not rule out an underlying fracture. Furthermore, swelling often masks underlying deformity. Treat any extremity injury as though an underlying fracture is present, and stabilize it appropriately.

4. What are some indicators of a fractured bone?

A fracture is defined as any break in the continuity of a bone and is classified as being open (overlying skin is not intact) or closed (overlying skin is intact). In many cases, the deformity is grossly obvious; in other cases, it is very subtle. Signs of a fracture include deformity, point tenderness, swelling, bruising, and crepitus:

5. How should you proceed with your assessment of this patient's injury?

This patient did not experience multisystem trauma or a significant mechanism of injury; therefore, a secondary assessment of the entire body is not indicated. Instead, focus on evaluating perfusion and sensory and motor functions distal to the injury. When you assess an extremity injury, remember the 6 Ps of musculoskeletal assessment: pain, paralysis, paresthesia, pulselessness, pallor, and pressure.

First, assess the patient's level of pain using a scale of 0 to 10. Next, assess perfusion. In some cases, a fractured bone end may compress or sever a blood vessel, resulting in inadequate or absent perfusion distal to the fracture. Compare the color of the skin with that of the uninjured limb. If perfusion is adequate, the skin should be pink and warm.

Palpate the dorsalis pedis pulse (on the top of the foot) and the posterior tibial pulse (on the posterior aspect of the ankle). Pulses that are weak or absent in comparison with pulses in the uninjured limb also suggest compromised perfusion.

Next, use a blunt object, and stroke it up the bottom and sides of her foot. If she is unable to feel you touching her foot, you should suspect that a nerve has been compressed or possibly severed by a fractured bone end. To test motor function, simply ask her to wiggle her toes; however, if this increases her pain, discontinue this part of the examination. Paresthesia (numbness or tingling) could indicate compromised perfusion and/ or nerve injury. A feeling of pressure distal to the injury site could indicate elevated pressure within a fascial compartment due to internal bleeding; if this continues, it could lead to compartment syndrome.

In addition to assessing perfusion and sensory and motor functions, assess the areas above and below the injury (the injury zone); in this case, the injury zone extends above her knee and below her ankle. Remember, her leg may be the most obvious injury, but it may not be the only injury.

6. How should you treat an injured extremity in which distal perfusion is absent?

As a general rule, you should splint an orthopaedic injury in the position it was found, provided that distal perfusion is intact. In some cases, an injured extremity may be so severely angulated that gentle longitudinal traction may be required in order to splint the injury effectively, even if distal perfusion is adequate.

If your assessment reveals that perfusion distal to the injury is compromised or absent (ie, pallor, absent distal pulses, cold skin), apply gentle longitudinal traction in order to realign the limb until perfusion is restored. The goal is not to return the extremity to its normal anatomic position, but rather to restore distal circulation. In many cases, gentle realignment of the limb restores adequate perfusion; however, if one attempt (local protocol may dictate more than one attempt) at realignment is unsuccessful, splint the injury, transport the patient as soon as possible, and notify the receiving facility early.

7. How should you splint this patient's injury?

Prior to splinting any extremity injury, assess the patient's distal perfusion and sensory and motor functions. Fractures of the tibia and fibula can be stabilized with a padded rigid leg splint; an air splint; or a vacuum splint that stabilizes the joints above and below the fracture site. In this case, stabilize the knee and ankle. As with most other fractures of the shaft of long bones, correct severe deformity before applying the splint by applying gentle longitudinal traction. Restore the deformed limb to a position that will accommodate a splint—not to its normal anatomic position. The affected leg, once splinted, should be secured to the opposite leg.

Immediately after the splint is secured in place, reassess distal perfusion and sensory and motor functions. If perfusion is found to be inadequate, the splint should be loosened or reapplied as necessary to restore this vital function.

8. What are some methods for providing pain relief from orthopaedic trauma?

Pain relief is an important aspect in the overall care of a patient with orthopaedic trauma. Pain increases anxiety, which only adds to the patient's problems.

After you apply the splint, which should be padded for comfort, elevate the injured extremity above the level of the heart. This will help reduce pain and swelling by encouraging blood to drain from the extremity.

Chemical cold packs wrapped with gauze or some other type of insulating material can be applied directly over the injury site. A cold stimulus applied to the skin constricts the blood vessels; this can help reduce swelling and pain.

Certain medications can be administered to the patient by a paramedic. In some cases, especially during a prolonged transport, it may be helpful to request ALS intervention.

9. What is the most likely cause of the patient's complaint? What can you can do to remedy the situation?

On the basis of the patient's complaint of numbness and tingling and your findings of pallor and weak pedal pulses, you should suspect that you applied the splint too tightly and that it is now impairing distal circulation.

Simply loosen the splint if it was applied too tightly. If you used padded board splints and triangular bandages (cravats), loosen the cravats. If you applied an air splint, release some of the air from the splint. If you applied a vacuum splint, gently attempt to spread the edges of the splint apart to the point at which the patient feels relief. If this is not possible and a prolonged transport time is anticipated, it would not be unreasonable to stop the ambulance and apply a different type of splint, provided that the patient's condition is stable. Regardless of the splint that you used, immediately reassess distal circulation after making any adjustments, and ask the patient whether the numbness and/or tingling has subsided. In most cases, these adjustments will lead to improvement.

10. What factors increase the risk of complications following orthopaedic trauma?

Orthopaedic injuries can lead to systemic complications. Do not focus all of your attention on the skeletal injury; after all, there is a patient attached to the injured extremity! The risk of complications following orthopaedic trauma is increased by a variety of factors, such as the amount of force that caused the injury, the injury location, and the patient's overall health. Injuries in patients who smoke cigarettes or who have diabetes, for example, tend to heal poorly and complications are more common.

Any fracture—open or closed—is accompanied by the risk of bleeding. In general, the severity of bleeding is directly related to the force that caused the injury. A significant loss of tissue may occur at the fracture site if the muscle is severely damaged or if the bone's penetration of the skin causes a large deformity.

Infection is another potential complication, especially in patients with open fractures or patients with other medical problems such as cigarette smoking or diabetes. To prevent contaminating an open fracture, and to minimize the risk of infection, brush away any obvious debris on the skin surrounding the fracture before covering it with a sterile dressing. Do not "probe" into an open fracture in an attempt to retrieve debris.

Long-term disability is one of the most devastating complications of orthopaedic trauma. In many cases, a severely injured limb can be successfully repaired; however, many patients may not be able to work for long periods because of severe, chronic pain and the extensive rehabilitation that is often required.

As an EMT, you can help reduce the risk of complications, thus reducing the risk or duration of long-term disability following orthopaedic trauma, by preventing further injury, properly splinting orthopaedic injuries, reducing the risk of wound infection, and transporting patients to an appropriate medical facility.

EMS Patient Care Report (PCR)

Date: 12-23-16	**Incident No.:** 012909	**Nature of Call:** Leg injury		**Location:** 404 Field Drive	
Dispatched: 1620	**En Route:** 1620	**At Scene:** 1625	**Transport:** 1644	**At Hospital:** 1656	**In Service:** 1707

Patient Information

Age: 21 **Sex:** F **Weight (in kg [lb]):** 50 kg (110 lb)	**Allergies:** Codeine **Medications:** Birth control pills **Past Medical History:** None **Chief Complaint:** Left leg pain

Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** Cold pack; elevated injured leg

Narrative

Medic 8 dispatched to a soccer field for a patient with a "possible broken leg." Arrived on scene and found the patient, a 21-year-old woman, sitting on the ground with her left leg extended and covered with an ice pack. She was conscious and alert; her airway was patent, and her breathing was adequate. Patient states that she injured her left leg when another player fell against it during the game. Assessment of her leg revealed obvious deformity to the midshaft tibial area. Patient describes pain severity as a "9" on a 0 to 10 scale. No open injuries were noted. Pulse and sensory and motor functions were grossly intact distal to the injury. A nurse was present at the scene and assisted EMS by manually stabilizing the injury site. The patient denies any other injuries; she further denies any past medical history. Secondary assessment was performed and revealed no gross evidence of injury to the areas above her knee and below her ankle on the injured extremity. Her right lower extremity was also normal. Vital signs were obtained and noted above. Splinted injured extremity with padded board splints; pulse and sensory and motor functions were assessed after splinting and were found to be grossly intact. Secured patient onto stretcher, elevated her left leg with pillows, loaded her into the ambulance, and began transport. Applied cold pack to injury site for pain relief. Patient stated that elevation of her leg and the cold pack reduced her pain to a 5/10. Monitored patient's vital signs en route and noted that they remained stable. Patient began reporting paresthesia to her left foot during transport. Reassessment of area distal to the injury revealed that her foot was cool and pale and her pedal pulse was weaker than before. Loosened bandages that were securing splints in place, after which patient stated that the paresthesias resolved; her foot regained a pink color and became warm, and her pedal pulse was stronger following this intervention. Remainder of transport was uneventful. Delivered patient to emergency department, and gave verbal report to staff nurse. Medic 8 cleared the hospital and returned to service at 1707.**End of report**

Prep Kit

Ready for Review

- Skeletal or voluntary muscle attaches to bone and forms the major muscle mass of the body. This muscle contains veins, arteries, and nerves.
- There are approximately 206 bones in the human body. When this living tissue is fractured, it can produce bleeding and significant pain.
- A joint is a junction where two bones come into contact. Joints are stabilized in key areas by ligaments.
- A fracture is a broken bone, a dislocation is a disruption of a joint, a sprain is a stretching injury to the ligaments around a joint, and strain is a stretching of the muscle.
- Depending on the amount of kinetic energy absorbed by tissues, the zone of injury may extend beyond the point of contact. Always maintain a high index of suspicion for associated injuries.
- Fractures of the bones are classified as open or closed. Both are splinted in a similar manner, but remember to control bleeding and apply a sterile dressing to the open extremity injury before splinting.
- Fractures and dislocations are often difficult to diagnose without a radiograph examination. You will treat these injuries similarly. Stabilize the injury with a splint, and transport the patient.
- Signs of fractures and dislocations include pain, deformity, point tenderness, false motion, crepitus, swelling, and bruising.
- Signs of sprain include bruising, swelling, and an unstable joint.
- Compare the unaffected extremity with the injured extremity whenever possible.
- There are three main types of splints used by EMTs: rigid splints, traction splints, and formable splints.
- Remember to splint the injured extremity from the joint above to the joint below the injury site for complete stabilization.
- A sling and swathe is used commonly to treat shoulder dislocations and to secure injured upper extremities to the body. Lower extremities can be secured to the unaffected limb or to a backboard.
- The most common life-threatening musculoskeletal injuries are multiple fractures, open fractures with arterial bleeding, pelvic fractures, bilateral femur fractures, and limb amputations.

Vital Vocabulary

acromioclavicular (AC) joint A simple joint where the bony projections of the scapula and the clavicle meet at the top of the shoulder.

amputation An injury in which part of the body is completely severed.

articular cartilage A pearly white layer of specialized cartilage covering the articular surfaces (contact surfaces on the ends) of bones in synovial joints.

calcaneus The heel bone.

closed fracture Any break in a bone in which the overlying skin is not broken.

compartment syndrome An elevation of pressure within a closed fascial compartment, characterized by extreme pain, decreased pain sensation, pain on stretching of affected muscles, and decreased power; frequently seen in fractures below the elbow or knee in children.

crepitus A grating or grinding sensation or sound caused by fractured bone ends or joints rubbing together.

dislocation Disruption of a joint in which ligaments are damaged and the bone ends are no longer in contact.

displaced fracture A fracture in which bone fragments are separated from one another, producing deformity in the limb.

ecchymosis Bruising or discoloration associated with bleeding within or under the skin.

false motion Movement that occurs in a bone at a point where there is no joint, indicating a fracture; also called free movement.

fascia The fiberlike connective tissue that covers arteries, veins, tendons, and ligaments.

fibula The outer and smaller bone of the two bones of the lower leg.

fracture A break in the continuity of a bone.

glenoid fossa The part of the scapula that joins with the humeral head to form the glenohumeral joint.

hematuria Blood in the urine.

joint The place where two bones come into contact.

ligament A band of fibrous tissue that connects bones to bones. It supports and strengthens a joint.

nondisplaced fracture A simple crack in the bone that has not caused the bone to move from its normal anatomic position; also called a hairline fracture.

open fracture Any break in a bone in which the overlying skin has been broken.

pelvic binder A device to splint the bony pelvis to reduce hemorrhage from bone ends, venous disruption, and pain.

point tenderness Tenderness that is sharply localized at the site of the injury, found by gently palpating along the bone with the tip of one finger.

position of function A hand position in which the wrist is slightly dorsiflexed and all finger joints are moderately flexed.

reduce To return a dislocated joint or fractured bone to its normal position; to set.

retroperitoneal space The space between the abdominal cavity and the posterior abdominal wall, containing the kidneys, certain large vessels, and parts of the gastrointestinal tract.

sciatic nerve The major nerve to the lower extremities; controls much of muscle function in the leg and sensation in most of the leg and foot.

sling A bandage or material that helps to support the weight of an injured upper extremity.

splint A flexible or rigid device used to protect and maintain the position of an injured extremity.

sprain A joint injury involving damage to supporting ligaments, and sometimes partial or temporary dislocation of bone ends.

strain Stretching or tearing of a muscle; also called a muscle pull.

swathe A bandage that passes around the chest to secure an injured arm to the chest.

tibia The larger of the two lower leg bones responsible for supporting the major weight-bearing surface of the knee and the ankle; the *shinbone*.

tourniquet The bleeding control method used when a wound continues to bleed despite the use of direct pressure and elevation; useful if a patient is bleeding severely from a partial or complete amputation.

traction Longitudinal force applied to a structure.

zone of injury The area of potentially damaged soft tissue, adjacent nerves, and blood vessels surrounding an injury to a bone or a joint.

Assessment *in Action*

You and your partner are assigned to a post at an extreme sports competition. You are called to assess a 23-year-old man who was performing a midair trick on his bike when he lost control and landed on the bottom of the concrete ramp. When you arrive on scene, the patient is awake and alert and in extreme pain. He tells you that he flew over his handlebars and felt both of his upper legs snap. He denies experiencing any loss of consciousness.

1. You perform a secondary assessment of the entire body and find instability in the pelvis and deformity to the midshaft area of the femur in both legs. The patient's injuries were the result of a/an:

   A. high-energy impact.
   B. indirect force.
   C. direct blow.
   D. twisting force.

2. During your assessment of the lower extremities, the patient reports pain when you palpate his thigh. This is cw3alled:

   A. guarding.
   B. tenderness.
   C. swelling.
   D. bruising.

3. When you assess distal circulation in the patient's lower extremities, you should palpate the __________ pulse.

   A. femoral
   B. dorsalis pedis
   C. popliteal
   D. iliac

4. Further assessment of the patient reveals no other injuries or life threats. His vital signs include the following: pulse rate, 104 beats/ min; blood pressure, 118/72 mm Hg; and respirations, 20 breaths/min. Using the musculoskeletal grading system, you would classify this patient's injuries as:

A. minor.
B. moderate.
C. severe.
D. critical.

5. The primary goal of placing the patient's legs in in-line traction is to:

 A. minimize pain.
 B. avoid further neurovascular compromise.
 C. reduce swelling.
 D. prevent permanent disability.

6. You found instability in the pelvis during your assessment. How will you move this patient to your stretcher?

 A. Log roll the patient onto a backboard.
 B. Use a scoop stretcher.
 C. Ask the patient to slide onto the stretcher.
 D. Perform a direct ground lift.

7. Neurovascular function should be reassessed every _________ minutes.

 A. 5 to 10
 B. 10 to 15
 C. 15 to 20
 D. 20 to 30

8. Will this patient need ALS intervention? Why or why not?
9. Is this patient at risk for shock? Why or why not?
10. How can you help minimize the risk or duration of long-term disability in patients with musculoskeletal injuries?

CHAPTER
32

Environmental Emergencies

Courtesy of Neil Malcom Winkelmann.

National EMS Education Standard Competencies

Trauma

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

Environmental Emergencies

Recognition and management of

› Submersion incidents (pp 1157–1160, 1164–1165)
› Temperature-related illness (pp 1143–1146, 1149–1152, 1154–1157)

Pathophysiology, assessment, and management of

› Near drowning (pp 1157–1160, 1162–1164)
› Temperature-related illness (pp 1143–1157)
› Bites and envenomations (pp 1166–1172)
› Dysbarism (p 1165)
  • High altitude (p 1165)
  • Diving injuries (pp 1160–1164)
› Electrical injury (pp 1165–1166)
› Radiation exposure (Chapter 40, *Terrorism Response and Disaster Management*)

Knowledge Objectives

1. Identify the four factors that affect how a person deals with exposure to a cold or hot environment. (pp 1141–1142)
2. Describe the five ways heat loss occurs in the body, and how the rate and amount of heat loss or gain can be modified in an emergency situation. (pp 1142–1143)
3. Describe the four general stages of hypothermia. (pp 1143–1144)
4. Describe local cold injuries and their underlying causes. (pp 1145–1146)

5. Describe the process of providing emergency care to a patient who has sustained a cold injury, including assessment of the patient, review of signs and symptoms, and management of care. (pp 1146–1150)
6. Explain the importance of following local protocols when rewarming a patient who is experiencing moderate or severe hypothermia. (p 1149)
7. Describe the three emergencies that are caused by heat exposure, including their risk factors, signs, and symptoms. (pp 1151–1152)
8. Describe the process of providing emergency care to a patient who is experiencing a heat emergency, including assessment of the patient, review of signs and symptoms, and management of care. (pp 1152–1157)
9. Describe drowning, including its incidence, risk factors, and prevention. (pp 1157–1158, 1165)
10. List the basic rules of performing a water and ice rescue. (p 1158)
11. Explain why EMTs should have a prearranged rescue plan based on the environment in which they work. (p 1158)
12. List five conditions that may result in a spinal injury following a submersion incident and the steps for stabilizing a patient with a suspected spinal injury in the water. (pp 1157–1160)
13. Discuss recovery techniques and resuscitation efforts EMTs may need to follow when managing a patient who has been involved in a submersion incident. (p 1160)
14. Describe the three types of diving emergencies, how they may occur, and their signs and symptoms. (pp 1160–1162)
15. Describe the process of providing emergency care to a patient who has been involved in a drowning or diving emergency, including assessment of the patient, review of signs and symptoms, and management of care. (pp 1162–1164)
16. Discuss the types of dysbarism injuries, including their incidence, risk factors, signs and symptoms, and emergency medical treatment. (p 1165)
17. Discuss lightning injuries, including their incidence, risk factors, signs and symptoms, and emergency medical treatment. (pp 1165–1166)
18. Describe the process of providing emergency care to patients who have been bitten by each of the following venomous spiders: (pp 1166–1167)
    - Black widow spider
    - Brown recluse spider
19. Describe the process of providing emergency care to a patient who has sustained a bite or sting from each of the following insects and arachnids, including steps the EMT should follow if a patient develops a severe reaction to the sting or bite: (pp 1167–1168, 1171–1172)
    - Hymenoptera (bees, wasps, yellow jackets, and ants)
    - Scorpions
    - Ticks
20. Describe the process of providing emergency care to a patient who has been bitten by each of the following types of snake and is showing signs of envenomation: (pp 1168–1171)
    - Pit viper
    - Coral snake
21. Describe the process of providing emergency care to a patient who has been stung by a coelenterate or other marine animal. (p 1173)

Skills Objectives

1. Demonstrate the emergency medical treatment of local cold injuries in the field. (p 1150)
2. Demonstrate how to use a warm-water bath to rewarm the limb of a patient who has sustained a local cold injury. (p 1150)
3. Demonstrate how to treat a patient with heat cramps. (p 1154)
4. Demonstrate how to treat a patient with heat exhaustion. (pp 1154–1156, Skill Drill 32-1)
5. Demonstrate how to treat a patient with heat stroke. (pp 1156–1157)
6. Demonstrate how to stabilize a patient with a suspected spinal injury in the water. (pp 1157–1160, Skill Drill 32-2)
7. Demonstrate how to care for a patient who is suspected of having an air embolism or decompression sickness following a drowning or diving emergency. (p 1164)
8. Demonstrate how to care for a patient who has been bitten by a pit viper and is showing signs of envenomation. (pp 1170–1171)
9. Demonstrate how to care for a patient who has been bitten by a coral snake and is showing signs of envenomation. (p

1171)

10. Demonstrate how to care for a patient who has sustained a coelenterate envenomation. (p 1173)

Introduction

The human body functions best when all body systems operate in balance, a concept known as **homeostasis**. Environmental factors such as temperature and atmospheric pressure can overwhelm the body's ability to cope with its surroundings. A variety of medical emergencies can result, particularly in children, older people, people with chronic illnesses, and young adults who overexert themselves. These can lead to mental status changes, functional changes and, possibly, death. Environmental emergencies can occur in any setting and often accompany other illnesses and injuries that require treatment at the same time. For example, a trauma patient with hypothermia has a higher risk of death than a patient with a normal body temperature. As an EMT, you can save lives by recognizing and responding properly to these emergencies, most of which require prompt treatment in the hospital.

In this chapter you will learn how the body regulates core temperature, and the ways in which heat loss can occur. The various forms of heat-, cold-, and water-related emergencies are described, including how to diagnose and treat hypothermia, frostbite, and hyperthermia. You will also learn about pressure-related emergencies, or dysbarism injuries, caused by diving and high-altitude climbing; injuries caused by lightning; and envenomation, caused by bites and stings.

Factors Affecting Exposure

The following four factors will affect how a person deals with a cold or hot environment. These can be used as prevention strategies for those who work or play in extreme environmental temperatures. Consider these factors during the assessment of your patient to determine whether he or she was prepared for a cold or hot environment. A hiker prepared for a warm summer hike in the foothills will present and respond to treatment differently than a traveler stranded in a hot vehicle because the radiator boiled over.

1. **Physical condition.** Patients who are ill or in poor physical condition will not be able to tolerate extreme temperatures as well as those whose cardiovascular, metabolic, and nervous systems are all functioning well. For example, an athlete in peak physical condition performs better and is less likely to experience injury or illness than someone with a less active lifestyle. Exertion also plays a role. For instance, a brisk walk will generate body heat when you are out in the cold but will also produce heat when it is not needed, such as walking on a hot asphalt road because your vehicle ran out of gasoline.

YOU are the Provider — PART 1

At 1415 hours, you are dispatched to a residence at 1102 Rosewood Avenue for a 55-year-old man who fainted after working in his garden. The temperature is 98°F (36.7°C) and the humidity is high. You and your partner proceed to the scene; your response time is 7 minutes.

1. How does the body normally balance heat production and elimination?
2. What factors can decrease the body's ability to eliminate excess heat?

2. **Age.** Children and older adults are more likely to experience temperature-related illness. Infants have poor thermoregulation (the body's ability to maintain normal temperature) at birth and do not have the ability to shiver and generate heat when needed until about 12 to 18 months. An infant's surface-area-to-mass ratio is larger than an adult's, so infants heat up and cool down faster. When you get cold, you put on a sweater; a small child may not think to do this or may have difficulty finding and putting one on. On the other end of the spectrum, older adults have a loss of subcutaneous tissues as they age, reducing the amount of insulation they have. Poor circulation also contributes to increased heat loss. This is why older people often wear extra layers of clothing. Medications can also affect an older person's body thermostat, putting him or her at increased risk for temperature-related emergencies. Finally, older patients are also at high risk for falls, and lying immobile on a hot or cold surface can rapidly lead to overexposure.
3. **Nutrition and hydration.** Your body needs calories for your metabolism to function. Staying well hydrated provides water as a catalyst for much of this metabolism. A lack of food or water will aggravate both hot and cold stress. Calories provide fuel to burn, creating heat during the cold, and water provides sweat for evaporation and removing heat. Alcohol use may increase fluid loss and place the patient at greater risk for temperature-related emergencies.
4. **Environmental conditions.** Factors such as air temperature, humidity level, and wind can complicate or improve environmental situations. A light breeze helps you stay cool when it is hot outside, but a cold wind when it is cold

outside can be uncomfortable. Extremes in temperature and humidity are not needed to produce hot or cold injuries. Many hypothermia cases occur at temperatures between 30°F (minus 1°C) and 50°F (10°C). Most heat stroke cases occur when the temperature is 80°F (26.7°C) and the humidity is 80%. When evaluating your patient's condition, consider the environment and whether your patient is prepared for that situation. Older patients may turn the heat down in the winter or neglect to use air conditioning in the summer because of cost concerns. Some people may not open windows in a heat wave for fear of burglars. An understanding of the environmental conditions may help in your treatment decisions and give you an idea about how the patient will respond to your care.

Cold Exposure

Normal body temperature is 98°F (36.7°C). Complicated regulatory mechanisms keep this internal temperature constant, regardless of the **ambient temperature**, the temperature of the surrounding environment. If the body, or any part of it, is exposed to cold environments, these mechanisms may be overwhelmed. Cold exposure may cause injury to individual parts of the body, such as the feet, hands, ears, or nose, or to the body as a whole.

Because heat always travels from a warmer place to a cooler place, body heat tends to move into the environment. Heat loss can occur in the following five ways:

- **Conduction** is the transfer of heat from a part of the body to a colder object or substance by direct contact, such as when a warm hand touches cold metal or ice, or is immersed in water with a temperature of less than 98°F (36.7°C). Heat can also be gained if the object or substance being touched is warm.
- **Convection** occurs when heat is transferred to circulating air, such as when cool air moves across the body surface. A person who stands outside in windy, wintry weather and wears only lightweight clothing is mainly experiencing heat loss by convection. A person can gain heat if the air moving across the person's body is hotter than the temperature of the environment, such as in deserts or industrial settings like foundries, but it is more common to see rapid heat gain in spas and hot tubs where the water temperature may be well above body temperature.
- **Evaporation** is the conversion of any liquid to a gas, a process that requires energy, or heat. Evaporation is the natural mechanism by which sweating cools the body. This is why swimmers coming out of the water feel a sensation of cold as the water evaporates from their skin. People who exercise vigorously in a cool environment may sweat and feel warm at first, but later, as their sweat evaporates, they can become cold.
- **Radiation** is the transfer of heat by radiant energy. Radiant energy is a type of invisible light that transfers heat. Radiation causes heat loss, such as when a person stands in a cold room. Heat can also be gained by radiation; for example, when a person stands by a fire.
- **Respiration** causes body heat loss as warm air in the lungs is exhaled into the atmosphere and cooler air is inhaled. In warm climates, the air temperature can be well above body temperature, causing an individual to gain heat with each breath.

The rate and amount of heat loss or gain by the body can be modified in three ways:

1. **Increase or decrease heat production.** One way for the body to increase its heat production is to increase the rate of metabolism of its cells; the body can accomplish this through shivering (active movement of many muscles to generate heat). Also, people often have a natural urge to move around when they are cold. When a person is hot, he or she tends to reduce the level of activity, thus reducing heat production.
2. **Move to an area where heat loss is decreased or increased.** The most obvious way to decrease heat loss from radiation and convection is to move out of a cold environment and seek shelter from the wind. The same holds true for a patient who is too hot. Simply moving the patient into the shade can reduce the ambient temperature by 10 degrees or more. If you cannot move the patient, create shade and increase air movement by fanning the patient.
3. **Wear the appropriate clothing for the environment.** To avoid heat loss in cold environments, wear layers of clothing that provide good insulation, such as wool, down, and synthetic fabrics. Protective clothing traps perspiration and prevents evaporation, which prevents cooling. Keep the head, hands, and feet covered, and remove wet clothing if possible. To encourage heat loss in hot environments, wear lightweight, loose-fitting clothing, particularly around the head and neck.

Hypothermia

When the entire body temperature falls, the condition is called **hypothermia**. Hypothermia means "low temperature." It is diagnosed when the **core temperature** of the body—the temperature of the heart, lungs, and vital organs—falls below 95°F

(35°C). The body can usually tolerate a drop in core temperature of a few degrees. However, below this critical point, the body cannot regulate its temperature and generate body heat. Progressive loss of body heat then begins.

To protect itself against heat loss, the body normally constricts blood vessels in the skin; this results in the characteristic appearance of blue lips and/or fingertips. As a secondary precaution against heat loss, the body tends to create additional heat by shivering. As cold exposure worsens and these mechanisms are overwhelmed, many body functions begin to slow down and mental status deteriorates. Eventually, the functioning of key organs such as the heart begins to slow. Untreated, this can lead to death.

Hypothermia can develop either quickly, as when someone is immersed in cold water, or gradually, as when a person is exposed to the cold environment for several hours or more. Recall that the temperature does not have to be below freezing for hypothermia to occur. In winter, hypothermia at temperatures above freezing may develop in people experiencing homelessness and those whose homes lack. Even in summer, swimmers who remain in the water for a long time are at risk of hypothermia. Like all heat-and cold-related injuries, hypothermia is more common among geriatric, pediatric, and ill people, who are less able to adjust to temperature extremes.

Patients with injuries or illness, such as burns, shock, head injury, stroke, generalized infection, injuries to the spinal cord, diabetes, and hypoglycemia, are more prone to hypothermia, as are patients who have taken certain drugs or consumed alcohol.

Signs and Symptoms

Signs and symptoms of hypothermia generally become more severe as the core temperature falls. Hypothermia generally progresses through four stages, as shown in Table 32-1. Although there is no clear distinction among the stages, the different signs and symptoms of each will help you estimate the severity of the condition. When you assess a patient in the field, you should be able to distinguish between mild and severe hypothermia.

Table 32-1 Characteristics of Systemic Hypothermia

Core Temperature	93° to 95°F (33.9° to 35°C)	89° to 92°F (31.7° to 33.3°C)	80° to 88°F (26.7° to 31.1°C)	<80°F (<26.7°C)
Signs and symptoms	Shivering, foot stamping	Loss of coordination, muscle stiffness	Coma	Apparent death
Cardiorespiratory response	Constricted blood vessels, rapid breathing	Slowing respirations, slow pulse	Weak pulse, dysrhythmias, very slow respirations	Cardiac arrest
Level of consciousness	Withdrawn	Confused, lethargic, sleepy	Unresponsive	Unresponsive

Figure 32-1 To assess a patient's core body temperature, pull back your glove and place the back of your hand on the patient's skin at the abdomen.

To assess the patient's core body temperature (CBT), pull back on your glove and place the back of your hand on the patient's skin at the abdomen **Figure 32-1**. This area of the body is usually well protected and will give you a quick, general idea of the patient's core temperature. If the skin feels cool, the patient is likely experiencing a generalized cold emergency.

If you work in a cold environment, and/or depending on local protocols, you may carry a hypothermia thermometer, which registers lower core temperatures. It must be inserted in the rectum for an accurate reading. Regular thermometers will not register the temperature of a patient who has significant hypothermia.

Mild hypothermia occurs when the core temperature is between 90°F and 95°F (32.2°C and 35°C). The patient is usually alert and shivering in an attempt to generate more heat through muscular activity. The patient may jump up and down and stamp his or her feet. Pulse rate and respirations are usually rapid. The skin in light-skinned people can be red, but may eventually appear pale, then cyanotic. People in a cold environment may have blue lips or fingertips because of the body's constriction of blood vessels at the skin to retain heat.

More severe hypothermia occurs when the core temperature is less than 90°F (32.2°C). Shivering stops and muscular activity decreases. At first, small, fine muscle activity such as coordinated finger motion ceases. Eventually, as the temperature falls further, all muscle activity stops and mental status deteriorates.

As the core temperature drops toward 85°F (29.4°C), the patient becomes lethargic, and usually stops fighting the cold. The level of consciousness decreases, and the patient may try to remove his or her own clothes. Poor coordination and memory loss follow, along with reduced or complete loss of sensation to touch, mood changes, and impaired judgment. The patient becomes less communicative, experiences joint or muscle stiffness, and has trouble speaking. The patient begins to appear stiff or rigid.

If the core temperature continues to fall to 80°F (26.7°C), vital signs slow; the pulse becomes slower and weaker, and respirations become shallow or absent. Cardiac dysrhythmias may occur as the blood pressure decreases.

At a core temperature of less than 80°F (26.7°C), all cardiorespiratory activity may cease, pupillary reaction is slow, and the patient may appear dead. However, *never assume that a cold, pulseless patient is dead.* Patients may survive severe hypothermia if proper emergency care is provided. It is critical that you perform an extended pulse check (up to a full minute). Assess at the carotid or femoral pulse. A patient in apparent cardiac arrest from hypothermia should not be considered dead until aggressive rewarming has been attempted, along with resuscitation. Remember the saying: "No one is dead unless they are *warm* and dead." It is important to note that patients who have died from a cause other than hypothermia will be cold to the touch; however, there will be additional, obvious signs of death such as rigor mortis. The "warm and dead" rule does not apply to such patients.

Words of Wisdom

The stress of the cold environment, a remote terrain, a feeling of impending doom, and impaired judgment may lead to suicidal tendencies in some patients with hypothermia. It is important to protect patients from harming themselves, while considering your own safety at all times.

Local Cold Injuries

Most injuries from cold are confined to exposed parts of the body. The extremities, particularly the feet and hands, and the ears, nose, and face are especially vulnerable to cold injury **Figure 32-2**. When exposed parts of the body become very cold but not frozen, injuries such as frostnip and immersion foot (also called trench foot) can result. When the parts become frozen, the injury is called **frostbite**.

If possible, determine the duration of the exposure, the temperature to which the body part was exposed, and the wind velocity during exposure. These important factors will help you determine the severity of a local cold injury. You should also investigate a number of underlying factors:

- Exposure to wet conditions
- Inadequate insulation from cold or wind
- Restricted circulation from tight clothing or shoes or circulatory disease
- Fatigue
- Poor nutrition
- Alcohol or drug abuse
- Hypothermia
- Diabetes
- Cardiovascular disease
- Age

In hypothermia, blood is shunted away from the extremities in an attempt to maintain the core temperature. This shunting of blood increases the risk of local cold injury to the extremities, ears, nose, and face. Thus, the patient with hypothermia should also be assessed for frostbite or other local cold injury. The reverse is also true. Remember, both local and systemic cold exposure injuries can occur in the same patient.

Figure 32-2 The extremities and the ears, nose, and face are particularly susceptible to frostbite.

Frostnip and Immersion Foot

After prolonged exposure to the cold, the skin may freeze whereas the deeper tissues are unaffected. This condition, which often affects the ears, nose, and fingers, is called frostnip. Because frostnip is usually painless, the patient often is unaware that a cold injury has occurred. Immersion foot occurs after prolonged exposure to cold water. It is particularly common in hikers or hunters who stand for a long time in a river or lake. With both frostnip and immersion foot, the skin is pale (blanched) and cold to the touch; normal color does not return after palpation of the skin. In some cases, the skin of the foot will be wrinkled, but it can also remain soft. The patient reports loss of feeling and sensation in the injured area.

Frostbite

Frostbite is the most serious local cold injury because the tissues are actually frozen. Freezing permanently damages cells, although the exact mechanism by which damage occurs is unknown. The presence of ice crystals within the cells may cause physical damage. The change in the water content in the cells may also cause changes in the concentration of critical electrolytes, producing permanent changes in the chemistry of the cell. When the ice thaws, further chemical changes occur in the cell, causing permanent damage or cell death, called necrosis or gangrene **Figure 32-3**. If gangrene occurs, the dead tissue must be surgically removed, sometimes by amputation. Following less severe damage, the exposed part will become inflamed, tender to touch, and unable to tolerate exposure to cold.

Figure 32-3 Gangrene (necrosis), or permanent cell death, occurs when tissue is frozen and destructive chemical changes occur in the cells.

Courtesy of Dr. Jack Poland/CDC.

Frostbite can be identified by the hard, waxy feel of the affected tissues **Figure 32-4**. The injured part feels firm to frozen as you gently touch it. If the frostbite is only skin deep, it will feel leathery or thick instead of hard. Blisters and swelling may be present. In light-skinned people with a deep injury that has thawed or partially thawed, the skin may appear red or white, or it may be mottled and cyanotic (purple and blue).

As with a burn, the depth of skin damage will vary. With superficial frostbite, only the skin is frozen; with deep frostbite, the deeper tissues are frozen as well. You may not be able to tell superficial from deep frostbite in the field. Even an experienced surgeon in a hospital setting may not be able to tell until several days have passed.

Figure 32-4 Frostbitten parts are usually hard and waxy to the touch.

Assessment of Cold Injuries

Management of hypothermia in the field, regardless of the severity of the exposure, consists of stabilizing the ABCs and preventing further heat loss.

Scene Size-up

Typically, your scene assessment begins with information provided by dispatch. Note environmental conditions. Air temperature, wind chill, and whether it is wet or dry are important aspects of scene size-up and will likely affect the patient.

Ensure that the scene is safe for you and other emergency responders. Identify potential safety hazards, such as wet grass, mud, or icy streets. Cold environments may present special challenges both for you and your patient; consider special hazards such as avalanches. Use appropriate standard precautions and consider the number of patients you may have. Summon additional help, such as a search and rescue team, as quickly as possible.

As you observe the scene, look for indicators of the mechanism of injury (MOI). For example, if you find a vehicle in a secluded ditch off the highway and the vehicle's roof and hood are covered with fresh snow, then you may assume that the patient was in a motor vehicle crash and has been exposed to the cold for a long period of time.

Primary Assessment

In a cold emergency, your patient's chief complaint may be only that he or she is cold, or the cold may be an additional complication of an existing medical injury or trauma. Perform a rapid examination to determine whether a life threat exists, and if so, treat it. If the chief complaint is simply feeling cold, quickly assess the patient's core temperature by placing the back of your hand on the abdomen. Evaluate the patient's mental status quickly using the AVPU scale. An altered mental status indicates the intensity of the cold injury. Consider spinal immobilization based on your scene size-up and the chief complaint.

Your assessment should take into account the physiologic changes that occur as a result of hypothermia. If you believe the patient is in cardiac arrest, proceed directly to ("C") by providing high-quality chest compressions, then address airway and breathing ("A" and "B") afterward. Ensure that the patient has an adequate airway and is breathing. If your patient's breathing is slow or shallow, ventilation with a bag-valve mask (BVM) may be necessary. Use warmed and humidified oxygen if it is available, because it helps to warm the patient from the inside out.

If you cannot feel a radial pulse, gently palpate for a carotid pulse and wait for up to 60 seconds before you decide whether the patient is pulseless. Some physicians disagree about performing cardiopulmonary resuscitation (CPR) on a patient with hypothermia who appears to be pulseless. Such a patient actually may be in a kind of "metabolic icebox," having achieved a metabolic balance that CPR may disrupt. Even a pulse rate of 1 or 2 beats/min indicates cardiac activity, and cardiac activity may spontaneously recover once the body core is warmed. However, there is evidence that CPR, when correctly done, will increase blood flow to the critical parts of the body. For this reason, some authorities recommend starting CPR on a patient with hypothermia and no pulse. The American Heart Association recommends that CPR be started if the patient has no detectable pulse or breathing. Again, for a patient with hypothermia, this may require a prolonged pulse check of up to 60 seconds.

Perfusion will be compromised based on the severity of the cold exposure. Your assessment of the patient's skin will not be helpful in determining shock. Assume that shock is present and treat it appropriately. Bleeding may be difficult to find because of the slow-moving circulation and thick clothing. If the scene size-up, MOI, or chief complaint suggests the potential for bleeding, look for it carefully.

Even mild hypothermia can have serious consequences and complications, including cardiac dysrhythmias and blood clotting abnormalities. Therefore, all patients with hypothermia require rapid transport for evaluation and treatment. Assess the scene for the safest way to quickly move your patient from the cold environment. As you package your patient for transport, work quickly, safely, and gently. Rough handling of a patient with hypothermia may cause a cold, slow, weak heart to fibrillate. If transportation is delayed, protect the patient from further heat loss.

History Taking

After the life threats have been managed during the primary assessment, investigate the chief complaint. Obtain a medical history and be alert for injury-specific signs and symptoms as well as any pertinent negatives.

Obtaining a patient's history in these situations may be difficult. If possible, find out how long your patient has been exposed to the cold environment, either from the patient or bystanders. Exposures may be short or prolonged in duration. For example, a patient may have acute hypothermia from sudden immersion in cold water or hypothermia that developed over the course of hours during an expedition. Your SAMPLE history can provide important information affecting both your treatment in the field and the treatment your patient will receive in the hospital. Recall that medications and underlying medical conditions may have an impact on the way cold affects the patient's metabolism. The patient's last oral intake and activity prior to the exposure will help to determine the severity of the cold injury.

Secondary Assessment

The secondary assessment is used to uncover injuries that may have been missed during the primary assessment. In some instances, such as a critically injured patient or a short transport time, you may not have time to conduct a secondary assessment.

Focus your physical examination on the severity of hypothermia, assessing the areas of the body directly affected by cold exposure, and the degree of damage. Is the whole body cold (hypothermia) or just parts (frostbite)? These determinations will impact your treatment decisions. For example, a patient who stops shivering, but remains in a cold environment, will experience a rapid decrease in body temperature—a sign of severe hypothermia and a life-threatening emergency.

Determine the degree and extent of cold injury, as well as any other injuries or conditions that may not have been initially detected. The numbing effect of cold, both on the brain and on the body, may impair your patient's ability to tell you about other injuries or illnesses. Therefore, a careful examination of your patient's entire body will help you avoid missing important clues to your patient's condition.

Keep in mind that vital signs may be altered by the effects of hypothermia and can be an indicator of its severity. Respirations may be slow and shallow, resulting in low oxygen levels in the body. Low blood pressure and a slow pulse also indicate moderate to severe hypothermia. Carefully evaluate your patient for changes in mental status using the AVPU scale.

Determine a core body temperature using a hypothermia thermometer, if local protocols allow. Pulse oximetry will often be inaccurate due to the lack of perfusion in the extremities.

Reassessment

Repeat the primary assessment. Reassess vital signs and the chief complaint. Has the patient's condition improved with the interventions? Identify and treat changes in the patient's condition. Keep a close eye on your patient's level of consciousness and vital signs. As the body rewarms, the sudden redistribution of fluids and the release of built-up chemicals can have harmful effects, including cardiac dysrhythmias. Be vigilant even if the patient's condition appears to be improving.

Review all treatments that have been performed. In a cold-related emergency, depending on your local protocols, your treatment may only include oxygen delivery. Reassess oxygen delivery and continue to provide for a warm environment by removing any wet or frozen clothing. Do not remove any clothing frozen to the patient's skin.

YOU are the Provider PART 2

You arrive at the scene and find the patient, sitting under a tree in his garden; he is conscious, but confused. His wife tells you that he has been working outside all day. She further states that despite her efforts, he refused to take a break and drink some water. As your partner opens the jump kit, you perform a primary assessment.

Recording Time: 0 Minutes	
Appearance	Flushed
Level of consciousness	Conscious, but confused
Airway	Open, clear of secretions or foreign bodies
Breathing	Increased rate and depth
Circulation	Radial pulses, weak and rapid; skin is hot and moist; no gross bleeding

Your partner applies high-flow oxygen via a nonrebreathing mask, and the patient's wife tells you that when she went to check on him, she found him sitting under a tree; initially, he did not respond to her. She further tells you that he has hypertension and angina, for which he takes furosemide (Lasix), potassium chloride (K-Dur), lisinopril (Prinivil), and nitroglycerin as needed.

3. What risk factors does this patient have that predispose him to a heat emergency?

4. What type of heat emergency do you suspect he is experiencing? Why?

Communicate all of the information you have gathered to the receiving facility, which may be essential in evaluating and treating your patient in the hospital. Your documentation should always include the patient's physical status, the conditions at the scene, information gathered from bystanders, and any changes in the patient's mental status during treatment and transport.

General Management of Cold Emergencies

In most cases, move the patient from the cold environment to prevent further heat loss. To prevent further damage to the feet, do not allow the patient to walk. Remove any wet clothing, and place dry blankets over and under the patient **Figure 32-5**. If available, give the patient warm, humidified oxygen if you have not already done so as part of the primary assessment.

Always handle the patient gently so that you do not cause any pain or further injury to the skin. Rough handling of a patient with moderate to severe hypothermia may cause the heart to go into ventricular fibrillation, which may not respond to defibrillation. Do not massage the extremities. Do not allow the patient to eat or to use any stimulants, such as coffee, tea, soda, or tobacco products. Stimulants are vasoconstrictors, which may further impair circulation to affected areas.

Figure 32-5 Place dry blankets over and under the patient with hypothermia; give warm, humidified oxygen, if available; assess the pulse for up to 60 seconds before considering CPR.

If the patient is alert, shivering, responds appropriately, and the core body temperature is between 90°F to 95°F (32.2°C to 35°C), then the hypothermia is mild. Begin passive rewarming slowly, which includes placing the patient in a warm environment, removing wet clothing, and applying heat packs or hot water bottles to the groin, axillary, and cervical regions. Turn the heat up high in the patient compartment of the ambulance. To avoid burns, do not place heat packs directly on the skin. If possible, you may give warm fluids by mouth, as allowed by local protocols, assuming that the patient is alert and can swallow without difficulty.

However, when the patient has moderate or severe hypothermia, active rewarming is best accomplished in the emergency department (ED) utilizing aggressive strategies to introduce heat into the body's core. Such therapies might include warm intravenous fluids, lavage with warm fluids, and rewarming blood outside the body before reintroducing it (extracorpeal rewarming). Rewarming the patient too quickly may cause a fatal cardiac dysrhythmia or other significant complications. For this reason, local protocols may dictate the appropriate type of rewarming strategies based on the patient's core body temperature.

With a patient with moderate or severe hypothermia, your goal is to prevent further heat loss. Remove the patient immediately from the cold environment, place the patient in the ambulance, remove wet clothing, cover the patient with blankets, and transport. Remember to handle the patient gently to decrease the risk of ventricular fibrillation.

If you cannot get the patient out of the cold immediately, move the patient out of the wind and away from contact with any object that will conduct heat away from the body. Place blankets and a waterproof protective cover on the patient. Remember that body heat loss easily occurs around the head and neck, both of which can be covered with a towel. Regardless of the nature or severity of the cold injury, remember that even an unresponsive patient may be able to hear you. Some patients have reported hearing a provider pronounce them dead—a provider who forgot the saying: "No one is dead unless they are warm and dead."

▶ Emergency Care of Local Cold Injuries

The emergency treatment of local cold injuries in the field should include the following steps:

1. Remove the patient from further exposure to the cold.
2. Handle the injured part gently, and protect it from further injury.
3. Remove any wet or restricting clothing from the patient, especially over the injured part.

If there is no chance of reinjury or if transport to the ED will be significantly delayed, consider active rewarming if local protocols allow. Consult medical control, if available. With frostnip, contact with a warm object may be all that the patient needs; you can use your hands or the patient's own body (for example, have the patient tuck his or her hands into the armpits). During rewarming, the affected part will often tingle and become red in light-skinned people. With immersion foot, remove wet shoes, boots, and socks, and rewarm the foot gradually, protecting it from further cold exposure. Next splint the extremity, and cover it loosely with a dry, sterile dressing. Never rub or massage injured tissues, which could cause further damage. Do not reexpose the injury to cold.

With a late or deep cold injury, such as frostbite, remove any jewelry from the injured part and cover the injury loosely with a dry, sterile dressing. Do not break blisters or rub or massage the area. Do not apply heat or rewarm the part. Unlike frostnip and trenchfoot, rewarming of the frostbitten extremity is best accomplished in the ED. You can cause further injury to fragile tissues by attempting to rewarm a frostbitten part. Never apply something warm or hot, such as the exhaust from the ambulance engine or, even worse, an open flame. Do not allow the patient to stand or walk on a frostbitten foot. Splinting a frostbitten extremity may also help prevent secondary injury by limiting use. Evaluate the patient's general condition for the signs or symptoms of systemic hypothermia. Support the vital functions as necessary, and provide rapid transport to the hospital.

If prompt hospital care is unavailable and medical control instructs you to begin rewarming in the field, use a warm-water bath. Immerse the frostbitten part in water with a temperature between 102°F and 104°F (38.9°C and 40°C). Check the water temperature with a thermometer before immersing the limb, and recheck it frequently during the rewarming process. The water temperature should never exceed 105°F (40.6°C). Stir the water continuously. Keep the frostbitten part in the water until it feels warm and sensation has returned to the skin. Dress the area with dry, sterile dressings, placing them also between injured fingers or toes. Expect the patient to report severe pain.

Never attempt rewarming if there is any chance that the part may freeze again before the patient reaches the hospital. Some of the most severe consequences of frostbite, including gangrene and amputation, have occurred when parts were thawed and then refrozen.

Cover the frostbitten part with soft, padded, sterile cotton dressings. If blisters have formed, do not break them. Remember, you cannot accurately predict the outcome of a case of frostbite early in its course. Even body parts that appear gangrenous may recover following proper treatment.

Cold Exposure and You

As an EMT, you are also at risk for hypothermia if you work in a cold environment. If cold weather search-and-rescue operations are a possibility in your assigned areas, you should receive survival training and precautionary tips. Become familiar with local conditions. Be aware of existing and potential weather conditions, and monitor changes that are forecast for the area. Make sure to wear proper clothing whenever appropriate. Your vehicle, too, must be properly equipped and maintained for a cold environment. You cannot help others if you do not protect yourself. Never allow yourself to become a victim!

Heat Exposure

Recall that normal body temperature is 98°F (36.7°C). In a hot environment or during vigorous physical activity, the body will try to rid itself of the excess heat. The two most efficient methods to decrease heat are sweating (and evaporation of the sweat) and dilation of skin blood vessels, which brings blood to the skin surface to increase the rate of heat radiation. In addition, a person who becomes overheated can remove clothing and seek a cooler environment.

Ordinarily, the heat-regulating mechanisms of the body work well, and people are able to tolerate significant temperature changes. When heat gain exceeds heat loss, hyperthermia can result. **Hyperthermia** is a high core temperature, usually 101°F (38.3°C) or higher.

Words of Wisdom

It is important to keep yourself hydrated while on duty, especially during periods of heavy exertion or when working in the heat. The color of urine (usually darker with dehydration) and frequency of urination correlate directly with the body's hydration status.

When the body's mechanisms to decrease body heat are overwhelmed and the body is unable to tolerate the excessive heat, a heat emergency develops in the patient. High air temperature can reduce heat loss by radiation; high humidity reduces heat loss through evaporation. The inability to acclimate (adjust) to the heat is a risk factor. Another risk factor is vigorous exercise, during which sweat loss can exceed one liter an hour, causing loss of fluid and electrolytes.

A heat emergency can take the following three forms:

- Heat cramps
- Heat exhaustion
- Heat stroke

All three forms may be present in the same patient because untreated heat exhaustion may progress to heatstroke. Heatstroke is life threatening.

People at greatest risk for a heat emergency are children; geriatric patients; patients with heart disease, COPD, diabetes, dehydration, and obesity; and those with limited mobility. Older people, newborns, and infants exhibit poor thermoregulation. Newborns and infants often wear too much clothing. Alcohol and certain drugs, including medications that dehydrate the body or decrease the ability of the body to sweat, also make a person more susceptible to heat emergencies. When you are treating someone for a heat emergency, always obtain a medication history.

Heat Cramps

Heat cramps are painful muscle spasms that occur after vigorous exercise. They do not occur only when it is hot outdoors. They may be seen in factory workers and even well-conditioned athletes. The exact cause of heat cramps is not well understood. It is known that sweat produced during strenuous exercise, particularly in a warm environment, causes a change in the body's electrolyte balance. The result may be a loss of essential electrolytes from the cells. Dehydration may also play a role in the development of muscle cramps. Large amounts of water loss can result from excessive sweating. This loss of water may affect muscles that are being stressed and cause them to spasm.

Heat cramps usually occur in the leg or abdominal muscles. When the abdominal muscles are involved, the pain and muscle spasm may be so severe that the patient appears to have an acute abdominal condition. If a patient with a sudden onset of abdominal cramps has been exercising vigorously in a hot environment, suspect heat cramps.

Heat Exhaustion

Heat exhaustion, also called heat prostration or heat collapse, is the most common heat emergency. Heat exposure, stress, and fatigue are causes of heat exhaustion, which is caused by hypovolemia as the result of the loss of water and electrolytes from heavy sweating. Recall that for sweating to be an effective cooling mechanism, the sweat must be able to evaporate from the body. Otherwise, the body will continue to produce sweat, with further loss of body water. People standing in the hot sun and particularly those wearing several layers of clothing, such as sports fans or parade watchers, may sweat profusely but experience little body cooling. High humidity will also decrease the amount of evaporation that can occur.

People working or exerting themselves in poorly ventilated areas are unable to release heat through convection. Thus, people who work or exercise vigorously and those who wear heavy clothing in a warm, humid, or poorly ventilated environment are particularly prone to heat exhaustion.

The signs and symptoms of heat exhaustion and those of associated hypovolemia are as follows:

- Dizziness, weakness, or syncope signifying a change in level of consciousness with accompanying nausea, vomiting, or headache. Muscle cramping may also be present, including abdominal cramping.
- Onset while working vigorously or exercising in a hot, humid, or poorly ventilated environment and sweating heavily.
- Onset, even at rest, in the older and infant age groups in hot, humid, and poorly ventilated environments or extended time in hot, humid environments. People who are not acclimatized to the environment may also experience onset at rest.
- Cold, clammy skin with ashen pallor.
- Dry tongue and thirst.
- Normal vital signs, although the pulse is often rapid and weak (an indication for use of pulse oximetry) and the diastolic blood pressure may be low.
- Normal or slightly elevated body temperature; on rare occasions, as high as 104°F (40°C).

Heat Stroke

Heat stroke, the least common but most serious heat emergency, occurs when the body is subjected to more heat than it can handle and normal mechanisms for getting rid of the excess heat are overwhelmed. The body temperature then rises rapidly to the level at which tissues are destroyed. Untreated heat stroke always results in death.

Heat stroke can develop in patients during vigorous physical activity or when they are outdoors or in a closed, poorly ventilated, humid space. It also occurs during heat waves among people (particularly geriatric patients) who live in buildings with no air conditioning or with poor ventilation. It may also develop in children who are left unattended in a locked vehicle on a hot day.

Many patients with heat stroke have hot, dry, flushed skin because their sweating mechanism has been overwhelmed. However, in the course of heat stroke, the skin may be moist or wet due to exertion by the patient. Keep in mind that a patient can have heat stroke even if he or she is still sweating. This presentation is often seen in endurance athletes, military personnel, or emergency providers who wear personal protective equipment, such as firefighters, SWAT team members, or HazMat workers. The body temperature rises rapidly in patients with heat stroke. It may rise to 106°F (41.1°C) or more. As the body core temperature rises, the patient's level of consciousness decreases, resulting in unconsciousness.

Often, the first sign of heat stroke is a change in behavior. However, the patient becomes unresponsive very quickly and seizures may occur. The pulse is usually rapid and strong at first, but as the patient becomes increasingly unresponsive, the pulse becomes weaker and the blood pressure falls. The respiratory rate increases as the body attempts to compensate. One of the telltale signs of heat stroke is when your patient no longer perspires, which means the body has lost its thermoregulatory mechanisms. If you are perspiring in the environment, your patient should also be perspiring.

Assessment of Heat Emergencies

Scene Size-up

As part of your scene size-up, perform an environmental assessment. How hot is it outside? How hot is it in the room where your patient is located? How well is the patient tolerating the heat? Dispatch may report the call initially as a medical or trauma emergency. The heat emergency may be secondary. Always look for hazards as well as clues as to what may have caused your patient's emergency. If the patient is unconscious, has an altered mental status, or requires intravenous fluids to treat shock, consider calling for ALS assistance.

As you observe the scene, look for indicators of the MOI. For example, you arrive on the scene at a shopping mall to find an older man with a decreased level of consciousness inside a parked vehicle on a warm, humid, sunny day. The MOI for this patient is sitting in a warm environment under direct sunlight with no ventilation.

Heat emergencies commonly occur in the context of athletic events and practices, often with athletic trainers present. In those instances, you may find the patient submerged in a cold-water immersion bath inside the athletic training room. It is harmful to allow heat to persist for any amount of time; therefore, cooling prior to transport is indicated if facilities such as an ice bath are available. If the patient is placed in a cold-water immersion bath upon your arrival, monitor the patient in the water and assist as necessary. Do not remove the patient until the temperature has normalized to the appropriate level, between 101°F and 102°F (38.3°C and 38.9°C). Do not overcool the patient. Overcooling can lead to shivering, which generates more heat. Monitor the patient closely.

Finally, if you anticipate a prolonged scene time, protect yourself from the heat and remember to stay hydrated. Use appropriate standard precautions, including gloves and eye protection. Long-sleeved shirts and long pants may be uncomfortable in warm weather; however, they can help protect you from being splashed by blood or other body fluids.

Primary Assessment

As you approach your patient, observe how the patient interacts with you and the environment. This will help identify the patient's degree of distress. Introduce yourself and ask about the chief complaint. A heat emergency may be the primary problem or it may simply be aggravating a medical or trauma condition. Remember, prolonged heat exposure may stress the heart, causing a heart attack. Use this initial interaction to guide you in assessing for immediate life threats and related problems. Perform a rapid scan and avoid tunnel vision.

Table 32-2 Skin Condition

Skin Condition	Indicates
Moist, pale, cool skin	Excessive fluid and salt loss
Hot, dry skin	Body is unable to regulate core temperature
Hot, moist skin	Body is unable to regulate core temperature

Assess the patient's mental status using the AVPU scale. Heat stroke is a life-threatening emergency. Gather clues about his or her mental status to identify the severity of your patient's condition. The more altered the patient's mental status is, the more serious the heat emergency.

Assess the patient's airway and breathing and treat any life threats. Unless the patient is unresponsive, the airway should be patent. Nausea and vomiting, however, may occur. Position the patient to protect the airway as necessary. If the patient is unresponsive, be cautious of how you open the airway; consider spinal immobilization if trauma is a possibility. If your patient is unresponsive, insert an airway and provide BVM ventilations.

If circulation is adequate, assess the patient for perfusion and bleeding. Assess the patient's skin condition carefully Table 32-2. Treat the patient aggressively for shock by removing the patient from the heat and positioning the patient to improve circulation. If the patient is bleeding, bandage according to protocol.

If your patient has any signs of heat stroke, provide rapid transport.

History Taking

After the life threats have been managed during the primary assessment, investigate the chief complaint. Obtain a medical history and be alert for specific signs and symptoms such as the absence of perspiration, decreased level of consciousness, confusion, muscle cramping, nausea, and vomiting.

Obtain a SAMPLE history. Patients with inadequate oral intake, or who are taking diuretics, may have difficulty tolerating exposure to heat. Remember, many medications used by geriatric patients affect how well they tolerate heat. Be thorough in your questioning. Determine your patient's exposure to heat and humidity and activities prior to the onset of symptoms.

Secondary Assessment

The secondary assessment is used to uncover injuries that may have been missed during the primary assessment. In some instances, such as a critically injured patient or a short transport time, you may not have time to conduct a secondary assessment.

If your patient is unresponsive, perform a secondary assessment of the entire body looking for problems or explanations as to what is wrong. Obtain the patient's vital signs to help understand the severity of the emergency.

If the patient is conscious, perform an assessment of specific areas of the body. Heat exposure has significant effects on the metabolism, muscles, and cardiovascular system. Assess the patient for muscle cramps or confusion. Examine the patient’s mental status and take the patient’s vital signs.

Perform a detailed examination if circumstances and time permit. Pay special attention to the patient’s skin temperature, **turgor**, and level of moisture. Skin turgor is the ability of the skin to resist deformation. It is tested by gently pinching skin on the forehead or back of the hand. Normally the skin will quickly flatten out. If the patient is dehydrated, the skin will remain tented (poor skin turgor). Perform a careful neurologic examination.

Patients with hyperthermia will often have tachycardia and tachypnea. As long as they maintain a normal blood pressure, their bodies will compensate for the fluid loss. Once their blood pressure begins to fall, it indicates they are no longer able to compensate for fluid loss and are going into shock. Your assessment of the patient’s skin will help determine the severity of the emergency. For example, in heat exhaustion, the skin temperature may be normal or may even be cool and clammy; however, in heat stroke, the skin is hot.

Check the patient’s body temperature with a thermometer, depending on protocol. Your unit equipment may include disposable or oral thermometers with disposable covers. Some agencies provide tympanic (ear) thermometers. You may not use these devices routinely, so become familiar with how they work. In patients with a heat-related emergency, monitoring of pulse oximetry is also useful.

Reassessment

Watch your patient’s condition carefully for deterioration. Remove your patient as quickly as possible from the hot environment. Patients with heat cramps or exhaustion usually respond well to passive cooling and fluids by mouth. Patients with symptoms of heat stroke should be transported immediately in a cool ambulance, passively cooled with clothing removal, and actively cooled by spraying the patient with water and fanning to enhance evaporation. Any decline in level of consciousness is an ominous sign. Monitor the patient’s vital signs at least every 5 minutes. Evaluate the effectiveness of your interventions. Be careful not to overcool a patient who is experiencing a heat emergency.

Inform the ED staff as soon as possible that your patient is experiencing heat stroke, because additional resources may be required. Document the environmental conditions and the activities the patient was performing prior to the emergency in your patient care report.

Management of Heat Emergencies

Heat Cramps

Take the following steps to treat heat cramps in the field **Figure 32-6**:

1. Promptly remove the patient from the hot environment, including direct sunlight. Loosen any tight clothing.

Figure 32-6 A patient with heat cramps should be moved to a cool environment as you begin your assessment and treatment.

2. Administer high-flow oxygen if indicated (the patient shows signs of hypoxia or respiratory distress), if this was not already done as part of the primary assessment.
3. Rest the cramping muscles. Have the patient sit or lie down until the cramps subside.
4. Replace fluids by mouth. Give water or a diluted (half-strength) balanced electrolyte solution, such as a sports drink. In most cases, plain water is the most useful. Do not give salt tablets or solutions that have a high salt concentration.
5. Cool the patient with cool water spray or mist, and add convection to the cooling method by manually or mechanically fanning the patient.

When the heat cramps are gone, the patient may resume activity. For example, an athlete can return to play once the heat cramps have disappeared. However, heavy sweating may cause the cramps to recur. The best preventive and treatment strategy is hydration by drinking sufficient quantities of water.

If the cramps do not go away after these measures, transport the patient to the hospital. If you are uncertain that the patient's cramps were caused by the heat or you note anything out of the ordinary, contact medical control or transport the patient to the hospital.

Heat Exhaustion

To treat the patient with heat exhaustion, follow the steps in Skill Drill 32-1:

1. Promptly remove the patient from the hot environment, preferably into the back of the air-conditioned ambulance. If outdoors, move out of direct sunlight. Remove any excessive layers of clothing, particularly around the head and neck Step 1.
2. Administer high-flow oxygen if indicated, if this was not already done as part of the primary assessment.
3. If the patient has an altered mental status, check the blood glucose level.
4. Cool the patient with misting and administration of ice packs to the trunk of the patient's body. If an ice bath or similar facility is available, provide cold-water immersion to the patient if allowed per local protocol. Cold-water (ice bath) immersion is recommended for patients with a core temperature of 104 degrees F (40 degrees C) or an altered

mental status.

5. Encourage the patient to lie down. Loosen any tight clothing and cool the patient by manually or mechanically fanning him or her **Step 2**.
6. If the patient is fully alert, encourage him or her to sit up and slowly drink up to a liter of water, as long as nausea does not develop. Never force fluids by mouth on a patient who is not fully alert, or allow drinking while supine, because the patient could aspirate the fluid into the lungs. If the patient does not become nauseated, transport the patient on the left side to prevent aspiration **Step 3**.

In most cases, these measures will reverse the symptoms, causing the patient to feel better within 30 minutes. Prepare to transport the patient to the hospital, and also consider a rendezvous with ALS for more aggressive treatment, such as IV fluid therapy and close monitoring, especially in the following circumstances:

- The symptoms do not clear up promptly.
- The level of consciousness decreases.
- The body temperature remains elevated.
- The person is very young, older, or has any underlying medical condition, such as diabetes or cardiovascular disease.

Skill Drill 32-1 Treating for Heat Exhaustion

Step 1

Move the patient to a cooler environment. Remove extra clothing.

Step 2

Give oxygen if indicated. Check the patient's blood glucose level if indicated. Perform cold-water immersion or other cooling measures as available. Place the patient in a supine position and fan the patient.

Step 3

If the patient is fully alert, give water by mouth.

Step 4

If nausea develops, secure and transport the patient on his or her left side.

7. Transport the patient on his or her left side if you think the patient may be nauseated, but make certain that the patient is secured **Step 4**.

Heat Stroke

Recovery from heat stroke depends on the speed with which treatment is administered, so you must identify this patient quickly. Emergency treatment has one objective: lower the body temperature by any means available. Take the following steps when treating a patient with heatstroke:

1. Move the patient out of the hot environment and into the ambulance.
2. Set the air conditioning to maximum cooling.
3. Remove the patient's clothing.

4. Administer high-flow oxygen if indicated, if this was not already done as part of the primary assessment. If needed, assist the patient's ventilations with a BVM and appropriate airway adjuncts as per your protocol. If the patient is unresponsive and unable to protect his or her airway, consider rapid transport and cooling en route. Consult medical control if available.
5. Provide cold-water immersion in an ice bath, if possible. Cooling should begin immediately and continue en route to the hospital **Figure 32-7**. If it is not possible to cool en route and cold-water immersion is available at the scene, continue cold-water immersion at the scene until the core body temperature is between 101°F and 102°F (38.3°C and 38.9°C).

Figure 32-7 As part of treatment of heat stroke, if available, immerse the patient in an ice water bath. If consistent with your local protocol.

YOU are the Provider — PART 3

You quickly place the patient onto the stretcher and load him into the ambulance. The air conditioner is on and set to high. You perform a secondary assessment, which does not reveal any gross signs of injury, while your partner assesses the patient's vital signs. You then depart the scene and begin further treatment en route to the hospital.

Recording Time: 6 Minutes	
Respirations	24 breaths/min; adequate depth
Pulse	130 beats/mm; weak and regular
Skin	Hot, flushed, and moist
Blood pressure	88/66 mm Hg
Oxygen saturation (Spo_2)	95% (on oxygen)

5. What specific treatment is required for this patient?
6. What is the most likely explanation for this patient's vital signs?

6. Cover the patient with wet towels or sheets, or spray the patient with cool water and fan him or her to quickly evaporate the moisture on the skin.
7. Aggressively and repeatedly fan the patient with or without dampening the skin.
8. Exclude other causes of altered mental status and check blood glucose level, if possible.
9. Provide rapid transport to the hospital.
10. Notify the hospital as soon as possible so that the staff can prepare to treat the patient immediately on arrival.
11. Do not overcool the patient. Call for ALS assistance if the patient begins to shiver.

Special Populations

Remember that the aging process alters the body's ability to compensate for its surroundings. Temperature-related emergencies can develop in older people over time, even in indoor environments that may not seem uncomfortable to you. Be vigilant for temperature-related illnesses.

Drowning

Drowning is the process of experiencing respiratory impairment from submersion or immersion in liquid. Some agencies may use the term "near drowning" to refer to a patient who survives at least temporarily (24 hours) after suffocation in water. According to the Centers for Disease Control and Prevention (CDC), an average of 10 people die from unintentional drownings per day. More than 25% are children younger than 14 years. Alcohol consumption, preexisting seizure disorders, geriatric patients with cardiovascular disease, and unsupervised access to water are among the major risk factors.

Drowning is often the last in a cycle of events caused by panic in the water. It can happen to anyone who is submerged in water for even a short period of time. Struggling toward the surface or the shore, the person becomes fatigued or exhausted, which leads him or her to sink even deeper. However, drowning also occurs in buckets, puddles, bathtubs, and other places where the person is not completely submerged. Young children can drown in as little as 1 inch (3 cm) of water if left unattended.

Inhaling very small amounts of either fresh water or salt water can severely irritate the larynx, sending the muscles of the larynx and the vocal cords into spasm, called laryngospasm. The average person experiences this to a mild degree when a small amount of liquid is inhaled and the patient coughs and seems to be choking for a few seconds. This is the body's attempt at self-preservation; laryngospasm prevents more water from entering the lungs. In severe cases such as water submersion, however, the patient's lungs cannot be ventilated because significant laryngospasm is present. Instead, progressive hypoxia occurs until the patient becomes unconscious. At this point, the spasm relaxes, making rescue breathing possible. Of course, if the patient has not already been removed from the water, the patient may now inhale deeply, and more water may enter the lungs.

Spinal Injuries in Submersion Incidents

Submersion incidents may be complicated by spinal fractures and spinal cord injuries. Assume that spinal injury exists with the following conditions:

- The submersion has resulted from a diving mishap or fall from a significant height.
- The patient is unconscious, and no information is available to rule out the possibility of a neck injury.
- The patient is conscious but reports weakness, paralysis, or numbness in the arms or legs.
- You suspect the possibility of spinal injury despite what witnesses say.

Most spinal injuries in diving incidents affect the cervical spine. When spinal injury is suspected, the neck must be protected from further injury. This means that you will have to stabilize the suspected injury while the patient is still in the water. To stabilize a suspected spinal injury in water, follow the steps in **Skill Drill 32-2**:

1. Turn the patient supine. Two rescuers are usually required to turn the patient safely, although in some cases one rescuer will suffice. Always rotate the entire upper half of the patient's body as a single unit. Twisting only the head, for example, may aggravate any injury to the cervical spine **Step 1**.
2. Restore the airway and begin ventilation. Immediate ventilation is the primary treatment of all drowning patients as

soon as the patient is faceup in the water. Use a pocket mask if it is available. Have the other rescuer support the head and trunk as a unit while you open the airway and begin artificial ventilation **Step 2**.

Safety Tips

You must ensure the safety of rescue personnel and request additional rescue resources, as appropriate, before a water rescue can begin. Water rescue is typically handled by specialized rescue personnel, but you may be involved if you arrive first or if water rescue is included in your scope of practice per local protocols. If the patient is conscious and still in the water, perform a water rescue. The saying: "Reach, throw, and row, and only then go" **Figure 32-8** sums up the basic rule of water rescue. First, try to reach for the patient. If that does not work, throw the patient a rope, a life preserver, or any floatable object that is available. For example, an inflated spare tire, rim and all, will float well enough to support two people in the water. Next, use a boat if one is available. Do not attempt a swimming rescue unless you are trained and experienced in the proper techniques. Even then, you should always wear a helmet and a personal flotation device **Figure 32-9**. Too many well-meaning rescuers have themselves become victims while attempting a swimming rescue. In cold climates or cold-water locations, rapid hypothermia is also a concern for rescuers. Be prepared for this potential event.

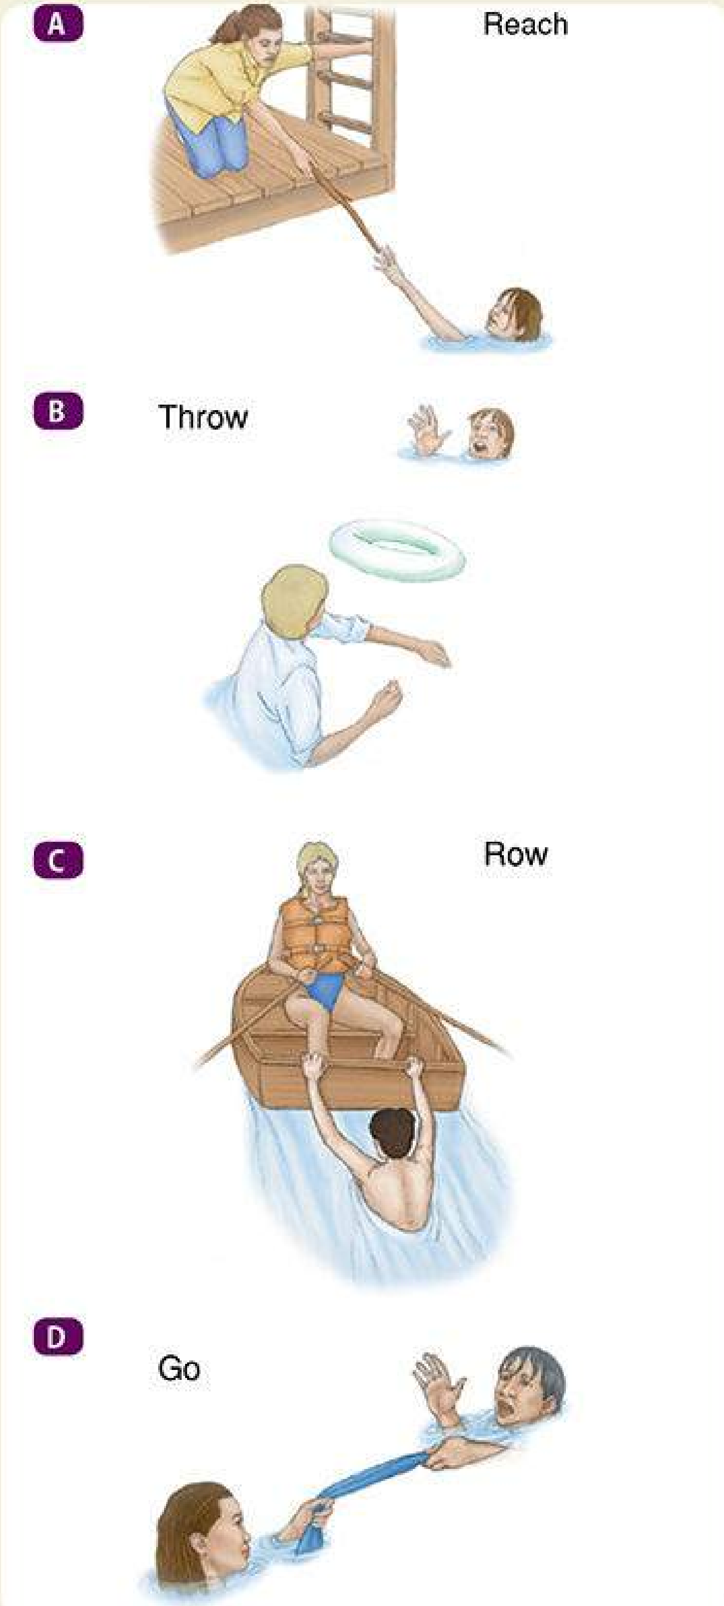

Figure 32-8 Basic rules of water rescue. **A.** Reach for the person from shore. If you cannot reach the person from shore, wade closer. **B.** If an object that floats is available, throw it to the person. **C.** Use a boat if one is available. **D.** If you must swim to the person, use a towel or board for him or her to hold onto. Do not let the person grab you.

The steps for ice rescue are similar and may involve reaching with a pole or ladder or throwing a rope or floatation device. A victim who has fallen through the ice may also be coached into placing his or her arms out of the water and onto the ice, kicking and rolling out of the water, and crawling to safety.

If you work in a recreation area near lakes, rivers, or the ocean, you should have a prearranged plan for water rescue. For colder areas, a plan for ice rescue is also necessary. This plan should include access to and cooperation with local providers who are trained and skilled in water rescue; these providers should help to develop the protocol for water rescue. Because the success of any water rescue depends on how rapidly the patient is removed from the water and ventilated, make sure you always have immediate access to personal flotation devices and other rescue equipment. Survival rates drastically decline the longer a victim is immersed. Cold-water drowning survival rates are somewhat higher.

Figure 32-9 When performing a water rescue, you must be properly trained and must wear proper personal protective equipment, including a personal flotation device.

Skill Drill 32-2 Stabilizing a Suspected Spinal Injury in the Water

Step 1

Turn the patient to a supine position by rotating the entire upper half of the body as a single unit.

Step 2

As soon as the patient is turned, begin artificial ventilation using the mouth-to-mouth method or a pocket mask.

Step 3

Float a buoyant backboard under the patient.

Step 4

Secure the patient to the backboard.

Step 5

Remove the patient from the water.

Step 6

Maintain the body's normal temperature and apply oxygen if the patient is breathing. Begin CPR if breathing and pulse are absent.

3. Float a buoyant backboard under the patient as you continue ventilation **Step 3**.
4. Secure the trunk and head to the backboard to immobilize the cervical spine. Do not remove the patient from the water until this is done **Step 4**.
5. Remove the patient from the water, on the backboard **Step 5**.
6. Cover the patient with a blanket. Give oxygen if the patient is breathing spontaneously. Begin CPR if there is no pulse. Effective cardiac compression or CPR is extremely difficult to perform when the patient is still in the water **Step 6**.

Recovery Techniques

On occasion, you may be called to the scene of a drowning and find that the patient is not floating or visible in the water. An organized rescue effort in these circumstances calls for providers who are experienced with recovery techniques and equipment, including snorkel, mask, and scuba gear. **Scuba gear** (self-contained underwater breathing apparatus) is a system that delivers air to the mouth and lungs at atmospheric pressures that increase with the depth of the dive.

Resuscitation Efforts

When a person is submerged in water that is colder than body temperature, heat will be conducted from the body to the water. The resulting hypothermia can protect vital organs from the lack of oxygen. In addition, exposure to cold water will occasionally activate certain primitive reflexes, which may preserve basic body functions for prolonged periods.

Also, whenever a person dives or jumps into very cold water, the **diving reflex**, slowing of the heart rate caused by submersion in cold water, may cause immediate bradycardia, a slow heart rhythm. Loss of consciousness and drowning may follow. However, the person may be able to survive for an extended period of time under water, thanks to a lowering of the metabolic rate associated with hypothermia. For this reason, local protocols often dictate that resuscitative efforts continue for up to one hour after submersion, while simultaneously rewarming the patient. Resuscitative efforts are not initiated for unwitnessed drowning victims who are found in a state of decomposition.

Diving Emergencies

Most serious water-related injuries are associated with dives, with or without scuba gear. Some of these injuries are related to the nature of the dive; others result from panic. Panic is not restricted to the person who is frightened by water. It can happen even to the experienced diver or swimmer.

There are more than 3,000,000 scuba sport divers in the United States, and approximately 200,000 new divers being trained annually. Medical emergencies relating to scuba diving techniques and equipment are becoming increasingly common. These injuries are separated into three phases of the dive: descent, bottom, and ascent.

Descent Emergencies

Descent problems are usually caused by the sudden increase in pressure on the body as the person dives deeper into the water. Some body cavities cannot adjust to the increased external pressure of the water; the result is severe pain. The usual areas affected are the lungs, the sinus cavities, the middle ear, the teeth, and the area of the face surrounded by the diving mask. Usually, the pain caused by these "squeeze problems" forces the diver to return to the surface to equalize the pressures, and the problem clears up by itself. A diver who continues to report pain, particularly in the ear, after returning to the surface should be transported to the hospital.

A special problem may develop in a person with a perforated tympanic membrane (ruptured eardrum) while diving. If cold water enters the middle ear through a ruptured eardrum, the diver may sustain a loss of balance and orientation. The diver may then shoot to the surface and experience ascent problems.

Emergencies at the Bottom

Problems related to the bottom of the dive are rarely seen. They include inadequate mixing of oxygen and carbon dioxide in the air the diver breathes and accidental feeding of poisonous carbon monoxide into the breathing apparatus. Both are the result of faulty connections in the diving gear. These situations can cause drowning or rapid ascent; they require emergency resuscitation and transport of the patient.

Ascent Emergencies

Most of the serious injuries associated with diving are related to ascending from the bottom and are referred to as ascent problems. These emergencies usually require aggressive resuscitation. Two particularly dangerous medical emergencies are air embolism and decompression sickness.

Air Embolism

The most dangerous, and most common, emergency in scuba diving is an **air embolism**, a condition involving bubbles of air in the blood vessels. An air embolism may occur on a dive as shallow as 6 feet (2 m). The problem starts when the diver holds his or her breath during a rapid ascent. The air pressure in the lungs remains at a high level while the external pressure on the chest decreases. As a result, the air inside the lungs expands rapidly, causing the alveoli in the lungs to rupture. The air released from this rupture can cause the following injuries:

- Air may enter the pleural space and compress the lungs (a pneumothorax).
- Air may enter the mediastinum (the space within the thorax that contains the heart and great vessels), causing a condition called pneumomediastinum.
- Air may enter the bloodstream and create bubbles of air in the vessels called air emboli.

Pneumothorax and pneumomediastinum both result in pain and severe dyspnea. An air embolus will act as a plug and prevent the normal flow of blood and oxygen to a specific part of the body. The brain and spinal cord are the organs most severely affected by air embolism because they require a constant supply of oxygen.

The following are potential signs and symptoms of an air embolism:

- Blotching (mottling of the skin)
- Froth (often pink or bloody) at the nose and mouth
- Severe pain in muscles, joints, or abdomen
- Dyspnea and/or chest pain
- Dizziness, nausea, and vomiting
- Dysphasia (difficulty speaking)
- Cough
- Cyanosis
- Difficulty with vision
- Paralysis and/or coma
- Irregular pulse and cardiac arrest

Decompression Sickness

Decompression sickness, commonly called the **bends**, occurs when bubbles of gas, especially nitrogen, obstruct the blood vessels. This condition results from too rapid an ascent from a dive, too long of a dive at too deep a depth, or repeated dives within a short period of time. During the dive, nitrogen that is being breathed dissolves in the blood and tissues because it is under pressure. When the diver ascends, the external pressure is decreased, and the dissolved nitrogen forms small bubbles within those tissues. These bubbles can lead to problems similar to those that occur in air embolism (blockage of tiny blood vessels, depriving parts of the body of their normal blood supply), but severe pain in certain tissues or spaces in the body is the most common problem.

Similarly, decompression sickness can occur even after a “safe dive” from driving a car up a mountain or flying in an unpressurized airplane that climbs too rapidly to a great height. However, the risk of this diminishes after 24 to 48 hours.

The most striking symptom is abdominal and/or joint pain so severe that the patient literally doubles up or “bends.” Dive tables and small diving computers are available to calculate and record the proper rate of ascent from a dive, including the number and length of pauses that a diver should make on the way up. However, even divers who stay within these limits can experience the bends.

You may find it difficult to distinguish between air embolism and decompression sickness. As a general rule, air embolism occurs immediately on return to the surface, whereas the symptoms of decompression sickness may not occur for several hours. The emergency treatment is the same for both. It consists of basic life support (BLS) followed by recompression in a hyperbaric chamber, a chamber or a small room that is pressurized to a level higher than atmospheric pressure **Figure 32-10**. Recompression treatment allows the bubbles of gas to dissolve into the blood and equalizes the pressures inside and outside the lungs. Once these pressures are equalized, gradual decompression can be accomplished under controlled conditions to prevent the bubbles from reforming.

Figure 32-10 A hyperbaric chamber, usually a small room, is pressurized to a level higher than atmospheric pressure and used in the treatment of decompression sickness and air embolism.

Assessment of Drowning and Diving Emergencies

Scene Size-up

In managing water emergencies, your standard precautions should include gloves and eye protection at a minimum. Check for hazards to your crew. Never drive through moving water—a small amount can cause the vehicle to be swept away. Use extreme caution when driving through standing water. Never attempt a water rescue without proper training and equipment. Call for additional resources early.

If your patient is still in the water, look for the best, safest means of removal. This may require additional help from search and rescue teams or special extrication equipment. Trauma and spinal immobilization must be considered when the scene is a recreational setting. Check for additional patients based on where and how the emergency occurred.

As you observe the scene, look for indicators of the MOI. As you put together information from dispatch and your observations of the scene, consider how the MOI produced the injuries expected.

Primary Assessment

Use your evaluation of the patient's chief complaint to guide you in your assessment of life threats and determine whether spinal immobilization is necessary. Pay particular attention to chest pain, dyspnea, and complaints related to sensory changes when a diving emergency is suspected. Determine the patient's level of consciousness using the AVPU scale. Be suspicious of drug and alcohol use and the effects on the patient's level of consciousness.

Standard measures should be taken for any patient found or injured while in the water. Begin with opening the airway and assessing breathing in unresponsive patients. Consider the possibility of spinal trauma and take appropriate actions. The airway may be obstructed with water. Suction according to protocol if the patient has vomited. Provide ventilations with a

BVM for inadequate breathing. Use an airway adjunct to facilitate BVM ventilations as necessary.

If the patient is responsive, provide high-flow oxygen with a nonrebreathing mask, and if there is no risk of spinal injury, position the patient to protect the airway from aspiration in the event of vomiting.

Auscultation and frequent reassessment of breath sounds in drowning patients is a key part of your assessment. You may hear diminished sounds or even gurgling sounds from the water that has been inhaled. Provide this information, and any changes in the patient's lung sounds, to the ALS providers who may rendezvous with your unit as well as to the receiving facility. Breath sounds are also particularly significant for patients with scuba diving injuries; while the patients ascended to the surface, a pneumothorax or tension pneumothorax may have developed.

Check for a pulse. It may be difficult to find a pulse because of constriction of the peripheral blood vessels and low cardiac output, resulting in cyanosis. Nevertheless, if the pulse is unmeasurable, the patient may be in cardiac arrest. Begin CPR and apply your AED according to BLS and the International Liaison Committee on Resuscitation (ILCOR) guidelines.

Evaluate the patient for adequate perfusion and treat for shock by maintaining normal body temperature and improving circulation through positioning. The patient's skin may be cold to the touch. If the MOI suggests trauma, assess for bleeding and treat appropriately.

Even if resuscitation in the field appears successful, always transport patients to the hospital. Inhalation of any amount of fluid can lead to delayed complications lasting for days or weeks. Patients with decompression sickness and air embolism must be treated in a recompression chamber. If you live in an area with a significant amount of scuba diving activity, you will have transport protocols in this regard. Usually, the patient will be stabilized in the nearest ED. Perform all interventions en route.

History Taking

After the life threats have been managed during the primary assessment, investigate the chief complaint. Obtain a medical history and be alert for injury-specific signs and symptoms as well as any pertinent negatives.

Obtain a SAMPLE history with special attention to the dive parameters, including depth, the length of time the patient was underwater, the time of onset of symptoms, and previous diving activity. Note any physical activity, alcohol or drug consumption, and other medical conditions. All of these factors may have an effect on the diving or drowning emergency.

Secondary Assessment

The secondary assessment is used to uncover injuries that may have been missed during the primary assessment. In some instances, such as a critically injured patient or a short transport time, you may not have time to conduct a secondary assessment.

If the patient is responsive, focus your physical examination on the basis of the chief complaint and the history obtained. This should include a thorough examination of the patient's lungs, including breath sounds.

Serious drowning situations typically result in an unresponsive patient. It is important to begin with a full-body scan in these situations to look for hidden life threats and potential trauma, even if trauma is not suspected. A scuba diver with problems should be assessed for indications of decompression sickness or an air embolism. Focus on pain in the joints and the abdomen. Pay attention to whether your patient is getting adequate ventilation and oxygenation, and check for signs of hypothermia.

Time and personnel permitting, complete a detailed assessment en route to the hospital. A careful examination may reveal additional injuries not initially observable. Examine the patient for respiratory, circulatory, and neurologic compromise. A careful distal circulatory, sensory, and motor function examination will be helpful in assessing the extent of the injury. Assess for peripheral pulses, skin color and discoloration, itching, pain, and paresthesia (numbness and tingling).

Check the patient's pulse rate, quality, and rhythm. Pulse and blood pressure may be difficult to palpate in a patient with hypothermia. Check carefully for both peripheral and central pulses, and listen over the chest for a heartbeat if pulses are weak. Check the respiratory rate, quality, and rhythm and listen for breath sounds. Assess and document pupil size and reactivity.

YOU are the Provider — PART 4

Your partner notifies the hospital and gives the hospital a patient report. You continue active cooling measures and initiate the appropriate shock treatment. When you reassess the patient, you note that his level of consciousness has decreased; he is responsive only to pain. His respirations are still rapid, but are now markedly shallow.

Recording Time: 11 Minutes	
Level of consciousness	Responsive only to pain
Respirations	26 breaths/min; shallow
Pulse	126 beats/min; weak and regular
Skin	Flushed, hot, and moist
Blood pressure	90/70 mm Hg
Spo_2	89% (on oxygen)

7. How should you adjust your treatment of this patient?
8. How will you know when you have adequately cooled the patient?

Although it is a valuable tool, oxygen saturation readings may produce a false low reading because of hypoperfusion of the patient's monitoring finger. Shivering also can interfere with obtaining an accurate reading because of excessive movement.

Reassessment

Repeat the primary assessment. Reassess vital signs and the chief complaint. Are the airway, breathing, and circulation still adequate? Recheck patient interventions. Are your treatments for problems with the ABCs still effective?

The condition of patients who have experienced submersion in water may deteriorate rapidly because of pulmonary injury, fluid shifts in the body, cerebral hypoxia, and hypothermia. Patients with pneumothorax, air embolism, or decompression sickness may decompensate quickly. Assess your patient's mental status constantly, and assess vital signs at least every 5 minutes. Pay particular attention to respirations and breath sounds.

Document the circumstances of the drowning and extrication. The receiving facility personnel will need to know how long the patient was submerged, the temperature of the water, the clarity of the water, and whether there was any possibility of cervical spine injury.

If you respond to a diving incident, the receiving facility personnel will also need a complete dive profile to properly treat your patient. This information may be available in a dive log, on a dive computer, or from the patient's diving partners. If possible, bring all of the diver's equipment to the hospital. It will be helpful in determining the cause of the incident. Be sure to document the disposition of this equipment.

Emergency Care for Drowning or Diving Emergencies

Treatment for drowning begins with rescue and removal from the water. Immobilize and protect the patient's spine when a fall from a significant height or suspected diving injury has occurred (or if this is a possibility when no information is provided). When necessary, begin artificial ventilation as soon as possible, even before the victim is removed from the water. Spinal immobilization must continue while artificial ventilation is performed. If the patient is not breathing, clear any vomit from the airway manually or with suction and assist ventilations with a BVM or pocket mask. Rolling patients onto their side or performing abdominal thrusts will not remove water from the lungs and should not be done unless the airway is obstructed. Frothy sputum in the patient's airway does *not* require removal with suctioning. When resuscitating a patient who has drowned, the usual CAB order (compressions, airway, breathing) is not used. Rather, address airway and breathing concerns first, then begin compressions and use the AED.

If the patient is breathing spontaneously, but has been submerged, administer oxygen (if this was not done as part of the primary assessment). Use pulse oximetry to titrate oxygen delivery, according to local protocols. Treat all drowning patients for hypothermia by removing wet clothing and wrapping them in warm blankets.

When treating conscious patients who are suspected of having an air embolism or decompression sickness from scuba diving, follow these accepted treatment steps:

1. Remove the patient from the water. Try to keep the patient calm.
2. Administer oxygen.
3. Consider the possibility of pneumothorax and monitor the patient's breath sounds for development of a tension pneumothorax.

4. Provide prompt transport to the ED or to the nearest recompression facility for treatment based on local protocols.

Injury from decompression sickness is sometimes reversible with proper treatment. However, if the bubbles block critical blood vessels that supply the brain or spinal cord, permanent central nervous system injury may result. Therefore, the key in emergency management of serious ascent problems is to recognize that an emergency exists and treat as soon as possible.

Other Water Hazards

Pay close attention to the body temperature of a person who is rescued from cold water. Treat hypothermia caused by immersion in cold water the same way you treat hypothermia caused by cold exposure. Prevent further heat loss from contact with the ground, stretcher, or air, and transport the patient promptly.

A person swimming in shallow water may experience **breath-holding syncope**, a loss of consciousness caused by a decreased stimulus for breathing. This happens to swimmers who breathe in and out rapidly and deeply before entering the water in an effort to expand their capacity to stay underwater. Whereas this technique increases the swimmer's oxygen level, the hyperventilation involved lowers the carbon dioxide level. Because an elevated level of carbon dioxide in the blood is the strongest stimulus for breathing, the swimmer may not feel the need to breathe even after using up all the oxygen in his or her lungs. This results in drowning. The emergency treatment for a patient with breath-holding syncope is the same as that for a drowning patient.

Prevention

Each year, many young children drown in residential pools. Appropriate precautions can prevent most immersion incidents. All swimming pools should be surrounded by a fence that is at least 6 feet (2 m) high, with slats no farther apart than 3 inches (8 cm), and self-closing, self-locking gates. The most common problem is a lack of adult supervision. An incident can occur when a child is unattended for only a few seconds. Half of all teenage and adult drownings are associated with alcohol use. As a health care professional, you should be involved in public education efforts to make people aware of the hazards of swimming pools and water recreation.

High Altitude

High altitudes can cause **dysbarism injuries**. Dysbarism injuries are any signs and symptoms caused by the difference between the surrounding atmospheric pressure and the total gas pressure in various tissues, fluids, and cavities of the body. Altitude illnesses occur when an unacclimatized person is exposed to diminished oxygen pressure in the air at high altitudes. These illnesses affect the central nervous system and pulmonary system, and range from common acute mountain sickness to high-altitude cerebral edema (HACE) and high-altitude pulmonary edema (HAPE).

Acute mountain sickness is caused by diminished oxygen pressure in the air at altitudes above 5,000 feet (1.5 km), resulting in diminished oxygen in the blood (hypoxia). It strikes those who ascend too high too fast and those who have not acclimatized to high altitudes. The signs and symptoms include a headache, light-headedness, fatigue, loss of appetite, nausea, difficulty sleeping, shortness of breath during physical exertion, and a swollen face. Treatment primarily consists of stopping the ascent and descending to a lower altitude. However, consider other possible causes for the same symptoms, such as hypoglycemia or carbon monoxide poisoning from a camping stove.

With HAPE, fluid collects in the lungs, hindering the passage of oxygen into the bloodstream. It can occur at altitudes of 8,000 feet (2 km) or greater. The signs and symptoms include shortness of breath, cough with pink sputum, cyanosis, and a rapid pulse.

HACE usually occurs in climbers and may accompany HAPE; it can quickly become life threatening. The signs and symptoms include a severe, constant, throbbing headache; ataxia (lack of muscle coordination and balance); extreme fatigue; vomiting; and loss of consciousness. The symptoms of HACE and HAPE may overlap.

In the field, treatment for HAPE and/or HACE consists of providing oxygen, descending to a lower altitude, and prompt transport. For inadequate respirations, provide positive-pressure ventilation with a BVM. If local protocols allow, continuous positive airway pressure (CPAP) may be very helpful for a patient with respiratory distress from HAPE.

Lightning

According to the National Weather Service, there are an estimated 25 million cloud-to-ground lightning flashes in the United States each year. On average, lightning kills between 60 and 70 people per year in the United States based on documented cases. While documented lightning injuries in the United States average about 300 per year, undocumented lightning injuries are likely much higher. Lightning is the third most common cause of death from isolated environmental phenomena.

The energy associated with lightning is comprised of direct current of up to 200,000 amps and a potential of 100 million volts or more. Temperatures generated from lightning vary between 20,000°F and 60,000°F (11,000°C and 33,000°C).

Most deaths and injuries caused by lightning occur during the summer months when people are enjoying outdoor activities, despite an approaching thunderstorm. Those most commonly struck by lightning include boaters, swimmers, and golfers. Any type of activity that exposes the person to a large, open area increases the risk of being struck by lightning.

Whether or not lightning injures or kills depends on whether a person is in the path of the lightning discharge. The current associated with the lightning discharge travels along the ground. Although some people are injured or killed by a direct lightning strike, many people are indirectly struck when standing near an object that has been struck by lightning, such as a tree (splash effect).

The cardiovascular and nervous systems are most commonly injured during a lightning strike; therefore, respiratory or cardiac arrest is the most common cause of lightning-related deaths. The tissue damage caused by lightning is different from that caused by other electric related injuries (ie, high-power line injuries) because the tissue damage pathway usually occurs over the skin, rather than through it. During your assessment, look for not only the entrance wound but also the exit wound. The exit wound does not necessarily occur on the same side of the body. Additionally, because the duration of a lightning strike is short, skin burns are usually superficial; full-thickness (third-degree) burns are rare. Lightning injuries are categorized as being mild, moderate, or severe:

- **Mild:** Loss of consciousness, amnesia, confusion, tingling, and other nonspecific signs and symptoms. Burns, if present, are typically superficial.
- **Moderate:** Seizures, respiratory arrest, dysrhythmias that spontaneously resolve, and superficial burns.
- **Severe:** Cardiopulmonary arrest. Because of the delay in resuscitation, often the result of occurrence in a remote location, many of these patients do not survive.

Emergency Medical Care

As with any scene response, your priority is safety. Take measures to protect yourself and your partner from being struck by lightning, especially if the thunderstorm is still in progress. Contrary to popular belief, lightning can, and does, strike in the same place twice. Move the patient to a place of safety, preferably in a sheltered area.

If you are in an open area and adequate shelter is unavailable, it is important to recognize the signs of an impending lightning strike and take immediate action to protect yourself. If you suddenly feel a tingling sensation or your hair stands on end, the area around you has become charged—a sure sign of an imminent lightning strike. Make yourself as small a target as possible by squatting down into a ball, close to—but not touching—the ground. If you are standing near a tree or other tall object, move away as fast as possible, preferably to a low-lying area. Lightning tends to strike objects that project from the ground (ie, trees, fences, buildings).

The process of triaging multiple victims of a lightning strike is different than the conventional triage methods used during a mass-casualty incident (see Chapter 39, *Incident Management*). When a person is struck by lightning, respiratory or cardiac arrest, if it occurs, usually occurs immediately. Delayed respiratory or cardiac arrest is much less likely to develop in those who are conscious following a lightning strike; most of these people will survive. Therefore, you should focus your efforts on those who are in respiratory or cardiac arrest. This process, called **reverse triage**, differs from conventional triage, where such patients would ordinarily be classified as deceased.

When a person is struck by lightning, it causes massive direct current shock, with the patient experiencing massive muscle spasms (tetany) that can result in fractures of long bones and spinal vertebrae. Therefore, manually stabilize the patient's head in a neutral in-line position and open the airway with the jaw-thrust maneuver. If the patient is in respiratory arrest with a pulse, begin immediate BVM ventilations with 100% oxygen. If the patient is in cardiac arrest, attach an AED as soon as possible and provide defibrillation if indicated. If severe bleeding is present, control it immediately.

Provide full spinal immobilization and transport the patient to the closest appropriate facility. If CPR or ventilations are not required, address other injuries (ie, splint fractures, dress and bandage burns) and provide continuous monitoring while en route to the hospital. A patient with signs and symptoms of a lightning strike, but no obvious life threats, should still be transported to the ED for evaluation.

Bites and Envenomations

This section discusses bites and stings from spiders, hymenoptera, snakes, scorpions, and ticks and injuries from marine animals.

Spider Bites

Spiders are numerous and widespread in the United States. Many species of spiders bite. However, only two, the female black widow spider and the brown recluse spider, are able to deliver serious, even life-threatening bites. When you care for a patient who has had some type of bite, be alert to the possibility that the spider may still be in the area, although it is unlikely. Remember that your safety is of paramount importance.

Black Widow Spider

The female black widow spider (*Latrodectus*) is fairly large, measuring approximately 2 inches (5 cm) long with its legs extended. It is usually black and has a distinctive, bright red-orange marking in the shape of an hourglass on its abdomen **Figure 32-11**. The female black widow spider is larger and more toxic than the male. Black widow spiders are found in every state except Alaska. They prefer dry, dim places around buildings, in woodpiles, and among debris.

The bite of the black widow spider is sometimes overlooked. If the site becomes numb right away, the patient may not even recall being bit. However, most black widow spider bites cause localized pain and symptoms, including agonizing muscle spasms. In some cases, a bite on the abdomen causes muscle spasms so severe that the patient may be thought to have an acute abdominal condition, possibly peritonitis. The main danger with this type of bite, however, is that the black widow's venom can damage nerve tissues (it is a neurotoxin). Other systemic symptoms include dizziness, sweating, nausea, vomiting, and rashes. Tightness in the chest and difficulty breathing develop within 24 hours, as well as severe cramps, with board-like rigidity of the abdominal muscles. Generally, these signs and symptoms subside over 48 hours.

Figure 32-11

Black widow spiders are distinguished by their glossy black color and bright red-orange hourglass marking on the abdomen.

If necessary, a physician can administer a specific **antivenin**, a serum containing antibodies that counteract the venom, but because of a high incidence of side effects, its use is reserved for very severe bites, for older or very feeble patients, and for children younger than 5 years. In children, these bites can be fatal. In general, emergency treatment of a black widow spider bite consists of BLS for the patient in respiratory distress. More often, the patient will only require pain relief. Transport the patient to the ED as soon as possible for treatment. If possible, safely bring the spider to the hospital or take a photo of the spider with a cell phone and send it to the hospital ahead of time so that it can be definitively identified.

Brown Recluse Spider

The brown recluse spider (*Loxosceles*) is dull brown and, at 1 inch (3 cm), smaller than the black widow Figure 32-12. The short-haired body has a violin-shaped mark, brown to yellow in color, on its back. Although the brown recluse spider lives mostly in the southern and central parts of the country, it may be found throughout the continental United States. The spider takes its name from the fact that it tends to live in dark areas—in corners of old, unused buildings, under rocks, and in woodpiles. In cooler areas, it moves indoors to closets, drawers, cellars, and clothing.

Figure 32-12

Brown recluse spiders are dull brown and have a dark, violin-shaped mark on the back.

Courtesy of Kenneth Cramer, Monmouth College.

In contrast to the venom of the black widow spider, the venom of the brown recluse spider is not neurotoxic but cytotoxic; that is, it causes severe local tissue damage. Typically, the bite is not painful at first but becomes so within hours. The area becomes swollen and tender, developing a pale, mottled, cyanotic center and possibly a small blister Figure 32-13. Over the next several days, a scab of dead skin, fat, and debris forms and digs down into the skin, producing a large ulcer that may not heal unless treated promptly. Transport patients with such symptoms as soon as possible.

Figure 32-13

The bite of a brown recluse spider is characterized by swelling, tenderness, and a pale, mottled, cyanotic center. There may also be a small blister on the bite.

Courtesy of Department of Entomology, University of Nebraska.

Brown recluse spider bites rarely cause systemic symptoms and signs. When they do, provide BLS and prompt transport to the ED. Again, it is helpful if you can identify the spider and either safely bring it to the hospital with the patient, or take a picture of the spider and send it to the hospital ahead of time.

Hymenoptera Stings

Typically **hymenoptera** (bees, wasps, yellow jackets, and ants) stings are painful but are not a medical emergency. Remove the stinger and, if still present, the venom sac. This is best done by using a firm-edged item such as a credit card to scrape the stinger and sac off the skin. Use ice packs to assist in controlling pain from a hymenoptera sting.

If the patient is allergic to the venom, then anaphylaxis may occur. The signs and symptoms of anaphylaxis are flushed skin, low blood pressure, difficulty breathing usually associated with reactive airway sounds such as wheezes, or in severe cases diminished or absent breath sounds. Hives (urticaria) may develop near the site of envenomation or centrally on the body. The patient can also have swelling to the throat and tongue. Anaphylaxis is a true emergency and can be fatal if not recognized and treated quickly. If anaphylaxis develops, be prepared to assist the patient in administering an epinephrine auto-injector (EpiPen). Also be prepared to support the airway and breathing should the patient experience significant respiratory compromise. Chapter 20, *Immunologic Emergencies*, has a detailed discussion on the treatment of anaphylaxis.

Snake Bites

Snake bites are a worldwide problem. According to the World Health Organization, more than 400,000 injuries from venomous snake bites occur annually, including at least 20,000 deaths. However, snake bite fatalities in the United States are extremely rare, about 15 a year for the entire country.

Figure 32-14 **A.** Rattlesnake. **B.** Copperhead. **C.** Cottonmouth (water moccasin). **D.** Coral snake.

A: © Photos.com; B: Courtesy of Ray Rauch/U.S. Fish & Wildlife Service; C: © SuperStock/Alamy; D: Courtesy of Luther C. Goldman/U.S. Fish & Wildlife Service.

Of the approximately 115 different species of snakes in the United States, only 19 are venomous. These include the rattlesnake (*Crotalus*), the copperhead (*Agkistrodon contortrix*), the cottonmouth, or water moccasin (*Agkistrodon piscivorus*), and the coral snakes (*Micrurus fulvius* and *Micruroides euryxanthus*) **Figure 32-14**. At least one of these venomous species is found in every state except Alaska, Hawaii, and Maine. As a general rule, these snakes are timid. They usually do not bite unless provoked or accidentally injured, as when they are stepped on. There are a few exceptions to these rules. Cottonmouths are often aggressive, and rattlesnakes are easily provoked. Coral snakes, in contrast, usually bite only when they are being handled.

Most snake bites occur between April and October, when the animals are active, and tend to involve young men who have been drinking alcohol. Texas reports the largest number of bites. Other states with a major concentration of snake bites are Louisiana, Georgia, Oklahoma, North Carolina, Arkansas, West Virginia, and Mississippi. If you work in one of these areas, you should be thoroughly familiar with the emergency handling of snake bites. Remember, almost any time you are caring for a patient with a snake bite, another snake may be in the area and create a second victim—you. Therefore, use extreme caution on these calls and be sure to wear the proper protective equipment for the area.

In general, only one-third of snake bites result in significant local or systemic injuries. Often, envenomation does not occur because the snake has recently struck another animal and exhausted its supply of venom for the time being.

Venomous snakes native to the United States all have hollow fangs in the roof of the mouth that inject the venom from two sacs at the back of the head. The classic appearance of the venomous snake bite, therefore, is two small puncture wounds, usually about 0.5 inch (1 cm) apart, with discoloration and swelling, and the patient usually reports pain surrounding the bite **Figure 32-15**. Fang marks are a clear indication of a venomous snake bite. A snake bite with other tooth marks may be from a nonvenomous snake. If you are unsure whether the snake was venomous, proceed as if it was, especially if the patient exhibits other signs and symptoms.

A person who has been bitten by any venomous snake needs prompt transport. Also, notify the hospital as soon as possible if a patient has been bitten by a pit viper or coral snake. Some venoms can cause paralysis of the nervous system, and hospitals may not have appropriate antivenin on hand.

Figure 32-15 A snake bite wound from a poisonous snake has characteristic markings: two small puncture wounds about 0.5 inch (1 cm) apart, discoloration, and swelling.

Pit Vipers

Rattlesnakes, copperheads, and cottonmouths are all pit vipers, with triangular-shaped, flat heads **Figure 32-16**. They take their name from the small pits located just behind each nostril and in front of each eye. The pit is a heat-sensing organ that allows the snake to strike accurately at any warm target, especially in the dark, when it cannot see through its vertical, slit-like pupils.

The fangs of the pit viper normally lie flat against the roof of the mouth and are hinged to swing back and forth as the mouth opens. When the snake strikes, the mouth opens wide and the fangs extend; in this way, the fangs penetrate whatever the mouth strikes. The fangs are actually special hollow teeth that act like hypodermic needles. They are connected to a sac containing a reservoir of venom, which in turn is attached to a poison gland. The gland itself is a specially adapted salivary gland, which produces enzymes that digest and destroy tissue. The primary purpose of the venom is to kill small animals and facilitate the digestive process.

In the United States, the most common form of pit viper is the rattlesnake. Several different species of rattlesnake can be identified by the rattle on the tail. The rattle is actually numerous layers of dried skin that were shed but failed to fall off, coming to rest against a small knob on the end of the tail. Rattlesnakes have many patterns of color, often with a diamond pattern. They can grow to 6 feet (2 m) or more in length.

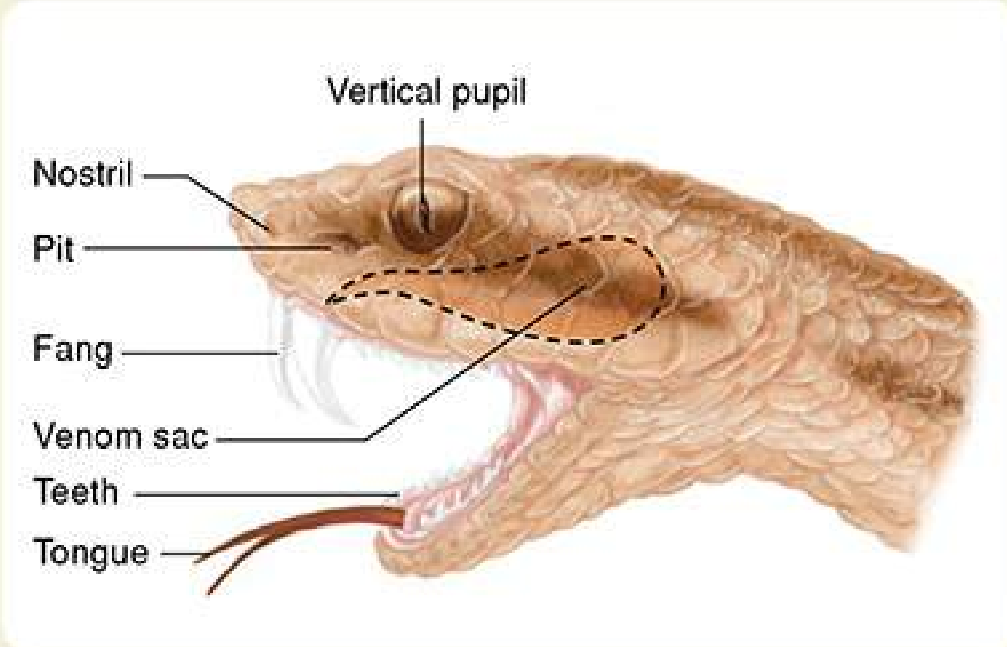

Figure 32-16 Pit vipers have small, heat-sensing organs (pits) located in front of their eyes that allow them to strike at warm targets, even in the dark.

Copperheads are smaller than rattlesnakes, usually 2 to 3 feet long (60 to 90 cm) with a red-copper color crossed with brown or red bands. These snakes typically inhabit woodpiles and abandoned dwellings, often close to areas of habitation. Although they account for most of the venomous snake bites in the eastern United States, copperhead bites are almost never fatal; however, note that the venom can cause significant damage to tissues in the extremities.

Cottonmouths grow to about 4 feet (1 m) in length. Also called water moccasins, these snakes are olive or brown, with black cross-bands and a yellow undersurface. They are water snakes and have a particularly aggressive pattern of behavior. Although fatalities from these snake bites are rare, tissue destruction from the venom may be severe.

The signs of envenomation by a pit viper are severe burning pain at the site of the injury, followed by swelling and a blue discoloration (ecchymosis) in light-skinned people that signals bleeding under the skin. These signs are evident within 5 to 10 minutes after the bite has occurred and last over the next 36 hours. In addition to destroying tissues locally, the venom of the pit viper can also interfere with the body's clotting mechanism and cause bleeding at various distant sites. This toxin affects the entire nervous system. Other systemic signs, which may or may not occur, include weakness, nausea, vomiting, sweating, seizures, fainting, vision problems, changes in level of consciousness, and shock. If swelling has occurred, use a pen to mark its edges on the skin. This will allow physicians to assess the timing and extent of the swelling with greater accuracy. If the patient has no local signs an hour after being bitten, it is safe to assume that envenomation did not take place.

The toxicity is related to the amount of toxin injected. A bite will affect children more than adults because there is less body mass to absorb the toxin. The same principle holds true for a small-statured adult.

In treating a snake bite from a pit viper, follow these steps:

1. Calm the patient; assure him or her that venomous snake bites are rarely fatal. Place the patient in a supine position and explain that staying still will slow the spread of any venom through the system. Determine the approximate time of the bite and document your time en route to a receiving facility. This time from onset to evaluation at the facility is one of the criteria used in grading the severity of the incident and in determining the amount of antivenin to be used.
2. Locate the bite area; clean it gently with soap and water or a mild antiseptic. Do not apply ice to the area.
3. If the bite occurred on an arm or leg, consider the use of a pressure immobilization bandage of the extremity (eg, 40 to

70 mm Hg in the arms and 55 to 70 mm Hg in the legs) and then place the affected extremity below the level of the heart.
4. Be alert for an anaphylactic reaction to the venom and treat with an epinephrine auto-injector, as appropriate.
5. Do not give anything by mouth, and be alert for vomiting.
6. If, as rarely happens, the patient was bitten on the trunk, keep him or her supine and quiet and transport as quickly as possible.
7. Monitor the patient's vital signs and mark the skin with a pen over the area that is swollen, proximal to the swelling, to note whether swelling is spreading.
8. If there are any signs of shock, place the patient supine and administer oxygen.
9. If the snake has been killed, as is often the case, be sure to bring it with you in a secure, hard-sided container so that physicians can identify it and administer the proper antivenin. Alternatively, take a picture of the snake with a cell phone and send it to the hospital ahead of time.
10. Notify the hospital that you are bringing in a patient who has a snake bite; if possible, describe the snake.
11. Transport the patient promptly to the hospital.

If the patient shows no sign of envenomation, provide BLS as needed, place a sterile dressing over the suspected bite area, and immobilize the injury site. All patients with a suspected snake bite should be taken to the ED, whether or not they show signs of envenomation. Treat the wound as you would any deep puncture wound to prevent infection.

Familiarize yourself with the venomous snakes in your region, as well as local protocols for handling snake bites. There may be specific hospitals where antivenin is more readily available, either in the facility or through zoos, health departments, or other services.

Coral Snakes

The coral snake is a small reptile with a series of bright red, yellow, and black bands completely encircling the body. Many harmless snakes have similar coloring, but only the coral snake has red and yellow bands next to one another, as this helpful rhyme suggests: "Red on yellow will kill a fellow; red on black, venom will lack."

A rare creature that lives in most southern states and in the Southwest, the coral snake is a relative of the cobra. It has tiny fangs and injects the venom with its teeth by a chewing motion, leaving behind one or more puncture or scratch-like wounds. Because of its small mouth and teeth and limited jaw expansion, the coral snake usually bites its victims on a small part of the body, such as a finger or toe.

Coral snake venom is a powerful toxin that causes paralysis of the nervous system. Within a few hours of being bitten, a patient will exhibit bizarre behavior, followed by progressive paralysis of eye movements and respiration. Often, there are limited or no local symptoms.

Successful treatment, either emergency or long-term, depends on positive identification of the snake and support of respiration. Antivenin is also available for coral snake bites, but most hospitals do not stock it. Therefore, you should notify the receiving hospital of the need for it as soon as possible. The steps for emergency care of a coral snake bite are the same as a pit viper bite.

Scorpion Stings

Scorpions are eight-legged arachnids from the biologic group *Arachnida* with a venom gland and a stinger at the end of their tail **Figure 32-17**. Scorpions are rare; they live primarily in the southwestern United States and in deserts. With one exception, a scorpion's sting is usually very painful but not dangerous, causing localized swelling and discoloration. The exception is the *Centruroi-des sculpturatus*. Although it is found naturally in Arizona and New Mexico, as well as parts of Texas, California, and Nevada, it may be kept as a pet by anyone. The venom of this particular species may produce a severe systemic reaction that leads to circulatory collapse, severe muscle contractions, excessive salivation, hypertension, convulsions, and cardiac failure. Antivenin is available but must be administered by a physician. If you are called to care for a patient with a suspected sting from *C. sculpturatus*, notify the receiving hospital as early as possible to facilitate the availability of this antivenin. Administer BLS and provide rapid transport to the ED.

Figure 32-17 The sting of a scorpion is usually more painful than it is dangerous, causing localized swelling and discoloration.

YOU are the Provider — PART 5

The patient's level of consciousness appears to have improved and he is now resisting your attempts to assist his ventilations. After reapplying the nonrebreathing mask, you reassess his vital signs and clinical condition. His skin, although still very warm, does not feel as hot as it did initially, and his skin appears less flushed. You will arrive at the hospital in approximately 5 minutes.

Recording Time: 16 Minutes	
Level of consciousness	Confused; somewhat combative
Respirations	22 breaths/min; depth has improved
Pulse	120 beats/min and regular; appears to be stronger
Skin	Less flushed, very warm to the touch, moist
Blood pressure	98/58 mm Hg
Spo_2	94% (on oxygen)

9. What other conditions should you consider as potential causes of the patient's altered mental status?

Tick Bites

Found most often on brush, shrubs, trees, sand dunes, or other animals, ticks usually attach themselves directly to the skin **Figure 32-18**. Only a fraction of an inch (about 3 mm) long, they can easily be mistaken for a freckle, especially since their bite is not painful. Indeed, the danger with a tick bite is not from the bite itself, but from the infecting organisms that the tick carries. Ticks commonly carry two infectious diseases, Rocky Mountain spotted fever and Lyme disease. Both are spread through the tick's saliva, which is injected into the skin when the tick attaches itself. The longer a tick stays embedded, the greater the chance that a disease will be transmitted.

Rocky Mountain spotted fever, which is not limited to the Rocky Mountains area, occurs within 7 to 10 days after a bite by an infected tick. Its symptoms include nausea, vomiting, headache, weakness, paralysis, and possible cardiorespiratory collapse.

Lyme disease has received extensive publicity. Lyme disease was originally seen only in Connecticut. According to the CDC, it has now been reported in all states with the exception of Hawaii. It occurs most commonly in the Northeast and the Great Lake states; Pennsylvania reported the largest number of cases from 2011 to 2013. The first symptoms are generally fever and flulike symptoms, sometimes associated with a bull's-eye rash that may spread to several parts of the body Figure 32-19. After a few days or weeks, painful swelling of the joints, particularly the knees, occurs. Lyme disease may be confused with rheumatoid arthritis and, like that disease, may result in permanent disability. However, if it is recognized and treated promptly with antibiotics, the patient may recover completely.

Figure 32-18

Ticks typically attach themselves directly to the skin.

© Joao Estevao A. Freitas (jefras)/ShutterStock.

Tick bites occur most commonly during the summer months, when people are out in the woods wearing little protective clothing. Do not attempt to suffocate the tick with gasoline or petroleum jelly, or burn it with a lighted match; you will only increase the risk of infection or burn the patient. For patients in conventional EMS settings with tick bites or signs and symptoms of Lyme disease, provide any necessary supportive emergency care and transport the patient for further evaluation. In a situation (such as wilderness EMS) where access to care is delayed, remove the tick from the patient. Using fine tweezers, grasp the tick by the head and pull gently but firmly straight up so that the skin is tented. Hold this position until the tick releases. Special tweezers are available for this, but are unnecessary. This method will usually remove the whole tick. (Partial removal can lead to infection.) Cleanse the area with antiseptic and save the tick in a glass jar or other container so that it can be identified. Do not handle the tick with your fingers. The patient should follow up with their health care provider as soon as possible.

Figure 32-19 The rash associated with Lyme disease has a characteristic bull's-eye pattern.

Injuries From Marine Animals

Coelenterates, including the fire coral, Portuguese man-of-war, sea wasp, sea nettles, true jellyfish, sea anemones, true coral, and soft coral, are responsible for more envenomations than any other marine animals **Figure 32-20**. The stinging cells of the coelenterate are called nematocysts, and large animals may discharge hundreds of thousands of them. Envenomation causes very painful, red lesions in light-skinned people extending in a line from the site of the sting. Systemic symptoms include headache, dizziness, muscle cramps, and fainting.

To treat a sting from the tentacles of a jellyfish, a Portuguese man-of-war, various anemones, corals, or hydras, remove the patient from the water and remove the tentacles by scraping them off with the edge of a stiff object, such as a credit card. Do not try to manipulate the remaining tentacles; this will only cause further discharge of the nematocysts. On very rare occasions, a patient may have a systemic allergic reaction to the sting of one of these animals. Treat such a patient for anaphylactic shock and provide rapid transport to the hospital.

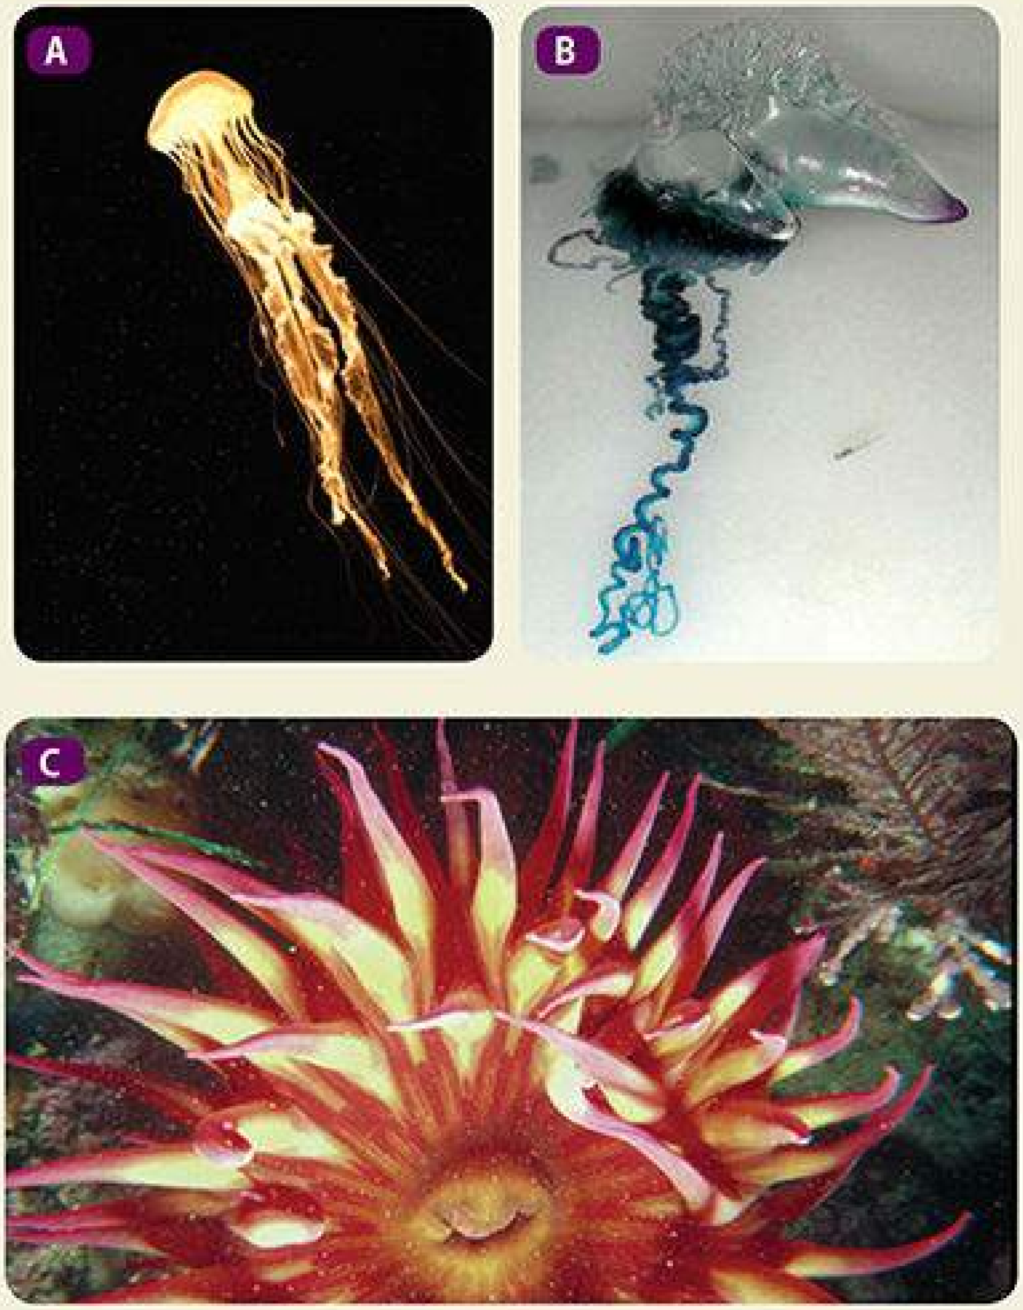

Figure 32-20 Coelenterates are responsible for many marine envenomations. **A.** Jellyfish. **B.** Portuguese man-of-war. **C.** Sea anemone.

A: © Creatas/Alamy; B: Courtesy of NOAA; C: Photos.com.

Toxins from the spines of urchins, stingrays, and certain spiny fish such as the lionfish, scorpion fish, or stonefish are also heat sensitive Table 32-3. Therefore, the best treatment for such injuries is also to soak the affected extremity in hot water for 30 minutes. This will often provide dramatic relief from local pain. However, the patient still needs to be transported to the ED because an allergic reaction or infection, including tetanus, could develop.

If you work near the ocean, you should be familiar with the marine life in your area. The emergency treatment of common coelenterate envenomations consists of the following steps:

1. Limit further discharge of nematocysts by avoiding fresh water, wet sand, showers, or careless manipulation of the tentacles. Keep the patient calm, and reduce motion of the affected extremity.

2. Remove the remaining tentacles by scraping them off with the edge of a stiff object such as a credit card. Do not use your ungloved hand to remove the tentacles, because self-envenomation will occur. Persistent pain may respond to immersion in hot water (110°F to 115°F [43.3°C to 46.1°C]) for 30 minutes. If available, immersion in vinegar may also help alleviate the symptoms.
3. Provide transport to the ED.

Table 32-3 Common Marine Envenomations

Dogfish	Marine snail	Starfish
Dragonfish	Portuguese man-of-war	Stingray
Fire coral	Ratfish	Stonefish
Hydroids	Scorpion fish	Tiger fish
Jellyfish	Sea anemone	Toadfish
Lionfish	Sea urchins	Weever fish

YOU are the Provider SUMMARY

1. How does the body normally balance heat production and elimination?

Normal core temperature—the temperature of the heart, lungs, and other vital organs—is usually around 98°F (36.7°C). A series of regulatory mechanisms keep this internal temperature constant, regardless of the ambient temperature (the temperature of the surrounding environment). However, heat elimination must balance heat production; if it does not, a temperature-related emergency occurs.

There are several ways the body removes excess heat, the most efficient of which are sweating (and evaporation of sweat) and dilation of the blood vessels. Ordinarily, the heat-regulating mechanisms of the body work very well and people are able to tolerate significant temperature changes.

2. What factors can decrease the body's ability to eliminate excess heat?

A number of factors can decrease a person's ability to eliminate excess heat. If air temperature is high, heat loss by radiation is reduced. Heat travels from a warmer place to a cooler place; if the ambient temperature is higher than body temperature, heat will move from the environment and into the body. If the relative humidity, the amount of moisture in the air, is high, heat loss by evaporation is reduced. Heat elimination is impaired the greatest when both the air temperature and relative humidity are high.

Vigorous exercise causes a loss of fluids and electrolytes, resulting in dehydration. Dehydration decreases heat loss through sweating and evaporation.

Small children and older patients exhibit poor thermoregulation; therefore, they are less able to eliminate excess body heat. The body's water content decreases with age, which reduces the ability to sweat.

Certain medical conditions, such as heart disease, chronic obstructive pulmonary disease, diabetes, dehydration, and obesity, interfere with the process of body heat elimination. In addition, alcohol and certain drugs, including medications that dehydrate the body (ie, diuretics) or decrease the ability of the body to sweat, also reduce heat elimination from the body.

3. What risk factors does this patient have that predispose him to a heat emergency?

Your patient has several risk factors for a heat emergency, the single most significant of which is prolonged exertion in a hot, humid environment. Also, the patient has not been drinking any water. In combination with profuse sweating that occurs during exposure to a hot environment, you should suspect that he is dehydrated.

The patient's past medical history also predisposes him to a heat emergency. Diabetes is a systemic condition that impairs many body functions, including thermoregulation. The patient also has hypertension, for which diuretics are often prescribed. Diuretics promote urination, further contributing to his dehydration.

4. What type of heat emergency do you suspect that he is experiencing? Why?

There are several clinical findings that indicate your patient is experiencing the most serious heat illness, heatstroke. Unlike other less severe forms of heat illness (eg, heat cramps, heat exhaustion), patients with heatstroke have an altered level of consciousness, ranging from confusion to coma, and flushed, hot skin. *Your patient has both of these*. Untreated heatstroke will cause permanent brain and tissue damage; in most cases, it causes death.

5. What specific treatment is required for this patient?

Immediate treatment of heatstroke includes moving the patient to a cool environment and administering oxygen. Further treatment is aimed at actively cooling the patient. Unless there are extenuating circumstances that will delay your transport, active cooling measures should be performed en route to the hospital. Heatstroke is a true emergency; it requires rapid cooling and rapid transport. Any delays in providing treatment increase the potential for permanent brain and tissue damage or death.

Remove the patient's clothes because they can trap heat. Place cold packs at the patient's groin and axillae and behind the neck. Spray or pour saline on the patient and aggressively fan him; this measure, in conjunction with the air conditioner, will facilitate heat loss through convection and evaporation.

Continue to actively cool the patient and notify the receiving facility early so the facility can continue treatment immediately on your arrival.

6. What is the most likely explanation for this patient's vital signs?

Your patient's vital signs—tachypnea, tachycardia, and hypotension—indicate shock. This is because heatstroke is associated with a severe loss of fluids and electrolytes, which results in hypovolemia. You should expect that patients with heatstroke will be tachypneic and tachycardic because of all the heat energy they have in their body. This response alone may enable patients to compensate for the severe fluid loss that occurs with heatstroke. The presence of hypotension, however, indicates that the body's compensatory mechanisms have failed (decompensated shock).

Patients with hypovolemic shock associated with heatstroke will need intravenous fluids and other treatment aimed at correcting electrolyte abnormalities at the hospital. Consider an ALS intercept, but do not delay transport to do this. AEMTs and paramedics are able to establish IV lines and administer fluids. Otherwise, continue high-flow oxygen and closely monitor him.

7. How should you adjust your treatment of this patient?

Your patient's level of consciousness has deteriorated, and his respirations are now shallow. Furthermore, his oxygen saturation level has decreased to 89%. These clinical signs indicate that your patient is no longer breathing adequately. This can result in hypoxia and a decreased ability to remove heat from the body.

Patients with inadequate breathing need assisted breathing with a BVM and high-flow oxygen. In addition to actively cooling the patient, ensure that oxygenation and ventilation remain adequate. Consider inserting an airway adjunct to assist in maintaining airway patency. In this case, a nasal airway is the best choice because the patient is not completely unconscious and likely has an intact gag reflex.

8. How will you know when you have adequately cooled the patient?

Ideally, you should monitor the patient’s core body temperature (CBT); this is most reliably obtained by assessing the patient’s rectal temperature, if local protocols allow. It is important to note that the CBT increases rapidly in patients with heatstroke, but does not decrease as quickly, even with aggressive cooling measures. Therefore, you will likely have to actively cool the patient throughout the entire transport, unless the destination hospital is a great distance away.

Follow your local protocols or contact online medical control regarding the “target temperature” that you should attempt to achieve. If your protocols do not allow you to monitor a patient’s CBT rectally, an axillary temperature should be assessed, although it is less accurate.

If you are unable to monitor the patient’s CBT, frequently reassess his skin temperature during the cooling process. Does it feel as hot as it was initially, or does it seem to be cooler than it was before? It is important to frequently assess the effectiveness of your interventions.

When actively cooling a patient with heatstroke, do not cool him or her to the point of shivering. Shivering generates more heat and can occur when cooling is not monitored closely.

9. What other conditions should you consider as potential causes of the patient’s altered mental status?

Altered mental status may be associated with heatstroke solely or could be the result of a completely different problem. An increase in heat energy causes the body to expend a lot of glucose; therefore, consider the possibility of hypoglycemia. You should also consider the possibility of a head injury. Recall that the patient apparently fainted. When this occurred, he may have fallen and struck his head, resulting in a concussion or intracranial hemorrhage. Do not rule out an occult head injury in the absence of obvious signs of trauma.

EMS Patient Care Report (PCR)

Date: 8-11-16	**Incident No.:** 013010	**Nature of Call:** Fainting		**Location:** 1102 Rosewood Avenue	
Dispatched: 1415	**En Route:** 1415	**At Scene:** 1422	**Transport:** 1430	**At Hospital:** 1443	**In Service:** 1450

Narrative

Medic 4 was dispatched to a residence for a man who fainted after working outside in the heat for a prolonged period of time. Arrived on scene and found the patient, a 55-year-old man, sitting under a tree in his garden. He was conscious but confused. His airway was patent and his breathing, although increased in rate, was producing adequate depth. Applied high-flow oxygen via nonrebreathing mask and quickly moved the patient to the air-conditioned ambulance. Secondary assessment was performed, but did not reveal any gross signs of injury. Patient's skin was flushed, hot, and moist. According to the patient's wife, he would not come out of the heat to take a break and drink some water. When she found him, he did not respond to her initially. Patient's past medical history includes hypertension and angina; medications listed above. Initial axillary temperature read 104.5°F (40.3°C). Removed patient's clothing and began rapid cooling measures by placing cold packs to his groin, axillae, and behind his neck. Began transport and continued cooling by spraying the patient with saline and fanning him. Vital signs indicated shock, so high-flow oxygen therapy was continued. Reassessment revealed that patient's mental status had markedly diminished; he was responsive only to pain. His respirations remained rapid, but were markedly decreased in depth. Inserted nasal airway and began assisting patient's ventilations with a BVM and high-flow oxygen. After cooling measures, reassessment revealed that the patient's skin, although very warm, did not feel as hot as it was initially; he also appeared less flushed. Patient became somewhat combative and would no longer tolerate assisted ventilation. Reapplied nonrebreathing mask and reassessed his axillary temperature; it read 102.5°F (39.2°C). Continued to reassess patient's vital signs as indicated and monitored him for signs of overcooling. Remainder of transport was uneventful; patient was delivered to the emergency department and verbal report was given to attending physician. Medic 4 cleared the hospital and returned to service at 1450.**End of report**

Prep Kit

Ready for Review

- Cold-related emergencies can be either a local or a systemic problem.
- Local cold injuries include frostbite, frostnip, and immersion foot. Frostbite is the most serious because tissues actually freeze. All patients with a local cold injury should be removed from the cold and protected from further exposure.
- If instructed to do so by medical control, rewarm frostbitten parts by immersing them in water at a temperature between 100°F and 112°F (37.8°C and 44.4°C).
- The key to treating patients with hypothermia is to stabilize vital functions and prevent further heat loss. Do not attempt to rewarm patients who have moderate to severe hypothermia because they are prone to dysrhythmias developing.
- Do not consider a patient dead until they are "warm and dead." Local protocols will dictate whether or not such patients receive CPR or defibrillation in the field.
- The body's regulatory mechanisms normally maintain body temperature within a very narrow range around 98°F (36.7°C). Body temperature is regulated by heat loss to the atmosphere via conduction, convection, evaporation, radiation, and respiration.
- Heat emergencies can take three forms: heat cramps, heat exhaustion, and heatstroke.
  - Heat cramps are painful muscle spasms that occur with vigorous exercise. Treatment includes removing the patient from the heat, resting the affected muscles, and replacing fluid loss.
  - Heat exhaustion is essentially a form of hypovolemic shock caused by dehydration. Symptoms include cold and clammy skin, weakness, confusion, headache, and rapid pulse. Body temperature can be high, and the patient may or may not still be sweating. Treatment includes removing the patient from the heat and treating for mild hypovolemic shock.
  - Heat stroke is a life-threatening emergency, usually fatal if untreated. Patients with heat stroke are usually dry and will have high body temperatures, typically greater than 104°F (40°C). Patients who have heat stroke due to exertion will have wet skin. Changes in mental status can include coma. Rapid lowering of the body temperature in the field is critical.
- The first rule in caring for drowning victims is to be sure not to become a victim yourself. Protect the spine when removing patients from the water because spinal cord injuries often occur in drownings. Be alert for hypothermia.
- Injuries associated with scuba diving may be immediately apparent or may show up hours later. Patients with an air embolism or decompression sickness may have pain, paralysis, or an altered mental status. Be prepared to transport such patients to a recompression facility with a hyperbaric chamber.
- Venomous spiders include the black widow spider and the brown recluse spider.
- Venomous snakes include pit vipers and coral snakes.
- A person who has been bitten by a venomous snake needs prompt transport; clean the bite area and keep the patient calm to slow the spread of venom.
- Notify the hospital as soon as possible if a patient has been bitten by a pit viper or coral snake. Some venoms can cause paralysis of the nervous system, and hospitals may not have appropriate antivenin on hand.
- Patients who have been bitten by ticks may be infected with Rocky Mountain spotted fever or Lyme disease and should see a doctor within a day or two. Remove the tick using tweezers, and save it for identification.
- Always provide prompt transport to the hospital for any patient who has been bitten by a venomous insect or animal. Remember that vital signs can deteriorate rapidly. Carefully monitor the patient's vital signs en route, especially for airway compromise.

Vital Vocabulary

air embolism Air bubbles in the blood vessels.

ambient temperature The temperature of the surrounding environment.

antivenin A serum that counteracts the effect of venom from an animal or insect.

bends A common name for decompression sickness.

breath-holding syncope Loss of consciousness caused by a decreased breathing stimulus.

conduction The loss of heat by direct contact (eg, when a body part comes into contact with a colder object).

convection The loss of body heat caused by air movement (eg, a breeze blowing across the body).

core temperature The temperature of the central part of the body (eg, the heart, lungs, and vital organs).

decompression sickness A painful condition seen in divers who ascend too quickly, in which gas, especially nitrogen, forms bubbles in blood vessels and other tissues; see *bends*.

diving reflex The slowing of the heart rate caused by submersion in cold water.

drowning The process of experiencing respiratory impairment from submersion or immersion in liquid.

dysbarism injuries Any signs and symptoms caused by the difference between the surrounding atmospheric pressure and the total gas pressure in various tissues, fluids, and cavities of the body.

evaporation The conversion of water or another fluid from a liquid to a gas.

frostbite Damage to tissues as the result of exposure to cold; frozen body parts.

heat cramps Painful muscle spasms usually associated with vigorous activity in a hot environment.

heat exhaustion A heat emergency in which a significant amount of fluid and electrolyte loss occurs because of heavy sweating; also called heat prostration or heat collapse.

heat stroke A life-threatening condition of severe hyperthermia caused by exposure to excessive natural or artificial heat, marked by warm, dry skin; severely altered mental status; and often irreversible coma.

homeostasis A balance of all systems of the body.

hymenoptera A family of insects that includes bees, wasps, ants, and yellow jackets.

hyperthermia A condition in which the body core temperature rises to 101°F (38.3°C) or more.

hypothermia A condition in which the body core temperature falls below 95°F (35°C) after exposure to a cold environment.

radiation The transfer of heat to colder objects in the environment by radiant energy; for example, heat gain from a fire.

respiration The loss of body heat as warm air in the lungs is exhaled into the atmosphere and cooler air is inhaled.

reverse triage A triage process used in treating multiple victims of a lightning strike, in which efforts are focused on those who are in respiratory and cardiac arrest. Reverse triage is different from conventional triage where such patients would be classified as deceased.

scuba gear A system that delivers air to the mouth and lungs at various atmospheric pressures, increasing with the depth of the dive; stands for self-contained underwater breathing apparatus.

turgor The ability of the skin to resist deformation; tested by gently pinching skin on the forehead or back of the hand.

Assessment *in Action*

You and your partner are called for a 25-year-old man who was found unresponsive by two hikers in a remote area of a national forest. On arrival, you observe a young man lying supine on the ground with a liquor bottle nearby. Despite near-freezing temperatures, he is dressed in a T-shirt and jeans.

1. After establishing unresponsiveness, what should be your next step in patient management?

   A. Provide manual in-line stabilization.
   B. Open the airway.
   C. Check for a pulse.
   D. Measure the core body temperature.

2. Hypothermia is diagnosed when the core body temperature falls below what temperature?

   A. 98°F (36.7°C)
   B. 95°F (35°C)
   C. 92°F (33.3°C)
   D. 90°F (32.2°C)

3. The patient has a respiratory rate of 4 breaths per minute. Your partner assists ventilations with a BVM while you perform a pulse check. How long should you assess for a carotid pulse?

   A. 5 to 10 seconds
   B. 15 to 30 seconds
   C. 30 to 45 seconds
   D. 45 to 60 seconds

4. The patient's core body temperature is 80°F (26.7°C). At this temperature, the patient's hypothermia would be classified as:

   A. mild.
   B. moderate.

C. severe.
D. extreme.

5. Your partner observes a medical alert bracelet on the patient's wrist. It says that the patient has diabetes. Other risk factors for hypothermia include all the following EXCEPT:

A. burns.
B. head injury.
C. shock.
D. acclimatization to cold.

6. Shivering stops and muscle activity ceases once the body core temperature reaches:

A. 95°F (35°C).
B. 90°F (32.2°C).
C. 85°F (29.4°C).
D. 80°F (26.7°C).

7. Rough handling of a patient with severe hypothermia may cause which of the following dysrhythmias?

A. Ventricular fibrillation
B. Sinus bradycardia
C. Asystole
D. Sinus tachycardia

8. Appropriate treatment of this patient includes all of the following EXCEPT:

A. removing wet clothing.
B. wrapping the patient in warm blankets.
C. placing the patient in a heated ambulance.
D. placing heat packs on the patient's extremities.

9. Discuss the controversy regarding performing CPR in a patient with severe hypothermia.

10. Why are children and infants at a greater risk of hypothermia developing than adults?

8

Special Patient Populations

CHAPTER 33

Obstetrics and Neonatal Care

National EMS Education Standard Competencies

Special Patient Populations

Applies a fundamental knowledge of growth, development, and aging and assessment findings to provide basic emergency care and transportation for a patient with special needs.

Obstetrics

› Recognition and management of:
- Normal delivery (pp 1191–1201)
- Vaginal bleeding in the pregnant patient (pp 1187–1189, 1191, 1193)

› Anatomy and physiology of normal pregnancy (pp 1183–1186)

› Pathophysiology of complications of pregnancy (pp 1186–1189)

› Assessment of the pregnant patient (pp 1191–1193)

› Management of
- Normal delivery (pp 1194–1201)
- Abnormal delivery (pp 1206–1209)
  - Nuchal cord (p 1200)
  - Prolapsed cord (pp 1207–1208)
  - Breech delivery (pp 1206–1207)
- Third trimester bleeding (pp 1187–1189)
  - Placenta previa (pp 1187–1188)
  - Abruptio placenta (pp 1187–1189)
- Spontaneous abortion/miscarriage (pp 1187–1188)
- Ectopic pregnancy (pp 1187–1188)
- Preeclampsia/Eclampsia (pp 1187–1188)

Neonatal care

Assessment and management

› Newborn care (pp 1201–1206)
› Neonatal resuscitation (pp 1202–1206)

Trauma

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

Special Considerations in Trauma

› Recognition and management of trauma in the:
  • Pregnant patient (pp 1189–1190)
  • Pediatric patient (Chapter 34, *Pediatric Emergencies*)
  • Geriatric patient (Chapter 35, *Geriatric Emergencies*)
› Pathophysiology, assessment, and management of trauma in the:
  • Pregnant patient (pp 1189–1190)
  • Pediatric patient (Chapter 34, *Pediatric Emergencies*)
  • Geriatric patient (Chapter 35, *Geriatric Emergencies*)
  • Cognitively impaired patient (Chapter 36, Patients With Special Challenges)

Knowledge Objectives

1. Identify the anatomy and physiology of the female reproductive system. (pp 1183–1185)
2. Explain the normal changes that occur in the body during pregnancy. (pp 1185–1186)
3. Recognize complications of pregnancy including abuse, substance abuse, hypertensive disorders, bleeding, spontaneous abortion (miscarriage), and gestational diabetes. (pp 1186–1189)
4. Discuss the need to consider two patients—the woman and the unborn fetus—when treating a pregnant trauma patient. (pp 1189–1190)
5. Discuss special considerations involving pregnancy in different cultures and with teenage patients. (pp 1190–1191)
6. Explain assessment of the pregnant patient. (pp 1191–1193)
7. Explain the significance of meconium in the amniotic fluid. (p 1192)
8. Differentiate among the three stages of labor. (pp 1193–1194)
9. Describe the indications of an imminent delivery. (p 1195)
10. Explain the steps involved in normal delivery management. (pp 1194–1201)
11. List the contents of an obstetrics kit. (p 1195)
12. Explain the necessary care of the fetus as the head appears. (p 1200)
13. Describe the procedure followed to clamp and cut the umbilical cord. (pp 1199–1201)
14. Describe delivery of the placenta. (pp 1201–1202)
15. Explain the steps to take in neonatal assessment and resuscitation. (pp 1202–1206)
16. Recognize complicated delivery emergencies including breech presentations, limb presentations, umbilical cord prolapse, spina bifida, multiple gestation, premature newborns, postterm pregnancy, fetal demise, and delivery without sterile supplies. (pp 1206–1209)
17. Describe postpartum complications and how to treat them. (pp 1209–1210)

Skills Objectives

1. Demonstrate the procedure to assist in a normal cephalic delivery. (pp 1197–1200, Skill Drill 33-1)
2. Demonstrate care procedures of the fetus as the head appears. (p 1200)
3. Demonstrate how to clamp and cut the umbilical cord. (pp 1199–1201)
4. Demonstrate the steps to follow in postdelivery care of the newborn. (pp 1201–1202)
5. Demonstrate how to assist in delivery of the placenta. (pp 1201–1202)
6. Demonstrate the postdelivery care of the woman. (pp 1201–1202)
7. Demonstrate procedures to follow for complicated delivery emergencies including vaginal bleeding, breech presentation,

limb presentation, and prolapsed umbilical cord. (pp 1206–1208)

Introduction

According to the Centers for Disease Control and Prevention (CDC), although there has been a recent trend of women choosing to give birth at home, most deliveries in the United States still occur in a hospital, with doctors and nurses in attendance. Occasionally, the birth process moves faster than the pregnant woman expects, or she is unable to get to a hospital, and you will find yourself needing to make a decision: Should you assist the delivery on the scene or transport the patient to the hospital? Are there other factors that affect this decision, such as trauma, weather, and distance to the hospital? This chapter explains how to make this decision and how to proceed if on-scene delivery is necessary. It describes the anatomy and physiology of a normal pregnancy and the normal process of childbirth. Also discussed are common complications, including trauma in a pregnant patient, so that you will be prepared to handle normal and abnormal deliveries. Finally, the chapter discusses the evaluation and care of the newborn and neonatal resuscitation.

Anatomy and Physiology of the Female Reproductive System

The female reproductive system includes the ovaries, fallopian tubes, uterus, cervix, vagina, and breasts. The ovaries are two glands, one on each side of the uterus, that are similar in function to the male testes. Each ovary contains thousands of follicles, and each follicle contains an egg (the female contribution to conception). Females are born with all the eggs they will release in their lifetime.

Once puberty is reached, the monthly process of the menstrual cycle begins. During each menstrual cycle, only one follicle (out of 10 to 20 that attempt the process each month) will be successful at maturing and releasing an egg. The remaining follicles die and are reabsorbed by the body. The processes that the follicle goes through and the actual release of the egg (ovulation) are stimulated by the release of specific hormones in the female body. Ovulation occurs approximately 2 weeks prior to menstruation. Immediately following ovulation, the **endometrium** (the lining of the inside of the uterus) begins to thicken in preparation for the potential implantation of a fertilized egg. If the egg is not fertilized within 36 to 48 hours after it has been released from the follicle, it will simply die, and the thickened endometrium will be shed because it is not needed. This shedding is the menstrual flow that occurs around the 28th day of a woman's cycle.

The fallopian tubes extend out laterally from the uterus, with one tube associated with each ovary. When an egg is released from the ovary, it travels through the fallopian tube to the uterus. Fertilization, which occurs when a sperm meets an egg, usually takes place when the egg is inside the fallopian tube. The fertilized egg then continues to the uterus where, if implantation occurs, the fertilized egg develops into an **embryo** (the stage from 0 to 10 weeks after fertilization) and then a **fetus** (the stage from 10 weeks until delivery) and grows until the time of delivery at approximately 9 months (40 weeks) of gestation **Figure 33-1**. The uterus is a muscular organ that encloses and protects the developing fetus. During labor, it produces contractions and ultimately helps to push the fetus through the **birth canal**. The birth canal is made up of the vagina and the lower third, or neck, of the uterus, called the **cervix**. During pregnancy, the cervix contains a mucous plug that seals the uterine opening, preventing contamination from the outside. When the cervix begins to dilate, this plug is discharged into the vagina as pink-tinged mucus, sometimes called **bloody show**. This small amount of bloody discharge often signals the beginning of labor.

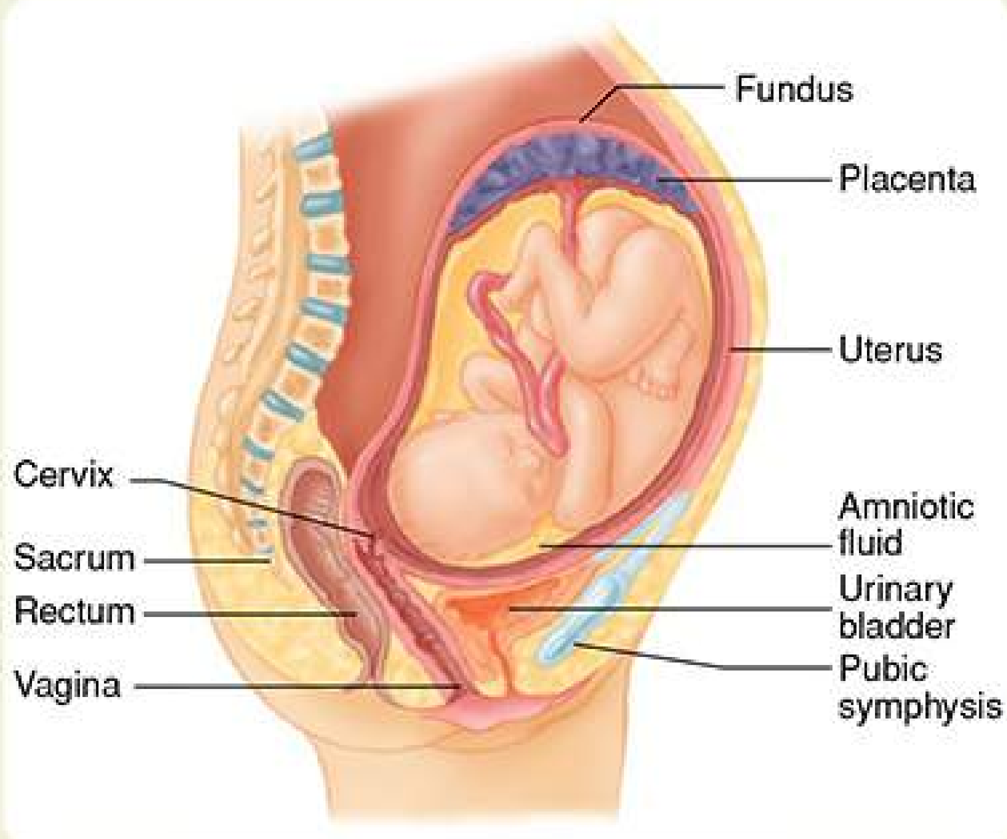

Figure 33-1 Anatomic structures of the pregnant woman.

The vagina is the outermost cavity of the female reproductive system and forms the lower part of the birth canal. It is about 3 to 5 inches (8 to 12 cm) in length, beginning at the cervix and ending as an external opening of the body. The vagina completes the passageway from the uterus to the outside world for the newborn. The area between the vagina and the anus is called the **perineum**.

The breasts (mammary glands) are also a part of the female reproductive system. In a pregnant woman, the breasts produce milk that is carried through small ducts to the nipples to provide nourishment for the newborn. Early signs of pregnancy include increased size and tenderness in the breasts.

As the fetus continues to develop, it requires increasingly more nourishment and support. The **placenta**, a disk-shaped structure attached to the uterine wall that provides nourishment to the fetus, develops while attached to the inner lining of the wall of the uterus and is connected to the fetus by the umbilical cord. Blood normally does not mix between the fetus and the pregnant woman because of the placental barrier **Figure 33-2**. This consists of two layers of cells, keeping the circulation of the woman and fetus separated but allowing nutrients, oxygen, waste, carbon dioxide, and, unfortunately, many toxins and most medications to pass between the fetus and woman. Anything ingested by a pregnant woman therefore has the potential to affect the fetus. After delivery of the newborn, the placenta separates from the uterus and is delivered. The **umbilical cord** is the lifeline of the fetus, connecting the woman and fetus through the placenta. The umbilical cord contains two arteries and one vein. The umbilical vein carries oxygenated blood from the placenta to the heart of the fetus, and the umbilical arteries carry deoxygenated blood from the heart of the fetus to the placenta. Oxygen and other nutrients cross from the woman's circulation through the placenta and then through the umbilical cord to support the fetus as it grows.

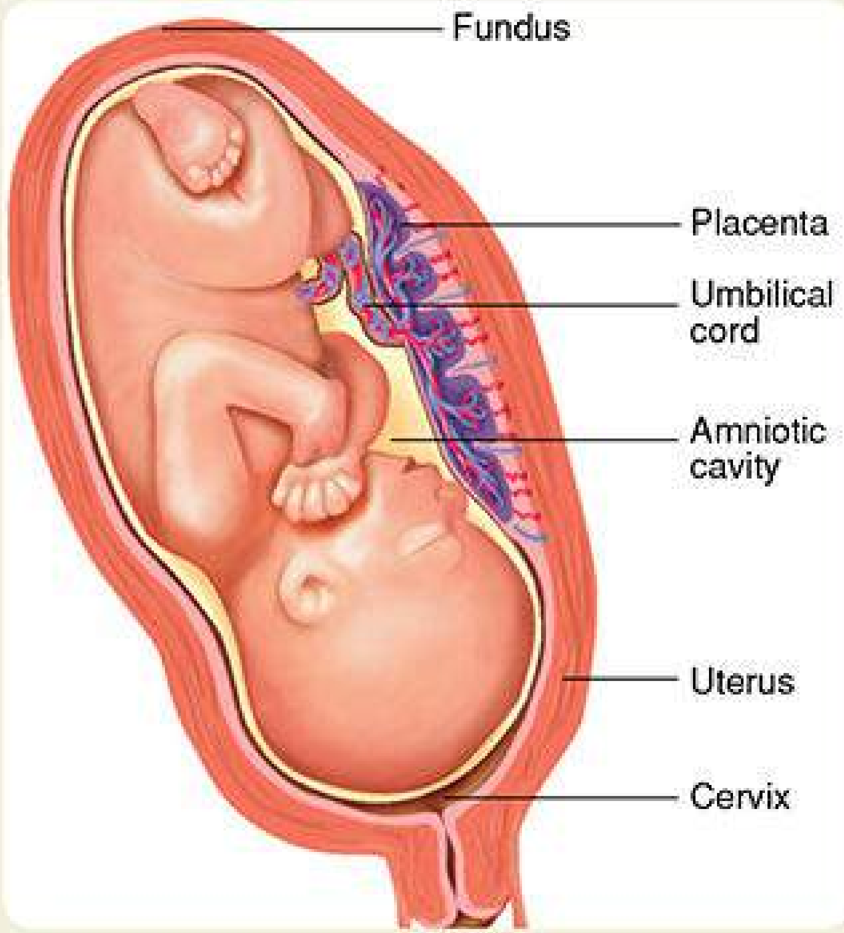

Figure 33-2 The placental barrier keeps the maternal and fetal blood separate but allows nutrients, oxygen, waste, carbon dioxide, toxins, and most medications to pass between the fetus and pregnant woman.

YOU are the Provider — PART 1

At 0625 hours, you are dispatched to a residence at 2505 Landa Park Boulevard for a woman in labor. You and your partner proceed to the scene, which is located a short distance away. While en route, dispatch advises you that the patient is 38 weeks pregnant and her contractions are 3 minutes apart.

1. What anatomic and physiologic changes occur during pregnancy? How will they affect your assessment of the patient?
2. How will you determine if delivery is imminent or if there is enough time to transport the pregnant patient?

Words of Wisdom

Predicting the due date is not an exact science and a due date is not a guarantee that a birth will occur on that day. Many factors influence when a baby is delivered, and neither the patient nor EMTs have much control over this. One point of confusion is that most medical models base the due date on the first day of the last menstrual cycle. That adds approximately 2 weeks to the actual pregnancy because conception occurs sometime after ovulation, which occurs approximately 2 weeks after the beginning of the last menstrual cycle. Most women have a general idea of the date their last menstrual cycle began, but young women, women who have very irregular cycles, and women who did not think they were pregnant are especially likely to have inaccurate due dates. Also, some women calculate their due date by counting the number of weeks from conception instead of menstruation. The important thing to remember is that a due date is not a good predictor of when a woman will deliver.

The fetus develops inside a fluid-filled, bag-like membrane called the **amniotic sac**, or bag of waters. The sac contains about 500 to 1,000 mL of amniotic fluid, which helps insulate and protect the fetus. When the sac ruptures, usually at the beginning of labor, the amniotic fluid is released in a gush. It is typical for the patient to tell you that her “water broke.” Some women may experience a small leak rather than a gush of fluid. This fluid helps to lubricate the birth canal and remove any bacteria.

A pregnancy is considered full term once it reaches 39 weeks but has not gone beyond 40 weeks, 6 days. A pregnancy that has reached full term is referred to as **term gestation**.

Normal Changes in Pregnancy

In addition to changes in the reproductive system, many other body systems undergo normal changes during pregnancy. It is important to understand these changes as you assess and treat a pregnant patient. The primary systems involved are the respiratory, cardiovascular, and musculoskeletal systems.

In the reproductive system, hormone levels increase to support fetal development and prepare the body for childbirth. These increased hormone levels also put the pregnant woman at an increased risk for complications from trauma, bleeding, and some medical conditions. As the fetus develops, the uterus grows, stretching to accommodate a full-term fetus. As the size of the uterus increases, so does the amount of fluid it contains. These factors eventually result in displacement of the uterus out of its well-protected position within the pelvic area and may expose it to injury. By the 20th week of pregnancy, the top of the uterus is at or above the belly button. This increases the chance of direct fetal injury in trauma.

Rapid uterine growth occurs during the second trimester of pregnancy. The increased size of the uterus directly affects the respiratory system. As the uterus grows, it pushes up on the diaphragm, displacing it from its normal position. As the pregnancy continues, respiratory capacity changes, with increased respiratory rates and decreased minute volumes. This is a normal change. You may observe that a pregnant patient has an increased breathing rate and a decreased ability to breathe deeply. These changes result in a less-than-normal respiratory reserve. The pregnancy also increases the patient’s overall demand for oxygen as her metabolic demands and workload increase to support the developing fetus.

Changes also occur in the cardiovascular system. Overall blood volume gradually increases throughout the pregnancy to allow for adequate perfusion of the uterus as the fetus grows and to prepare for the blood loss that will occur during childbirth. Blood volume may increase by as much as 50% by the end of the pregnancy. The number of red blood cells also increases, which increases the woman’s need for iron. Pregnant women often take prenatal vitamin supplements containing iron to avoid becoming **anemic**, a condition in which a person has too few red blood cells, resulting in a decreased ability to transport oxygen throughout the body. Blood clotting factors also change as the woman’s body prepares for childbirth. The speed of clotting increases to protect against excessive bleeding during delivery. By the end of the pregnancy (third trimester), the pregnant patient’s heart rate increases up to 20% (about 20 more beats per minute) to accommodate the increase in blood volume. Cardiac output is significantly increased by the end of the pregnancy.

A woman in the third trimester of pregnancy has an increased risk of vomiting and potential aspiration following trauma because of changes in the gastrointestinal tract. The filling and emptying of the stomach into the small intestine is under the control of key hormones and the nervous system. Changes in these systems and the displacement of the stomach upward because of the increased size of the uterus significantly increase the chance that a pregnant trauma patient will vomit and aspirate. You should be prepared to quickly manage the patient’s airway if needed.

Changes in the cardiovascular system and the increased demands of supporting the fetus significantly increase the workload of the heart. A healthy woman’s body can handle the increased workload and demand. Not all pregnant women are healthy when they begin their pregnancy, however. Cardiac compromise is a life-threatening possibility.

Weight gain during pregnancy is normal; however, the increase in body weight eventually challenges the heart and impacts the musculoskeletal system. Increased hormones affect the musculoskeletal system by making the joints “looser,” or less stable. Women in the third trimester of pregnancy also experience a change in the body’s center of gravity, making them prone to slipping and falling.

Complications of Pregnancy

Although most pregnant women are healthy, some may be ill when they conceive or become ill during pregnancy. You may safely administer oxygen to treat any heart or lung disease in a pregnant patient without harm to the fetus.

Diabetes

Diabetes develops during pregnancy in many women who have not had diabetes previously. This condition, called **gestational diabetes**, resolves in most women after delivery. Treatment of a pregnant woman with diabetes is the same as treatment for any patient who has diabetes. A pregnant woman may control her blood glucose level with diet and exercise or may take medication. In some cases, the woman will have to manage her condition with insulin injections. A pregnant woman experiencing hyperglycemia or hypoglycemia should be cared for in the same manner as any patient with diabetes. If a pregnant woman has an altered level of consciousness, your assessment should include determining if she has a history of diabetes, and you should check the blood glucose level if local protocols permit.

YOU are the Provider — PART 2

When you arrive at the scene, you are greeted at the door by the patient's husband. He is obviously anxious and tells you, "She's having the baby! I thought I could get her to the hospital in time, but I was wrong." You find the patient, a 28-year-old woman, lying supine in her bed. You introduce yourself and your partner and perform a primary assessment.

Recording Time: 0 Minutes	
Appearance	Diaphoretic; in obvious pain
Level of consciousness	Conscious and alert
Airway	Open; clear of secretions and foreign bodies
Breathing	Increased rate; adequate depth
Circulation	Pulse rate is increased; strong and regular; no gross bleeding

The patient tells you that she feels like she needs to move her bowels and that her contractions are now about 2 minutes apart and last about 45 seconds. A brief visual examination of her perineum does not reveal crowning. According to the patient's husband, this is her third delivery, and she has had gestational diabetes and preeclampsia with this pregnancy. Her amniotic sac ruptured about 5 hours ago.

3. What are gestational diabetes and preeclampsia? How can they affect this delivery?
4. Is there time to transport this patient, or should you prepare for imminent delivery?

Many women experience nausea before labor and may not have eaten recently. These factors can lead to hypoglycemia and weakness in the woman and fetus. Consult with medical control if delivery is imminent.

Hypertensive Disorders

As delivery nears, complications can occur. One complication of pregnancy that occasionally occurs, typically in patients who are pregnant for the first time, is **preeclampsia**, or **pregnancy-induced hypertension**. This condition can develop after the 20th week of gestation and is characterized by the following signs and symptoms:

- Severe hypertension
- Severe or persistent headache
- Visual abnormalities such as seeing spots, blurred vision, or sensitivity to light
- Swelling in the hands and feet (edema)
- Anxiety

A related condition, **eclampsia**, is characterized by seizures that occur as a result of hypertension. To treat a patient having seizures caused by eclampsia, lay the patient on her left side, maintain her airway, and administer supplemental oxygen, if necessary. If vomiting occurs, suction the airway. Provide rapid transport for a pregnant patient having seizures, and call for an advanced life support (ALS) intercept, if available.

Transporting the patient on her left side can also prevent **supine hypotensive syndrome**. This condition is caused by compression of the inferior vena cava by the pregnant uterus when the patient lies supine, reducing the amount of blood that is returned to the heart. Hypotension (low blood pressure) may result from this compression. Any patient in the third trimester of pregnancy should always be positioned on her left side during transport except during delivery.

Bleeding

An **ectopic pregnancy** is when an embryo develops outside of the uterus, most often in a fallopian tube. A patient with an ectopic pregnancy may present with signs of internal bleeding when the fallopian tube ruptures **Figure 33-3**. An ectopic pregnancy occurs about once in every 300 pregnancies. The leading cause of maternal death in the first trimester of pregnancy is internal hemorrhage into the abdomen following rupture of an ectopic pregnancy. For this reason, consider the possibility of an ectopic pregnancy in a woman who has missed a menstrual cycle and reports sudden, severe, usually unilateral pain in the lower abdomen. A history of pelvic inflammatory disease, tubal ligation, or previous ectopic pregnancies should heighten your suspicion of a possible ectopic pregnancy.

Hemorrhage from the vagina that occurs before labor begins may be very serious. If you see this, call for ALS backup. In early pregnancy, it may be a sign of a spontaneous abortion, or **miscarriage**. In the later stages of pregnancy, vaginal hemorrhage may indicate a serious condition involving the placenta. In **abruptio placenta**, the placenta separates prematurely from the wall of the uterus **Figure 33-4**. The most common causes are hypertension and trauma. A patient with abruptio placenta often reports severe pain; however, vaginal bleeding may not be heavy. She may also present with signs of shock such as weak, rapid pulse and pale, cool, diaphoretic skin. In **placenta previa**, the placenta develops over and covers the cervix **Figure 33-5**. When early labor begins and the cervix begins to dilate, the pregnant woman may experience heavy vaginal bleeding, often without significant pain. Both abruptio placenta and placenta previa are life-threatening conditions and require immediate rapid transport.

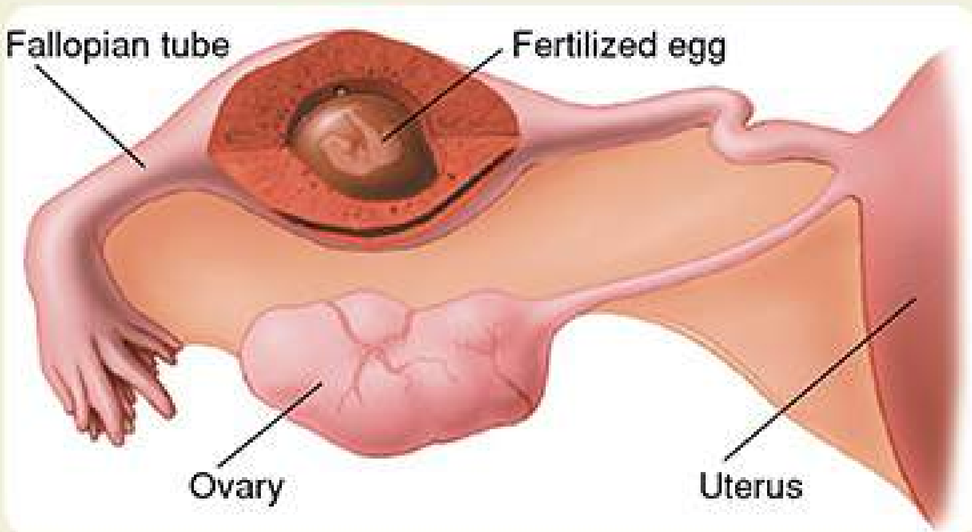

Figure 33-3 In an ectopic pregnancy, a fertilized egg implants somewhere other than in the uterus. Here, it is implanted in one of the fallopian tubes.

Figure 33-4 In abruptio placenta, the placenta separates prematurely from the wall of the uterus.

Regardless of the cause of the bleeding, the pregnant patient may be emotional and very concerned about her baby. Your professional approach in communicating with the patient will play a crucial part in calming her emotions and gaining control of the situation. Decreasing the patient's anxiety can impact how she and the fetus respond during this emergency.

Any bleeding from the vagina in a pregnant woman is a serious sign and should be treated promptly in the hospital. If the patient shows signs of shock, position her on her left side and administer high-flow oxygen per local protocols. Place a sterile pad or sanitary pad over the vagina, and replace it as often as necessary. Save the pads so that hospital personnel can estimate how much blood loss the patient experienced. Also save any tissue that may be passed from the vagina. Do not put anything into the vagina to control bleeding.

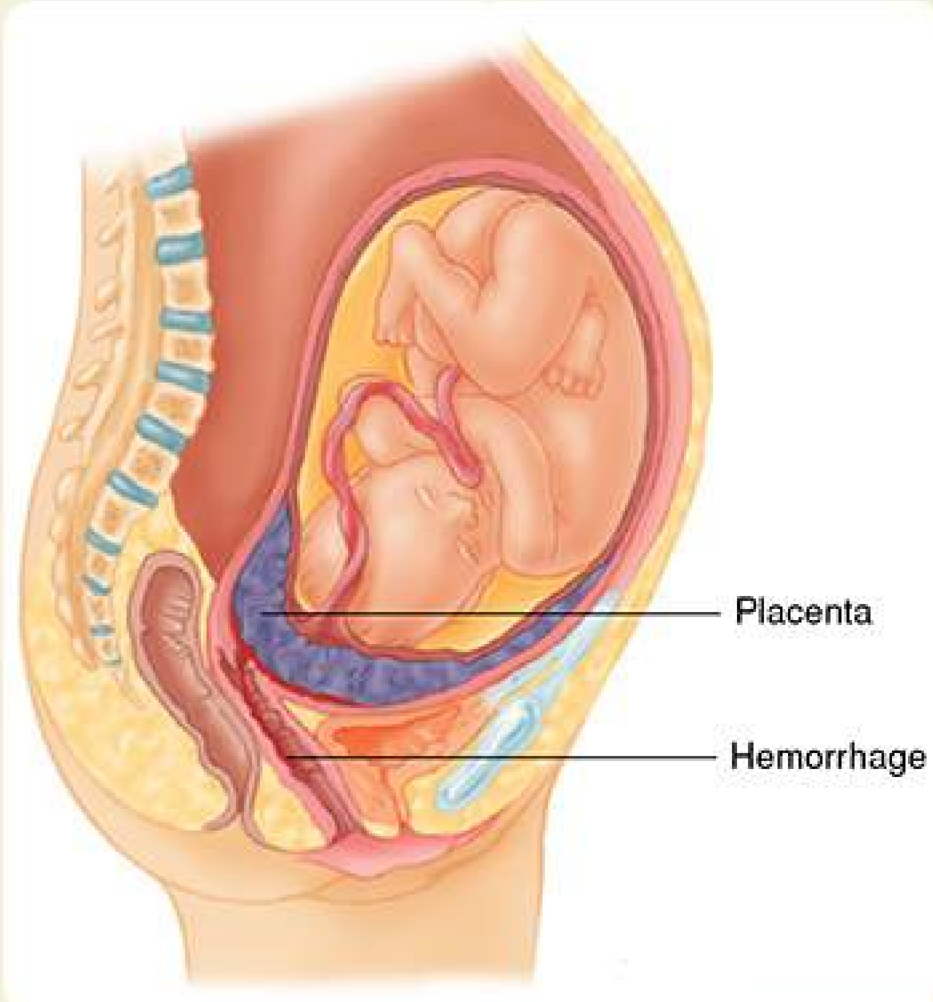

Figure 33-5 In placenta previa, the placenta develops over and covers the cervix.

Abortion

Passage of the fetus and placenta before 20 weeks is called abortion. Abortions may be spontaneous (commonly called miscarriage), often without any obvious known cause, or induced. Deliberate abortions may be self-induced, by the pregnant woman herself or by someone else, or planned and performed in a hospital or clinic. Regardless of the reason or the cause of the abortion, complications are possible.

The most serious complications of abortion are bleeding and infection. Bleeding can result when portions of the fetus or placenta are left in the uterus (incomplete abortion) or when the wall of the uterus is injured (perforation of the uterus and possibly the adjacent bowel or bladder). Infection can result from perforation and from the use of nonsterile instruments. If the patient is in shock, treat and transport her promptly to the hospital. Collect and bring to the hospital any tissue that passes through the vagina. Never try to pull tissue out of the vagina. Place a sterile pad or sanitary pad on the vagina. In rare cases, massive bleeding may occur and cause severe hypovolemic or hemorrhagic shock. In these cases, treat for shock and provide immediate transport.

Abuse

Pregnant women have an increased chance of being victims of domestic violence and abuse. Abuse is a common cause of complications in pregnancy and may harm the woman or the fetus. Abuse during pregnancy increases the chance of spontaneous abortion, premature delivery, and low birth weight. The woman is at risk of bleeding, infection, and uterine rupture. A calm, professional approach is especially important if you suspect your patient has been abused. Pay attention to the environment for any signs of abuse. Your attention to detail will be helpful in your documentation and in informing the physicians and staff who will be caring for the patient at the hospital.

Pregnant patients who are abused are often afraid to explain how their injuries occurred. If possible, talk to the patient in a private area, away from the potential abuser. Suspect abuse when the story of how an injury happened does not make sense. An abused patient who is pregnant will be concerned about her baby. The best way for you to care for the fetus is to treat the pregnant woman. Reassure the patient as you provide treatment. Support the patient's ABCs, control any bleeding, stabilize extremity injuries, treat for shock, and keep her warm.

Words of Wisdom

By 20 weeks of gestation, the top of the uterus has grown to the level of the patient's belly button. That position makes the fetus more prone to injury. This is important to remember when managing a pregnant patient who has sustained trauma and to aid in your assessment of a pregnant patient's abdomen.

Substance Abuse

Some pregnant women are addicted to alcohol or other drugs. These women often have had little or no prenatal care. The effects of the addiction on the fetus can include prematurity, low birth weight, and severe respiratory depression. Some of these infants will die. **Fetal alcohol syndrome** is a condition seen in infants born to women who have abused alcohol.

If you are called to handle a delivery of an addicted woman, pay special attention to your own safety. Follow standard precautions. Wear eye protection, a face mask, and gloves at all times. Clues that you may be dealing with an addicted patient include the presence of drug paraphernalia, empty wine or liquor bottles, and statements made by family or bystanders or by the patient herself. The newborn of an addicted woman will probably need immediate resuscitation. Assist with the delivery, and be prepared to support the newborn's respirations and administer oxygen during transport. Do not judge or lecture the patient. Your job is to help with the delivery, provide treatment to the mother and the newborn, and transport both to the hospital.

Special Considerations for Trauma and Pregnancy

When you are dispatched to a trauma call that involves a pregnant woman, you have two patients to consider—the woman and the unborn fetus. Trauma to a pregnant woman may have a direct effect on the condition of the fetus. Pregnant women may be victims of many types of trauma, including assaults, motor vehicle crashes, and shootings.

Pregnant women also have an increased risk of falling compared with nonpregnant women. Contributing factors include hormonal changes that loosen the joints and the increased weight of the uterus and displacement of abdominal organs, which can affect the woman's balance. Pregnant women have an increased overall total blood volume and an approximate 20% increase in their heart rate by the third trimester of pregnancy. Therefore, a pregnant trauma patient may experience a significant amount of blood loss before you detect signs of shock. The fetus also may be in trouble well before signs of shock are present in the pregnant woman. The body of a woman who has sustained serious trauma often reduces the blood supply to the fetus so that the woman receives an adequate amount of blood.

When called to a trauma patient who is pregnant, be alert to additional concerns and be ready to assess and manage unique types of injuries. For example, as a pregnancy progresses, the uterus enlarges substantially, making it especially vulnerable to penetrating trauma and blunt injuries. The fetus may be injured directly from penetrating types of trauma such as gunshot wounds and stabbings. A traumatic injury to the abdomen can be life threatening to the woman and fetus because the pregnant uterus has a rich blood supply. If the woman is hypoxic, is in shock, or has hypovolemia, the fetus will be in distress. In most cases, the only chance to save the fetus is to adequately resuscitate the woman.

When a pregnant woman is involved in a motor vehicle crash or a similarly violent mechanism of injury (MOI), severe hemorrhage may result from injuries to the pregnant uterus. Trauma is one of the leading causes of abruptio placenta, which results in significant intrauterine hemorrhage that can cause life-threatening hypovolemic shock in the woman and also increases the chance of fetal death. In a pregnant trauma patient, suspect abruptio placenta when the MOI is blunt trauma to the abdomen and the patient's signs and symptoms suggest shock. Common symptoms include vaginal bleeding and severe abdominal pain. In this situation, quickly assess and transport the patient, support the airway, administer high-flow oxygen, place sanitary pads on the vagina, position the patient on her left side, and call for ALS backup.

Improper positioning of the seat belt can result in injury to a pregnant woman and the fetus if they are involved in a motor vehicle crash. The lap belt should be placed under the abdomen and over the pelvic bones (iliac crests), and the shoulder belt should be positioned between the breasts. Carefully assess a pregnant woman's abdomen and chest for seat belt marks, bruising, and obvious trauma. Maintain a high index of suspicion for internal abdominal bleeding in the woman and possible direct injury to the fetus, regardless of seat belt placement.

Maternal Cardiac Arrest

Occasionally a pregnant woman will go into cardiac arrest, often as the result of trauma. If the woman dies, the fetus will most certainly die as well, so resuscitation efforts need to be aggressively geared toward saving the woman. Perform cardiopulmonary resuscitation (CPR) and provide transport to the hospital according to local protocol.

Treatment of cardiac arrest in a pregnant patient is no different than in the nonpregnant patient, with a few minor exceptions. If a woman is in the last month or two of pregnancy, compressions may need to be applied a little higher on the sternum than usual. In addition, if possible, one provider should be assigned to manually displace the uterus toward the patient's left side to facilitate blood return to the right side of the heart. See Chapter 13, *BLS Resuscitation*, for how to perform this procedure.

Notify the receiving facility personnel as soon as possible that you are en route with a pregnant trauma patient in cardiac arrest so they will have time to prepare. It is possible that upon arrival at the hospital, if the woman cannot be saved, a cesarean section may be performed to save the fetus. Performing a cesarean section is not within the scope of practice for EMS providers.

Assessment and Management

Although you have two patients to care for when your patient is pregnant, your focus should be on the assessment and management of the woman. It is difficult to assess the extent of internal blood loss in a pregnant patient. The MOI should be the basis of suspicion of shock because the physiologic changes that occur with pregnancy can obscure the typical signs and symptoms of shock. As you assess and treat the patient, be prepared for vomiting, and anticipate the need to manage the airway to protect the patient from aspirating. Attempt to determine the gestational age (in number of weeks). This will help you determine the size of the fetus and the position of the uterus in the patient's abdominal cavity. It is nearly impossible for you to accurately assess or determine the status of the fetus, so you should aggressively provide emergency medical care to the woman to provide the best possible outcome for the fetus.

Follow these guidelines when treating a pregnant trauma patient:

1. **Maintain an open airway.** A pregnant patient has an increased risk of vomiting and aspiration. Be prepared for and anticipate vomiting; keep your suction unit readily available.
2. **Administer high-flow oxygen.** Remember that the patient's body is also supplying oxygen to the fetus. Keep the oxygen saturation level high and administer high-flow, 100% oxygen by nonrebreathing mask.
3. **Ensure adequate ventilation.** Listen to breath sounds, and confirm that bilateral breath sounds are present. If the patient's ventilations are inadequate, provide or assist ventilation with a bag-valve mask (BVM) and 100% oxygen.
4. **Assess circulation.** Control any external bleeding with direct pressure. Maintain a high index of suspicion for internal bleeding and shock based on the MOI. Keep the patient warm.
5. **Transport considerations.** Transport the patient on her left side. If the patient is on a backboard because spinal injury is suspected, tilt the backboard 30 degrees to the left. Call early for ALS assistance or a medical helicopter for significant MOIs or major traumatic injuries. Transport the patient to a trauma center if one is available in your area; give early notification that you have a pregnant trauma patient in transport.

Cultural Value Considerations

Cultural sensitivity is important when you are assessing and treating a pregnant patient from a culture different from yours. Women of some cultures may have a value system that will affect the choice of how they care for themselves during pregnancy and how they have planned the childbirth process. Some cultures may not permit a male health care provider, especially in the prehospital setting, to assess or examine a female patient. Some cultures may view pregnancy differently than you do in terms of social, psychologic, and emotional issues. Some may see pregnancy as a means of achieving status and recognition within the family unit, whereas others may experience a drop in self-esteem. Respect these differences and honor requests from the patients. Always remember that your responsibility is to the patient and is limited to providing care and transport, and keep in mind that a competent, rational adult has the right to refuse all or any part of your assessment or care.

Teenage Pregnancy

The United States has one of the highest teenage pregnancy rates among developed countries. It is likely that at some point you will respond to a pregnant teenager who may or may not be in labor. A pregnant teenager may not know that she is pregnant, or she may be in denial about her pregnancy. As you begin to assess any female teenager, you should remember that pregnancy is a possibility. The pregnancy itself may not be related to the nature of the call, but consider the possibility when assessing the patient, talking to the patient, obtaining a history, and providing treatment. Respect the teenager's privacy and need for independence. If possible, perform your assessment and obtain the history away from the teenager's parents. Be aware that in most states, once a teenager becomes pregnant, she is considered emancipated, or having the rights of an adult, at least as it relates to giving or refusing consent for medical treatment. Become familiar with the laws in your state so that you will know when pregnant teenagers can give or refuse consent for themselves.

Patient Assessment

Childbirth is seldom an unexpected event, but there are occasions when it becomes an emergency. Dispatch protocols usually include the dispatcher asking simple questions to determine whether birth is imminent. Some of this information may be passed on to you to help you prepare for the situation. Trauma or medical conditions may cause premature contractions, or your patient may be full term and experiencing contractions because it is time to deliver.

Scene Size-up

Take standard precautions—gloves and eye and face protection are a minimum if delivery has already begun or is complete. If the call is going to result in a field delivery and if time allows, a gown should also be used. Do not be lax in your safety observations and precautions because a delivery is in progress or the family is anxious. Rushing may endanger not only you but also the fetus and pregnant woman. Remain calm and professional. Consider calling for additional or specialized resources.

Not every call to a pregnant patient will be because she is in labor, of course, so it is important to determine the MOI or nature of illness in a pregnant patient. Do not develop tunnel vision during a call, assuming that because the patient is pregnant, that is the reason for the call! Because a pregnant woman's balance may be altered, trauma from falls and the necessity of spinal immobilization must be considered.

Primary Assessment

Form a general impression as to whether the patient is in active labor and, if so, whether you have time to assess for imminent delivery and address other possible life threats. Perform a rapid examination of the patient to assess for airway, breathing, or circulation problems. The chief complaint may be, "The baby is coming!" Take a moment to confirm whether the fetus will be delivered in the next few minutes or whether you have time to continue to evaluate the situation. When trauma or medical problems such as vaginal bleeding or seizures are the presenting complaint, evaluate these first and then assess the impact of these problems on the fetus.

During an uncomplicated birth, life-threatening conditions involving the woman's airway and breathing are not usually an issue. However, a motor vehicle crash, an assault, or any number of medical conditions in a pregnant woman may cause a life threat to exist and may result in a complicated delivery. In these situations, assess the airway and breathing to ensure they are adequate. If needed, provide airway management and administer high-flow oxygen.

External and internal bleeding are potential life threats to the patient and should be assessed early. Blood loss after delivery is expected, but significant bleeding is not. Recall that normal changes in pregnancy result in increased overall blood volume, increased heart rate, and changes in blood clotting. These changes can have a significant impact on a pregnant patient who is bleeding, regardless of the cause. Quickly assess for any potential life-threatening bleeding, and begin treatment immediately. Assess the skin for color, temperature, and moisture, and check the pulse to determine if it is too fast or too slow. If there are signs of shock, control the bleeding, administer oxygen, and keep the patient warm.

If delivery is imminent, you must prepare to deliver at the scene. The ideal place to deliver is in the security of your ambulance or the privacy of the woman's home. The area should be warm and private, with plenty of room to move around.

If the delivery is not imminent, prepare the patient for transport and perform the remainder of the assessment en route to the emergency department. Administer oxygen. Women in the second and third trimesters of pregnancy should be transported lying on the left side when possible to prevent supine hypotensive syndrome. If spinal immobilization is indicated, secure the woman to the backboard and elevate the right side of the board with rolled towels or blankets **Figure 33-6**. Provide rapid transport for pregnant patients who have significant bleeding and pain, are hypertensive, are having a seizure, or have an altered mental status.

Figure 33-6 Place a blanket under the right side of the backboard to prevent supine hypotensive syndrome in pregnant patients.

History Taking

Regardless of whether the patient is in active labor, is having an obstetric emergency, or is a pregnant patient with another complaint (eg, trauma), obtain a thorough history that includes her expected due date, any complications she is aware of, if she has been receiving prenatal care, and a complete medical history. Obtain a SAMPLE history. Some pregnant women will have a history of medical problems for which they take prescription medications. Some women with no history of medical problems require medications during pregnancy. Pertinent history should include questions related specifically to prenatal care. Identify any complications the patient may have had during the pregnancy or potential complications during delivery that her physician has identified. These complications may include the size or position of the fetus or the position and health of the placenta. Determine the due date, fetal movement, frequency of contractions, and history of previous pregnancies and deliveries and their complications, if any. Determine whether there is a possibility of multiples. Ask whether the woman has taken any drugs or medications during the pregnancy. If her water has broken, ask whether the fluid was green. Green fluid is due to **meconium** (fetal stool). The presence of meconium can indicate newborn distress, and it is possible for the fetus to aspirate meconium during delivery.

YOU are the Provider — PART 3

Shortly after your partner assesses the patient's vital signs and administers supplemental oxygen you observe the fetus's head crowning at the vaginal opening. As the head delivers, you can feel the umbilical cord wrapped around the fetus's neck.

Recording Time: 7 Minutes	
Respirations	24 breaths/min; adequate depth
Pulse	110 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	122/82 mm Hg
Oxygen saturation (Spo_2)	98% (on oxygen)

5. How should you manage the umbilical cord situation?
6. What would you do if the amniotic sac were still intact?

Secondary Assessment

Perform a complete assessment of the major body systems as needed, with emphasis on the patient's chief complaint. Assess for fetal movement by asking the patient whether she can feel the fetus moving. If the patient is in labor, the physical examination should focus on contractions and possible delivery. Assess the length and frequency of contractions by asking the patient and by placing your hand on the abdomen. Compare what you feel with the patient's experience during each contraction. If at any point you suspect that delivery is imminent, check for crowning. This assessment should be performed only when appropriate and according to local protocol. If you do not suspect an imminent delivery and the patient reports other problems unrelated to delivery, you should not visually inspect the vaginal area. Be sure to protect the woman's privacy during the physical examination.

The secondary assessment of a pregnant patient should include a complete set of vital signs and pulse oximetry. Vital signs should include pulse; respirations; skin color, temperature, and condition; and blood pressure. Be especially alert for tachycardia and hypotension (which could mean hemorrhage or compression of the vena cava) or hypertension (possibly indicating preeclampsia). A woman's blood pressure typically drops slightly during the first two trimesters of pregnancy but returns to normal during the third trimester. Compare your findings with previous blood pressure readings the patient may know of from prenatal visits. Hypertension, even when mild, may indicate more serious problems.

Reassessment

As time allows, repeat the primary assessment with a focus on the patient's ABCs and vaginal bleeding, particularly after delivery. Obtain another set of vital signs and compare the results with those obtained earlier. Frequent reassessment of vital signs may identify hypoperfusion from excessive blood loss as a result of delivery. Recheck interventions and treatments to see whether they were effective. For example, is the vaginal bleeding slowing with uterine massage? Uterine massage, discussed later in this chapter, can slow vaginal bleeding after delivery.

In most cases, childbirth is a natural process that does not require your assistance. When childbirth is complicated by trauma or other conditions, however, any interventions you provide for the patient will benefit the fetus. For example, if a pregnant patient has a pulse oximetry level of 94% or lower, the fetus will be hypoxic, too. Administering oxygen to the patient will improve the oxygen level of the fetus. Administer oxygen if the assessment findings indicate a need, even in the absence of pulse oximetry readings.

If your assessment determines that delivery is imminent, notify staff at the receiving hospital. Provide an update on the status of the woman and newborn after delivery. On the rare occasion that the delivery of the placenta does not occur within 30 minutes or you determine that a complication is occurring that cannot be treated in the field, notify the hospital staff of your findings and provide rapid transport. Be sure to notify staff at the receiving hospital of all relevant information so they have time to prepare. The information you provide may help the hospital staff determine whether the patient will be seen in the emergency department or the labor and delivery unit. For a pregnant patient with problems unrelated to childbirth (such as trauma or difficulty breathing), be sure to include the pregnancy status of your patient in your radio report. The hospital staff will want to know the number of weeks of gestation, her due date, and any known complications of the pregnancy.

Thorough documentation is essential, especially in the case of a newborn where delivery occurred in the field. In this situation, you will have two patient care reports to complete. Obstetrics is among the most litigated specialties in medicine; therefore, scrupulous documentation is essential.

Stages of Labor

The three stages of labor are (1) dilation of the cervix, (2) delivery of the fetus, and (3) delivery of the placenta. The first stage begins with the onset of contractions and ends when the cervix is fully dilated. Because the cervix has to be stretched thin by uterine contractions until the opening is large enough for the fetus to pass through into the vagina, the first stage of labor is usually the longest, lasting an average of 16 hours for a first delivery. You will usually have time to transport the woman if she is in the first stage of labor.

The onset of labor starts with contractions of the uterus. Other signs of the beginning of labor are the bloody show (blood-streaked mucus) and the rupture of the amniotic sac (water breaking). These events usually occur near the first contraction or early in the first stage of labor. Initially, the uterine contractions may not occur at regular intervals. The woman may think that she simply has a nagging backache. In true labor, the frequency and intensity of contractions increase with time. The uterine contractions become more regular and last about 30 to 60 seconds each. The length of labor varies greatly. As a general rule, labor is longer in a **primigravida**, a woman who is experiencing her first pregnancy, and shorter in a **multigravida**, a woman who has experienced previous pregnancies.

Table 33-1 False Labor Versus True Labor

False Labor (Braxton-Hicks Contractions)	True Labor
Contractions are not regular and do not increase in intensity or frequency. Contractions come and go.	Contractions, once started, consistently get stronger and closer together.
Pain and contractions start and stay in the lower abdomen.	Pain and contractions may start in the lower back and "wrap around" to the lower abdomen.
Physical activity or a change in position may alleviate the pain and contractions.	Physical activity may intensify the contractions. A change in position does not relieve contractions.
Bloody show, if present, is brownish.	The bloody show is pink or red and generally accompanied by mucus.
If leakage of fluid occurs, it is usually urine. It will be in small amounts and smell of ammonia.	The amniotic sac may have broken just before the contractions started or it may break during contractions. A moderate amount of fluid that may smell sweet will be present, and fluid will continue to leak.

Table 33-1 lists characteristics of true labor versus false labor, or Braxton-Hicks contractions. With false labor, you should provide transport for the patient. With true labor, you may need to prepare for a delivery, depending on the stage of labor, the patient's condition, and transport time.

Some women experience a premature rupture of the amniotic sac, before the fetus is ready to be born. When this occurs, the patient may or may not go into labor. Some patients may experience this premature rupture of the membranes as long as several months before they are due to deliver. In this situation, you will need to provide supportive care and transport to the hospital. These patients are usually placed on bed rest and followed up closely by an obstetrician.

Toward the end of the third trimester of pregnancy, the head of the fetus normally descends into the woman's pelvis as the fetus positions for delivery. This movement down into the pelvis is called **lightening**. Your patient may tell you that she has felt this. Some women describe this as a relief because once the fetus has moved from under their rib cage, breathing becomes easier. Lightening may also occur gradually and not be noticed by some patients.

The second stage of labor begins when the fetus enters the birth canal, and it ends with delivery of the newborn (spontaneous birth). During this stage, you will have to make a decision about whether to help the woman deliver at the scene or provide transport to the hospital. Because the fetus goes through positional changes as it moves through the birth canal during this stage, the uterine contractions are usually closer together and last longer. Pressure on the rectum may make the woman feel as if she needs to have a bowel movement. Under no circumstances should you let the woman sit on the toilet. She may also have the uncontrollable urge to push down. The perineum will begin to bulge significantly. When the top of the fetus's head begins to appear at the vaginal opening, this is called crowning.

The third stage of labor begins with the birth of the newborn and ends with the delivery of the placenta. During this stage, the placenta must separate completely from the uterine wall. Contractions continue, assisting the separation process and clamping down and closing the blood vessels that connected the placenta to the uterine lining. This may take up to 30 minutes.

Normal Delivery Management

Preparing for Delivery

Consider delivery at the scene when delivery is imminent (will occur within a few minutes) or when a natural disaster, inclement weather, or other environmental factor makes it impossible to reach the hospital. If the patient has delivered before, she may be able to tell you whether she is about to deliver. Otherwise, her answers to the following questions will help you determine whether delivery is imminent:

- How long have you been pregnant?
- When are you due?
- Is this your first pregnancy?
- Are you having contractions? How far apart are the contractions? How long do the contractions last?
- Have you had any spotting or bleeding?
- Has your water broken?
- Do you feel as though you need to have a bowel movement?
- Do you feel the need to push?

Ask these questions to help determine any potential complications:

- Were any of your previous deliveries by cesarean section?
- Have you had any problems in this or any previous pregnancy?
- Do you use drugs, drink alcohol, or take any medications?
- Is there a chance you will have multiple deliveries (having more than one baby)?
- Does your physician expect any other complications?

If the patient says that she is about to deliver, says she has to move her bowels, or feels the need to push, immediately prepare for a delivery and consider calling for additional resources. The fetus's head is probably pressing on the rectum, and delivery is about to occur. Otherwise, does she have an extremely firm abdomen? Visually inspect the vagina to check for crowning. Crowning is an indication that the delivery is occurring. Do not touch the vaginal area until you have determined that delivery is imminent. In general, you should touch the vaginal area only during the delivery (under certain circumstances) and when your partner is present. Gently spread the pregnant woman's legs apart, explaining that you are doing so to decide whether the baby should be delivered immediately or whether she should be transported to the hospital for the delivery.

Once labor has begun, it cannot be slowed or stopped. Never attempt to hold the patient's legs together, because this will only complicate the delivery. Do not let her go to the bathroom. Instead, reassure her that the sensation of needing to move her bowels is normal and that it means she is about to deliver.

If your decision is to deliver at the scene, remember that you are only assisting the woman with the delivery. Your part is to help, guide, and support the baby as it is born. Use standard precautions at all times. Administer oxygen to the patient if indicated. Limit distractions for yourself and the patient. You want to appear calm and reassuring while protecting the woman's privacy. Most important, recognize when the situation is beyond your level of training. If there is any doubt, contact medical control for further guidance. Always recognize your own limitations. If you are unsure about what to do, transport the patient even if delivery might occur during transport.

Your emergency vehicle should always be equipped with a sterile emergency obstetric (OB) kit containing the following items Figure 33-7:

- Surgical scissors or a scalpel
- Umbilical cord clamps
- A small rubber bulb syringe
- Towels, drapes, or sheets
- 4-inch × 4-inch (10-cm × 10-cm) gauze sponges and/or 2-inch × 10-inch (5-cm × 25-cm) gauze sponges

- Sterile gloves
- Infant blanket
- Sanitary pads
- An infant-sized BVM
- Goggles
- A plastic bag

Once you have determined that delivery is imminent, and you have positioned the patient in an acceptable location, open the OB kit and continue to prepare for the delivery.

Figure 33-7 Your unit should contain a sterile obstetric kit.

Patient Position

The patient's clothing and undergarments should be removed or pushed up to her waist. Preserve the patient's privacy as much as you can while helping her to move into position. If the emergency delivery is occurring at home, move the patient to a sturdy, flat surface or the floor if she will allow it. You will find it easier to work with the patient on a firm surface that is padded with blankets, folded sheets, or towels rather than on a bed. Put a pillow or blankets beneath her hips to elevate them about 2 to 4 inches (5 to 10 cm). It is sometimes more comfortable for the woman to put a pillow under one hip to allow her to turn to one side. Allow the patient to get comfortable. Support the patient's head, neck, and upper back with pillows and blankets. Have her keep her legs and hips flexed, with her feet flat on the surface beneath her and her knees spread apart. Women who have delivered before may prefer another delivery position, such as on the side. Another position is acceptable if both you and the patient are comfortable with it. You should also begin preparing for the newborn's arrival. Communicate with your crew, and have a plan for where you will place the newborn after delivery, who will be responsible for drying the newborn and keeping the newborn warm, and who will be responsible for caring for the mother and the newborn after delivery.

Track the progression of the delivery closely at all times. You do not want an explosive delivery to occur, when the crowning head pops out uncontrollably and too quickly.

Preparing the Delivery Field

Take the following steps to prepare the area where the delivery will occur:

1. Put on protective face shield and gown. As time allows, place towels or sheets on the floor around the delivery area to help soak up body fluids and to protect the woman and the newborn.
2. Carefully open the OB kit so its contents remain sterile.
3. Put on the sterile gloves. After this, handle only sterile materials.
4. Use the sterile sheets and drapes from the OB kit to make a sterile delivery field. Place one drape under the patient's buttocks, and unfold it toward her feet. Wrap another behind the patient's back and drape it over each thigh **Figure 33-8A**, and drape one sheet across her abdomen **Figure 33-8B**.

Figure 33-8 Preparing the delivery field. **A.** Use sterile sheets and drapes from the obstetric kit to make a clean delivery field. Place one sheet under the woman's buttocks. Wrap another sheet behind her back with either end draped over the thighs. **B.** Drape another sheet over the woman's abdomen.

The Delivery

Your partner should be at the patient's head to comfort, soothe, and reassure the woman during the delivery. If she will allow it, administer oxygen. The patient may want to grip someone's hand. She may yell, cry, or say nothing at all. It is common for patients to become nauseated during delivery, and some may vomit. If this occurs, have your partner assist her and ensure that her airway remains clear.

You must continually check for crowning. Some patients, especially those who have previously had children, may experience precipitous (fast) labor and birth. When labor is too fast, the tissues do not have time to stretch, and the patient is at risk for tears in the perineal area (see the section, *Delivering the Head* in this chapter). Position yourself so that you can see the perineal area at all times. Time the patient's contractions, starting at the beginning of one and ending with the beginning of the next, to determine the frequency of the contractions. In addition, time the duration of each contraction by feeling the patient's abdomen from the moment the contraction begins (uterus and abdomen tightening) to the moment it ends (uterus and abdomen relaxing). Remind the patient to take quick, short breaths during each contraction but not to strain. Encourage the patient to rest and breathe deeply through her mouth between contractions.

Follow the steps in **Skill Drill 33-1** to deliver the newborn:

1. Crowning is the definitive sign that delivery is eminent and transport should be delayed until after the child has been born **Step 1**.
2. Allow the woman to push the head out. Use your hands to support the bony parts of the head as it emerges. The child's body will naturally rotate to the right or left at this point in the delivery. Continue to support the head to allow it to turn in the same direction. Avoid the eyes and fontanelles (soft spots on the newborn's skull). Feel at the neck to see if the umbilical cord is wrapped around it. If it is, gently lift it over the head without pulling hard on the cord. **Step 2**.
3. Once the head is delivered, it will rotate on its own to one side. At the next contraction, the upper shoulder will be visible. Guide the head down slightly by applying gentle downward traction to help the upper shoulder deliver **Step 3**.
4. Support the head and upper body as the shoulders deliver. You may need to guide the head up slightly to help deliver the lower shoulder **Step 4**.
5. Once the body is delivered, support the newborn firmly but gently. The newborn will be very slippery. Support the newborn's head with the neck in a neutral position to keep the airway open **Step 5**.
6. If the mother is willing and able, place the newborn directly on the mother's abdomen, with the cord still intact. This skin-to-skin technique keeps the newborn warm and perfused; the mother's skin provides warmth while the placental perfusion continues until the pulsations in the cord stop.
7. After delivery and prior to cutting the cord, if the child is gurgling or shows other signs of respiratory distress, suction the mouth and oropharynx to clear any amniotic fluid and facilitate the infant's initiation of air exchange **Step 6**.

YOU are the Provider — PART 4

You have successfully removed the umbilical cord from around the neck and have completed delivery of the rest of the body. It is a girl! As you assess the newborn, your partner reassesses the patient's vital signs.

Recording Time: 12 Minutes	
Level of consciousness	Conscious and alert
Respirations	22 breaths/min; adequate depth
Pulse	114 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	130/60 mm Hg
Spo_2	98% (on oxygen)

After providing immediate postdelivery care to the newborn, you assess her and note that she is breathing; has a heart rate of 80 beats/min; and has cyanosis of her face, trunk, and extremities.

7. What is involved in the routine postdelivery care of a newborn?

8. What immediate treatment is indicated for this newborn?

Skill Drill 33-1 Delivering the Newborn

Step 1

Crowning is the definitive sign that delivery is imminent and transport should be delayed until after the child has been born.

Step 2

Use your hands to support the bony parts of the head as it emerges. The child's body will naturally rotate to the right or left at this point in the delivery. Continue to support the head to allow it to turn in the same direction.

Step 3

As the upper shoulder appears, guide the head down slightly by applying gentle downward traction to deliver the shoulder.

Step 4

Support the head and upper body as the lower shoulder delivers, guide the head up if needed.

Step 5

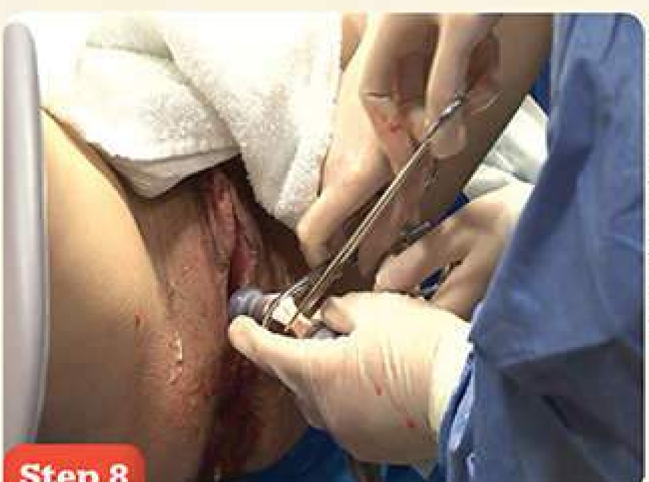
Handle the newborn firmly but gently, support the head and keep the neck in a neutral position to maintain the airway. Consider placing the newborn on the mother's abdomen with the umbilical cord still intact, allow skin-to-skin contact to warm the newborn. Otherwise, keep the newborn approximately at the level of the vagina until the cord has been cut.

Step 6

After delivery and prior to cutting the cord, if the child is gurgling or shows other signs of respiratory distress, suction the mouth and oropharynx to clear any amniotic fluid and ease the infant's initiation of air exchange.

Step 7

Wait for the umbilical cord to stop pulsing. Place a clamp on the cord. Milk the blood from a small section of the cord on the placental side of the clamp. Place a second clamp 2 to 3 inches away from the first.



Step 8

Cut between the clamps.

Step 9

Allow the placenta to deliver itself. Do not pull on the cord to speed delivery.

8. Place a clamp on the umbilical cord. Milk the blood from a small section of the cord on the placental side of the clamp. This prevents the cord blood located between the clamps from spilling onto the floor when you eventually cut the cord. Then place a second clamp 2 to 3 inches away from the first **Step 7**.
9. Cut between the two clamps **Step 8**.
10. The placenta will deliver itself, usually within 30 minutes of birth. Never pull on the end of the umbilical cord in an attempt to speed delivery of the placenta **Step 9**.

Words of Wisdom

When a fetus is positioned head first in the birth canal, this is called the *cephalic presentation*. Most births are cephalic presentation.

Delivering the Head

Observe the head as it begins to exit the vagina so you can provide support as it emerges. It may take many contractions from the time the head begins to crown until the head delivers. Once it is obvious that the head is coming out farther with each contraction, place your sterile gloved hand over the emerging bony parts of the head, avoid the eyes and fontanelles, and, by exerting minimal pressure, control the delivery of the head. This will allow the head to come out smoothly and prevent it and the rest of the newborn from suddenly popping out during a strong contraction, possibly causing injury to the patient's perineal area and/or to the newborn. Continue to support the head as it rotates.

The risk of perineal tearing during labor can be reduced by applying gentle pressure across the perineum with a sterile gauze pad. Also be prepared for the possibility of the patient having a bowel movement because of the increased pressure on the rectum.

As you assist with the delivery of the head, be careful that you do not poke your fingers into the newborn's eyes or the fontanelles. The fontanelles are soft spots on the newborn's skull that will eventually become covered with bone. At birth, the brain is covered only with skin and membranes at these areas. There are two primary fontanelles, one on the top of the head and one near the back of the head.

Unruptured Amniotic Sac. The amniotic sac will usually rupture at the beginning of labor; if not, it may rupture during contractions. If the amniotic sac has not ruptured by the time the fetal head is crowning, it will appear as a fluid-filled sac (like a water balloon) emerging from the vagina. This situation is potentially life threatening for the fetus because the sac will suffocate the fetus if it is not removed. If the sac has not ruptured spontaneously, you may puncture it with a clamp or tear it by twisting it between your fingers. Make sure that the puncture site is away from the fetus's face, and perform this procedure only as the head is crowning. Do not puncture the sac if the fetus's head is not crowning. As the sac is punctured, amniotic fluid will gush out. Push the ruptured sac away from the fetus's face as the head is delivered. Clear the newborn's mouth and nose, using the bulb syringe if required by your protocols, and wipe the mouth and nose with gauze. If the amniotic fluid is greenish (indicating meconium staining) instead of clear or has a foul odor, make sure you notify the receiving hospital. Meconium in the amniotic fluid may result in respiratory distress or an airway obstruction in the newborn.

Umbilical Cord Around the Neck. As soon as the head is delivered, use one finger to feel whether the umbilical cord is wrapped around the neck. This commonly is called a **nuchal cord**. A nuchal cord that is wound tightly around the neck could strangle the fetus, so it must be released immediately from the neck. Usually, you can slip the cord gently over the delivered head (or over the shoulder, if necessary). If this is not possible, you must cut the cord by placing two clamps about 2 inches apart on the cord and cutting between the clamps. Once the cord is cut, you must attempt to speed the delivery by encouraging the woman to push harder and possibly more often because the fetus will now have no oxygen supply until it is delivered and breathing spontaneously. In the rare case of the cord being wrapped more than once around the neck, you will need to clamp and cut only once; then you can unwrap the cord from around the neck. Handle the cord very carefully; it is fragile and easily torn. Fortunately, the cord is usually not wrapped around the fetus's neck and does not have to be cut until after the entire newborn has been delivered and pulsations have stopped. However, you must always check for a nuchal cord.

Delivering the Body

Once the head has been delivered, it usually rotates to one side or the other. This rotation places the body in a better position for delivery. By this time, the woman will most likely be ready to push again, and the upper shoulder will be visible in the vagina. The head is the largest part of the fetus. Once it is delivered, the body usually delivers easily. Support the head and upper body as the shoulders deliver. Make sure to always support the head with one hand. Lower the head a little to deliver the upper shoulder, and then very gently raise it to deliver the lower shoulder. Do not pull the fetus from the birth canal.

Once the shoulders deliver, the abdomen and hips will appear and will slide out easily. The newborn will be extremely slippery, so make sure to support the body with your other hand as it delivers. The newborn may be covered with a white, cheesy substance called **vernix caseosa**. Support and hold the newborn with both of your hands. Handle the newborn firmly but carefully.

Words of Wisdom

With the delivery of a newborn, you must divide your attention between two patients. This can keep two EMTs busy, even when things go well. To ensure that possible special care needs do not result in neglect of one of the patients, designate one member of the crew to pay primary attention to each patient. Call for additional help early if you suspect that both will need special care or that one will require resuscitation.

Postdelivery Care

As soon as the newborn is delivered, if the mother is able and willing, hand the newborn to the mother or place the newborn on her abdomen so skin-to-skin contact can begin immediately. As described earlier, this helps keep the newborn warm and may improve perfusion. Dry the newborn, then wrap him or her in a clean blanket or towel to maintain warmth. Newborns are very sensitive to temperature, so keep the blanket or towel warm, if possible, before you use it. Wrap the newborn so that only the face is exposed, making sure that the top of the head is covered. Keep the neck in a neutral position so the airway remains open. Consider placing the newborn on one side, with the head slightly lower than the rest of the body. If circumstances prevent placing the newborn on the mother, cradle the newborn in your arms, but always keep the head slightly downward to help prevent aspiration. Use a sterile gauze pad to wipe the newborn's mouth and nose as needed. If your local protocols specify, keep the newborn at the same level as the woman's vagina until the umbilical cord has been cut.

Postdelivery care of the umbilical cord is important because infection is easily transmitted through the cord to the newborn. Once the cord has stopped pulsating, using the two clamps in the OB kit, clamp the cord between the woman and the newborn, preferably 6 inches (15 cm) from the newborn's body. Place the clamps about 2 to 4 inches (5 to 10 cm) apart. When they are firmly in place, carefully cut the cord between them with sterile scissors or a scalpel. Remember, the cord is fragile; if handled roughly, it could be torn from the newborn's abdomen, resulting in a fatal hemorrhage. Once the clamps are in place, there is no need to rush.

Words of Wisdom

Recording the time of birth is important because this information is needed for the birth certificate. It also provides you with a starting point from which to time the intervals for Apgar scores. This is even more important with multiple births. You will be busy, so you might consider asking a family member to act as "timekeeper." Use two hands to support the infant's entire body including the head while holding him or her. One hand should support the back, chest, and head without squeezing or otherwise placing excess pressure on the neck. The second hand should support the buttocks.

By now, the newborn should be pink and breathing on his or her own **Figure 33-9**. At this time, evaluate the newborn for term gestation, good muscle tone, and breathing/crying; also obtain the 1-minute Apgar score (see the section, *The Apgar Score* in this chapter). If the mother is alert and in stable condition and you have not done so already, hand the newborn to her so that skin-to-skin contact can begin while you dry and wrap the newborn. If this is not possible, give the newborn, wrapped in a warm blanket, to your partner; he or she can monitor the newborn and complete the initial care. You need to return your attention to the woman and the delivery of the placenta.

Delivery of the Placenta

The placenta is attached to the end of the umbilical cord, which is coming out of the woman's vagina. The placenta will deliver itself, usually within a few minutes of the birth, although it may take as long as 30 minutes, so do not delay transport waiting for the placenta to deliver. Again, your job is only to assist. Never pull on the end of the umbilical cord in an attempt to speed delivery of the placenta. You may tear the cord, the placenta, or both and cause serious, perhaps life-threatening hemorrhage in the patient. Some bleeding, usually less than 500 mL, occurs before the placenta delivers and is normal and expected.

Figure 33-9 Use two hands to support the infant's entire body including the head while holding him or her. One hand should support the back, chest, and head without squeezing or otherwise placing excess pressure on the neck. The second hand should support the buttocks.

The normal placenta is round, about 7 inches (18 cm) in diameter, and about 1 inch (2.5 cm) thick. One surface is smooth and covered with a shiny gray membrane. The other surface is rough, divided into lobes, and is a dark reddish-brown color similar to raw liver. Wrap the entire placenta and cord in a towel, place them into a plastic bag, and take them to the hospital. Hospital personnel will examine the placenta and the cord to make certain that the entire placenta has been delivered. If a piece of the placenta has been retained inside the woman, it could cause persistent bleeding or infection.

After delivery of the placenta and before transport, place a sterile pad or sanitary pad over the vagina and straighten the woman's legs. You can help to slow bleeding by massaging the woman's abdomen with a firm, circular, kneading motion **Figure 33-10**. The abdominal skin will be wrinkled and very soft. You should be able to feel a firm, grapefruit-sized mass in the lower abdomen; this is called the **fundus**. The fundus is the upper end of the uterus. As you massage the fundus, the uterus will contract and become firmer. This may be uncomfortable for the woman. Reassure her and explain that it is necessary to help control the bleeding. Breastfeeding also stimulates the uterus to contract because, like massaging the uterus, it causes the production of oxytocin, a hormone that helps to contract the uterus and slow bleeding. Take a minute to congratulate the new mother and thank anyone who assisted. Be sure to record the time of birth in your patient care report.

Figure 33-10 After delivery, massage the woman's abdomen in a firm, circular motion.

The following are emergency situations:

- The placenta has not delivered after 30 minutes.
- More than 500 mL of bleeding occurs before delivery of the placenta.
- Significant bleeding occurs after delivery of the placenta.

If any of these events occur, promptly transport the woman and newborn to the hospital. Never put anything into the vagina. Place a sterile pad or sanitary pad over the woman's vagina, administer oxygen, keep her and the newborn warm by preventing any heat loss, and monitor her vital signs closely.

Neonatal Assessment and Resuscitation

To determine whether the newborn requires resuscitation, begin by assessing for term gestation, good muscle tone, and breathing/crying. Follow standard precautions, and always put on gloves before handling a newborn. The normal respiratory and cardiovascular physiologic responses expected are that the newborn will begin breathing spontaneously within 15 to 30 seconds after birth, and the heart rate will be 120 beats/min or higher. If you do not observe these responses, gently tap or flick the soles of the newborn's feet or rub the back to stimulate breathing. Many newborns require some form of stimulation that will encourage them to breathe air and begin circulating blood through the lungs Table 33-2. These measures include positioning of the airway, drying, warming, suctioning, and tactile stimulation. To maximize the effects of these measures, follow these tips:

- Position the newborn on his or her back with a towel or blanket under the shoulders so that the head is down and the neck is slightly extended.
- If necessary, suction the mouth and then the nose using a bulb syringe or suction device with an 8- or 10-French catheter. Suction both sides of the back of the mouth, where secretions tend to collect, but avoid deep suctioning of the mouth and

throat; this can cause the heart rate to slow down. Aim blow-by oxygen at the newborn's mouth and nose during resuscitation.

- In addition to vigorously drying the newborn's head, back, and body with dry towels, you may rub the newborn's back and gently flick or slap the soles of his or her feet. If the newborn does not breathe after 10 to 15 seconds of stimulation, begin resuscitation efforts.

Table 33-2 Resuscitation for a Newborn Who Is Not Breathing

Assess and support	▪ Temperature (warm and dry) ▪ Airway (position and suction) ▪ Breathing (stimulate to cry) ▪ Circulation (heart rate and skin color)
Basic life support interventions	▪ Dry and warm the newborn. ▪ Clear the airway with a bulb syringe if needed. ▪ Stimulate the newborn if he or she is unresponsive. ▪ Use a BVM to ventilate the newborn if needed. This is seldom required. ▪ Perform chest compressions if there is no pulse or if the heart rate is < 60 after 30 seconds of ventilation and heart rate is not increasing.

You should be properly equipped for resuscitation measures in case the newborn is in distress. Most of the equipment and supplies needed to resuscitate a newborn can be found in your OB kit. Other items you may need are clean, dry towels; an infant blanket; a BVM with a 450-mL reservoir; and masks in both newborn and premature sizes.

Additional Resuscitation Efforts

Observe the newborn for spontaneous respirations, skin color, and movement of the extremities. If the respiratory effort appears appropriate, evaluate the heart rate by palpating the pulse at the brachial artery or listening to the newborn's chest with a stethoscope. The heart rate is the most important measure in determining the need for further resuscitation Table 33-3.

If chest compressions are required, use the hand-encircling technique for two-person resuscitation Figure 33-11. Perform BVM ventilation during a pause after every third compression. Avoid giving a compression and a ventilation simultaneously, because one will decrease the effectiveness of the other. Cardiac arrest in neonates is nearly always the result of ventilation compromise. Use a compression-to-ventilation ratio of 3:1, which will yield a total of 120 "actions" per minute (90 compressions and 30 ventilations). Remember that adequate ventilation is absolutely critical to the successful resuscitation of the neonate.

YOU are the Provider PART 5

You reassess the newborn and find that she is breathing adequately and has a heart rate of 120 beats/min. Her body is pink except for her hands and feet, which remain slightly cyanotic. You hand the newborn to the mother, placing her on the mother's abdomen while you dry and wrap the newborn. Once the umbilical cord stops pulsing, you clamp and cut the umbilical cord. The placenta delivers and is appropriately cared for. You reassess the mother's vital signs and then prepare for transport.

Recording Time: 20 Minutes	
Level of consciousness	Conscious and alert
Respirations	20 breaths/min; adequate depth
Pulse	98 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	126/60 mm Hg
Spo_2	97% (on oxygen)

En route to the hospital, you reassess the newborn and mother. The mother remains conscious and alert and has mild vaginal bleeding. The newborn's body is pink, but her hands and feet remain blue; her heart rate is 130 beats/min, and her respirations are rapid; she pulls her foot away when you flick the sole; and she resists your attempts to straighten her knees. You call the receiving hospital and give your radio report; your estimated time of arrival is 6 minutes.

9. What further treatment is indicated for the mother?
10. What Apgar score should you assign to this newborn?

Table 33-3 Additional Neonatal Resuscitation Efforts

If the Heart Rate Is …	More Than 100 Beats/Min	60 to 100 Beats/Min	Fewer Than 60 Beats/Min
Do this:	Keep the newborn warm. Transport the newborn. Assess the newborn continuously.	Begin assisted ventilation with a BVM and room air. Reassess the newborn after 90 seconds and if the heart rate and respirations are not normal, begin to ventilate with 100% oxygen. Continue to reassess the newborn. Call for ALS backup if available. Keep the newborn warm.	Begin assisted ventilation with a BVM and 100% oxygen. Reassess the newborn every 90 seconds until heart rate and respirations are normal. Begin chest compressions. Call for ALS backup if available. If the heart rate does not increase, medication and ALS will be needed.

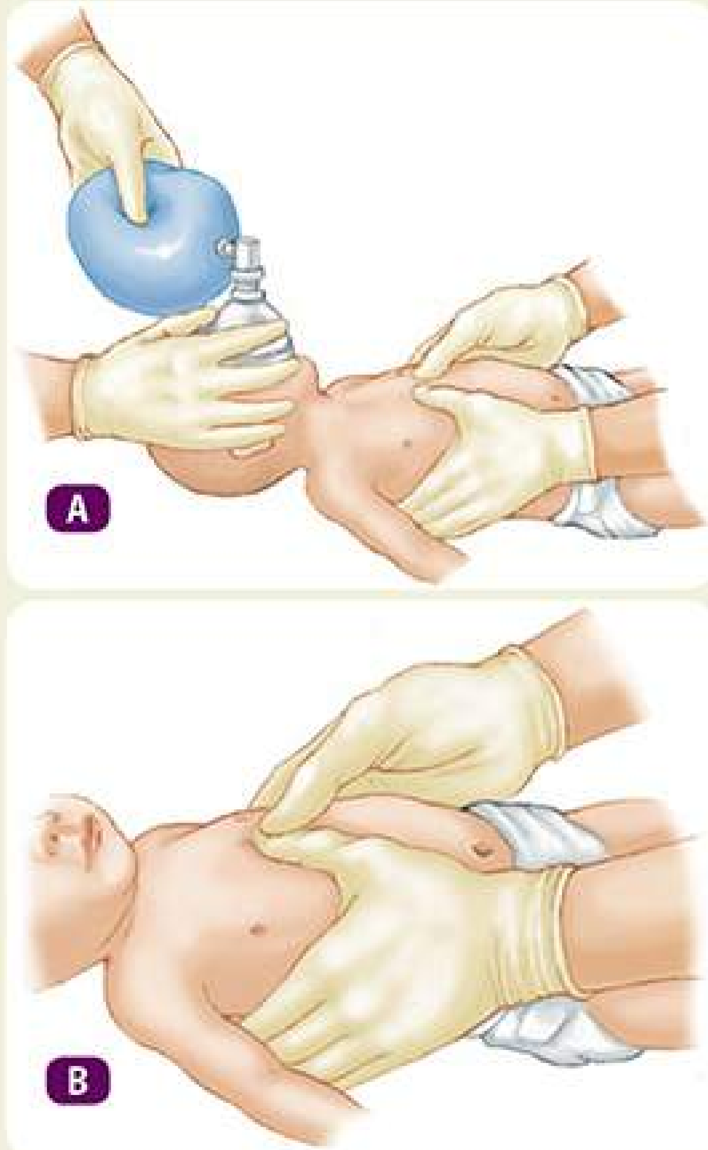


Figure 33-11 **A.** Chest compressions should be given with the hands encircling the newborn and thumbs side by side. **B.** In very small newborns, you may need to overlap the thumbs.

A, B: © Jones & Bartlett Learning.

Transport any newborn who requires more than routine resuscitation to a hospital with a level III neonatal intensive care unit, if available in your area. This type of unit is designed for newborns who require specialized care. If a level III neonatal intensive care unit is not available in your area, provide rapid transport to the closest appropriate facility.

About 12% to 16% of deliveries are complicated by the presence of meconium in the amniotic fluid. Meconium can be thick or thin. If the newborn aspirates thick meconium, significant lung disease and even death can occur. If you see meconium in the amniotic fluid or meconium staining and the newborn is not breathing adequately, consider quickly suctioning the newborn's mouth then nose after delivery before providing rescue ventilations.

▶ The Apgar Score

The **Apgar score** is the standard scoring system used to assess the status of a newborn. This system assigns a numeric value

(0, 1, or 2) to five areas of activity of the newborn:

- **Appearance.** Shortly after birth, the skin of a light-skinned newborn and the mucous membranes of a dark-skinned newborn should turn pink. Newborns often have cyanosis of the extremities for a few minutes after birth, but hands and feet should “pink up” quickly. Blue skin all over or blue mucous membranes signal a central cyanosis.
- **Pulse.** Measure the pulse by chest auscultation. If a stethoscope is not available, you can measure pulsations with your fingers at the brachial pulse. A newborn with no pulse requires immediate CPR.
- **Grimace or irritability.** Grimacing, crying, or withdrawing in response to stimuli is normal and indicates that the newborn is doing well. Test this by snapping a finger against the sole of the newborn’s foot.
- **Activity or muscle tone.** The degree of muscle tone indicates the oxygenation of the tissues. Normally, the hips and knees are flexed at birth, and, to some degree, the newborn will resist attempts to straighten them. A newborn should not be floppy or limp.
- **Respirations.** Normally, a newborn’s respirations are regular and rapid, with a good strong cry. If the respirations are slow, shallow, or labored, or if the cry is weak, the newborn may have respiratory insufficiency and need assistance with ventilation. Complete absence of respirations or crying is obviously a very serious sign; in addition to assisted ventilation, CPR may be necessary.

The total of the five numbers is the Apgar score. A perfect score is 10. The Apgar score should be calculated at 1 minute and again at 5 minutes after birth. Most newborns will have a score of 7 or 8 at 1 minute and a score of 8 to 10 at 5 minutes. Table 33-4 shows the Apgar scoring system. Figure 33-12 shows a photo of a newborn with an Apgar score of less than 9.

Follow these steps when assessing a newborn:

1. Quickly calculate the Apgar score to establish a baseline on the newborn’s status.
2. Stimulation should result in an immediate increase in respiration rate. If not, you must begin ventilations with a BVM. Unlike adults, in whom sudden cardiac arrest may precede respiratory arrest, newborns who are in cardiac arrest usually have had a respiratory arrest first. Therefore, it is essential to keep the newborn ventilating and oxygenating well.

Figure 33-12 Newborns who have blue extremities immediately after delivery would receive only 1 of 2 points for "Appearance" on the Apgar scale.

Table 33-4 Apgar Scoring System

	Score		
Area of Activity	**2**	**1**	**0**
Appearance	Entire newborn is pink.	Body is pink, but hands and feet remain blue.	Entire newborn is blue or pale.
Pulse	More than 100 beats/min	Fewer than 100 beats/min	Absent pulse
Grimace or irritability	Newborn cries and tries to move foot away from finger snapped against sole of foot.	Newborn gives a weak cry in response to stimulus.	Newborn does not cry or react to stimulus.
Activity or muscle tone	Newborn resists attempts to straighten hips and knees.	Newborn makes weak attempts to resist straightening.	Newborn is completely limp, with no muscle tone.
Respiration	Rapid respirations	Slow respirations	Absent respirations

3. If the newborn is breathing well, check the pulse rate by feeling the brachial pulse or auscultating the chest with a stethoscope. The pulse rate should be at least 100 beats/ min. If it is not, begin ventilations with a BVM. This alone may increase the newborn's heart rate. Reassess respirations and heart rate at least every 30 seconds to make sure that the pulse rate is increasing and respirations are becoming spontaneous.
4. Assess the newborn's oxygenation via pulse oximetry and observe for central cyanosis. If central cyanosis is present or the oxygen saturation does not improve, administer blow-by oxygen by holding oxygen tubing or an oxygen mask close to the newborn's face. Set the oxygen flow rate at 5 L/min.
5. Remember that you now have two patients. Request a second unit as soon as possible if you determine that the newborn is in any distress and will require resuscitation.

In situations where assisted ventilation is required, you should use a newborn BVM. Cover the newborn's mouth and nose with the mask, and begin ventilation with high-flow oxygen at a rate of 40 to 60 breaths/ min. Make sure you have a good mask-to-face seal. Use gentle pressure to make the chest rise with each ventilation. You may need to bypass the pop-off valve to accomplish this, especially during the first few breaths.

Special Populations

Current information on neonatal resuscitation may vary from what you learned in your class on CPR, which usually does not differentiate between CPR for an infant and CPR for a neonate (newborn). Be sure to know your specific local protocols on neonatal resuscitation.

If the newborn does not begin breathing on his or her own or does not have an adequate heart rate, continue CPR and rapidly transport. Once CPR has been started, do not stop until the newborn responds with adequate respirations and heart rate or is pronounced dead by a physician. Do not give up! Many newborns have survived without brain damage after prolonged periods of effective CPR. If the newborn presents in distress, do not take time to assess the Apgar score—begin resuscitation immediately.

Complicated Delivery Emergencies

Breech Delivery

The position in which an infant is born or the body part that is delivered first is called the **presentation**. Most infants are born head first, in what is called a **vertex presentation**. Occasionally, the buttocks are delivered first. This is called a **breech presentation** **Figure 33-13**. With a breech presentation, the fetus is at great risk for trauma from the delivery. In addition, a prolapsed cord is more common in a breech delivery. Breech deliveries are usually longer than a normal delivery, so there is time to get the pregnant woman to the hospital. If the buttocks have already passed through the vagina, however, the delivery has begun. You should provide emergency care and call for ALS backup if available. In general, if the woman does not deliver within 10 minutes of the buttocks presentation, provide prompt transport. Consult medical control to guide you in this difficult situation.

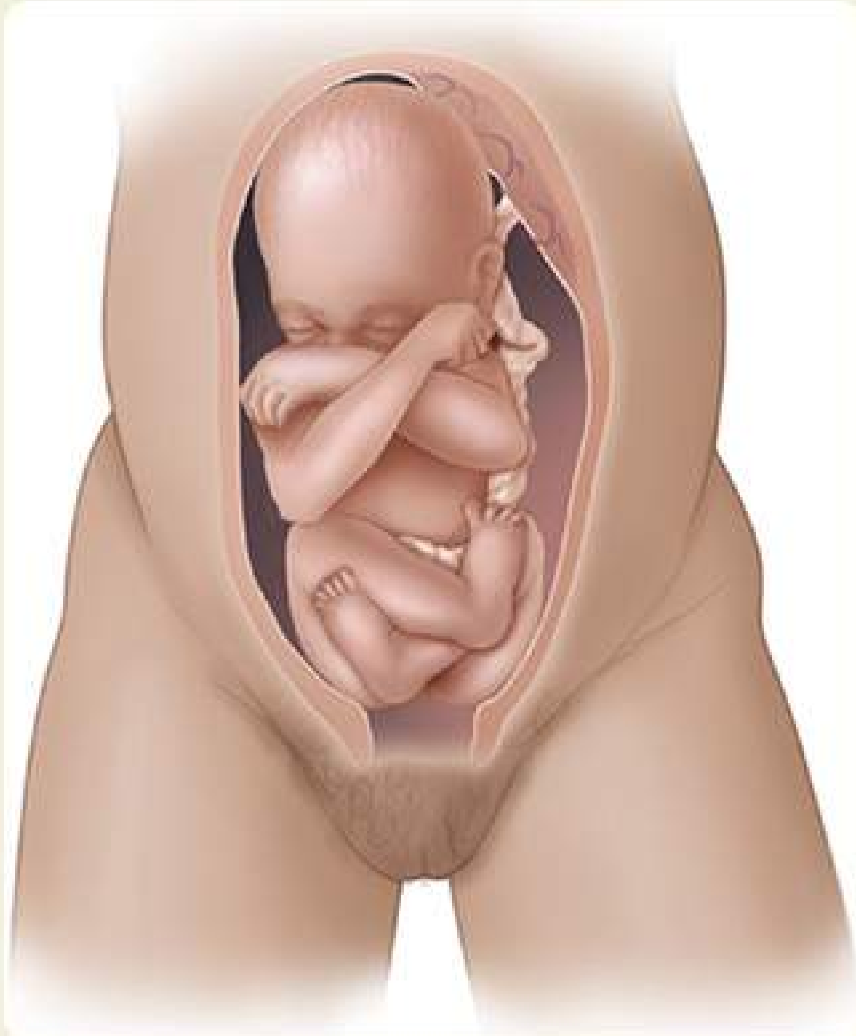

Figure 33-13 In a breech presentation, the buttocks are delivered first. Breech deliveries are usually slow, so you will often have time to transport the woman to the hospital.

Preparing for a breech delivery is the same as for a normal childbirth. Position the pregnant woman, prepare the OB kit, and place yourself and your partner as you would for a normal delivery. Allow the buttocks and legs to deliver spontaneously, supporting them with your hand to prevent rapid expulsion. The buttocks will usually come out easily. Let the legs dangle on either side of your arm while you support the trunk and chest as they are delivered. The head is almost always facedown and should be allowed to deliver spontaneously. As the head is delivering, you will need to perform a potentially lifesaving procedure to manage the newborn's airway. Make a "V" with your gloved fingers and position them in the vagina to keep the walls of the vagina from compressing the fetus's airway. This situation, and a prolapsed cord are the only two circumstances in which you should insert your fingers into the vagina.

Presentation Complications

On rare occasions, the presenting part of the fetus is neither the head nor the buttocks but a single arm or leg. This is called a **limb presentation** **Figure 33-14**. You cannot successfully deliver a fetus with a limb presentation in the field. These fetuses usually must be delivered surgically. If you are faced with a limb presentation, you must transport the patient to the hospital immediately. If a limb is protruding, cover it with a sterile towel. Never try to push it back in, and never pull on it. Place the patient on her back, with her head down and pelvis elevated. Because the woman and fetus are likely to be physically stressed, remember to administer high-flow oxygen to the woman

Figure 33-14 In rare cases, a limb, usually a single arm or leg, presents first. This is a life-threatening situation, and you must provide prompt transport for hospital delivery.

Prolapse of the umbilical cord, a situation in which the umbilical cord comes out of the vagina before the fetus **Figure 33-15**, is another rare presentation that must be treated in the hospital. This situation is dangerous because the fetus's head will compress the cord during birth and cut off circulation, depriving the fetus of oxygenated blood. Do not attempt to push the cord back into the vagina. Prolapse of the umbilical cord usually occurs early in labor when the amniotic sac ruptures. There is usually time to get the patient to the hospital. Your job is to try to keep the fetus's head from compressing the cord.

Place the pregnant woman supine with the foot end of the cot raised 6 to 12 inches (15 to 30 cm) higher than the head, with her hips elevated on a pillow or folded sheet. Alternatively, the woman may be placed in the knee-chest position: kneeling and bent forward, facedown. Either of these positions will help keep the weight of the fetus off the prolapsed cord. Carefully insert your sterile gloved hand into the vagina, and gently push the fetus's head away from the umbilical cord. Note that this is one of only two situations (the other being a breech presentation) in which you should place a hand or finger into the vagina. Maintain this position and continue to keep the pressure off of the cord continuously throughout the transport to the hospital and possibly until the patient is in the operating room. Wrap a sterile towel, moistened with saline, around the exposed cord. Administer high-flow oxygen, and transport rapidly.

Figure 33-15 A prolapsed umbilical cord is a life-threatening situation for the fetus and must be treated at the hospital.

▶ Spina Bifida

Spina bifida is a developmental defect in which a portion of the spinal cord or meninges may protrude outside of the vertebrae and possibly outside of the body. When it protrudes outside the body, the protrusion is seen on the newborn's back, usually in the lumbar area. It is important to cover the open area of the spinal cord with a moist, sterile dressing and then an occlusive dressing to seal the area immediately after birth to help prevent a potentially fatal infection. This treatment will have a positive impact on the newborn's outcome. Maintenance of the newborn's body temperature is important, so if you must use moist dressings, which can lower the body temperature, have someone hold the newborn against his or her body. Chapter 36, *Patients with Special Challenges*, discusses spina bifida in greater detail.

▶ Multiple Gestation

According to the CDC, twins occur about once in every 30 births; triplets or higher multiples occur much less frequently.

The woman will usually know if she is carrying multiple fetuses. Sometimes, there is a family history of twins or the woman suspects that she is having twins because she has an unusually large abdomen. Usually, however, multiple fetuses are diagnosed early in pregnancy with modern ultrasound techniques. With multiple fetuses, always be prepared for more than one resuscitation, and call for assistance.

Twins are usually smaller than single fetuses, and delivery is typically not difficult. Consider the possibility that you are dealing with twins any time the first newborn is small or the woman's abdomen remains fairly large and firm after the birth. You should also ask the patient about the possibility of multiples. If twins are present, the second one will usually be born within 45 minutes of the first. About 10 minutes after the first birth, contractions will begin again, and the birth process will repeat itself.

The procedure for delivering twins is the same as that for a single fetus; however, you will need some supplies from an additional OB kit. Clamp and cut the cord of the first newborn as soon as it has been delivered and before the second newborn is delivered. The second fetus may deliver before or after the first placenta. There may be only one placenta, or one for each fetus. When the placenta has been delivered, check whether there is one umbilical cord or two. If you see only one umbilical cord coming out of the first placenta, another placenta is still to be delivered. If both cords are attached to one placenta, the delivery is complete. Identical twins are always the same sex; fraternal twins may be the same or different sexes.

Record the time of birth of each twin separately. Twins may be so small that they look premature; handle them carefully, and keep them warm. Identify the first newborn delivered as "Baby A." With the delivery of two or more newborns, you can indicate the order of delivery by writing on a piece of tape and placing it on the blanket or towel that is wrapped around each newborn.

Premature Birth

Full-term gestation is considered to be between 39 weeks and 40 weeks, 6 days, approximately 9 calendar months. A normal, full term, single newborn will weigh approximately 7 pounds (3 kg) at birth. Any newborn who delivers before 8 months (36 weeks of gestation) or weighs less than 5 pounds (2 kg) at birth is considered premature. This determination is not always easy to make. Often, the exact gestation time cannot be determined. A premature newborn is smaller and thinner than a full-term newborn, and the head is proportionately larger in comparison with the rest of the body **Figure 33-16**. The vernix caseosa will be absent or minimal on a premature newborn. There will also be less body hair.

Figure 33-16 Premature newborns (right) are smaller and thinner than full-term newborns.

© American Academy of Orthopaedic Surgeons.

Premature newborns need special care to survive. They often require resuscitation, which should be performed unless physically impossible. With such care, premature newborns as small as 1 pound (0.5 kg) have survived.

Postterm Pregnancy

Approximately 10% of pregnancies are postterm, meaning that the gestation period is longer than 42 weeks. Sometimes, however, a pregnancy is incorrectly believed to be postterm because the due date was miscalculated.

A true postterm pregnancy can lead to problems with both the woman and fetus. Postterm fetuses can be larger than a typical 40-week fetus, sometimes weighing more than10 pounds (5 kg), which can lead to a more difficult labor and delivery and an increased chance of injury to the fetus as it travels through the birth canal. The likelihood of a cesarean section being required is increased. The woman is also at increased risk for perineal tears and infection. Postterm newborns have an increased risk of meconium aspiration, infection, and being stillborn and may not have developed normally because of the restricted size of the uterus. Be prepared to resuscitate the newborn, as respiratory and neurologic functions may have been affected. The larger size of the fetus causes it to take up more space inside the uterus, resulting in compression of the structures, including the blood vessels of the placenta and the umbilical cord.

Fetal Demise

Unfortunately, you may find yourself delivering a fetus that died in the woman's uterus before labor began. This situation will test your medical, emotional, and social abilities. Grieving parents will be emotionally distraught and may be hostile, requiring all your professionalism and support skills. Chapter 34, *Pediatric Emergencies*, discusses how to handle the death of a child in detail.

The onset of labor may be premature, but labor will otherwise progress normally in most cases. If an intrauterine infection has caused the demise, you may note an extremely foul odor. Depending on the stage of decomposition, the delivered fetus may have skin blisters, skin sloughing, and a dark discoloration. The head will be soft and perhaps grossly deformed.

Do not attempt to resuscitate an obviously dead neonate. However, do not confuse this situation with that in which a newborn is in cardiopulmonary arrest as a complication of the birthing process. You must attempt to resuscitate normal-appearing newborns.

Delivery Without Sterile Supplies

On rare occasions, you may have to deliver a newborn without a sterile OB kit. Even if you do not have an OB kit, you should always have eye protection, gloves, and a protective mask with you. Carry out the delivery as if sterile supplies were available. If possible, use freshly laundered sheets and towels. As soon as the newborn is delivered, wipe the inside of the mouth with your finger to clear away blood and mucus. Without the OB kit, you should not cut or clamp the umbilical cord. Instead, as soon as the placenta delivers, wrap it in a clean towel or put it in a plastic bag and transport it with the newborn and mother to the hospital. Always keep the placenta and the newborn at the same level. Be sure to keep the newborn warm.

Postpartum Complications

Some bleeding always occurs with delivery, but bleeding that exceeds approximately 500 mL is considered excessive. If bleeding continues after delivery of the placenta, continue to massage the uterus, but check your technique and hand placement. If the woman appears to be in shock, treat her accordingly and transport, massaging the uterus en route. Excessive bleeding after birth is usually caused by the muscles of the uterus not fully contracting. This can be from delivering more than one infant, a long labor process so the uterus is too "tired" to contract, or parts of the placenta still being inside the uterus. This condition is potentially life threatening for the woman. Cover the vagina with a sterile pad, changing the pad as often as necessary. Do not discard any blood-soaked pads; hospital personnel will use them to estimate the amount of blood loss. Also save any tissue that may have passed from the vagina.

Administer oxygen if necessary, monitor vital signs frequently, and transport the patient immediately to the hospital. Never hold the woman's legs together or pack the vagina with gauze pads in an attempt to control bleeding.

Postpartum patients are also at increased risk of an embolism. One reason is the increased clotting ability that is a normal change of pregnancy. Also, a pregnant woman who has been on bed rest for any length of time is more prone to clots. The most common embolism seen in postpartum women is a pulmonary embolism, which is a clot that travels through the bloodstream and becomes lodged in the pulmonary circulation. This obstruction will block blood flow to the lungs and is potentially life threatening. If you deliver a newborn in the field and the woman begins to report sudden difficulty breathing or shortness of breath, consider the possibility that she has a pulmonary embolism.

You should also suspect a pulmonary embolism in patients of childbearing age with respiratory complaints who have recently delivered, especially with the sudden onset of difficulty breathing or altered mental status. Women have died of a postpartum pulmonary embolism from days to several weeks or months after childbirth. Provide supportive care of the ABCs with high-flow oxygen and rapid transport to the hospital.

YOU are the Provider — SUMMARY

1. What anatomic and physiologic changes occur during pregnancy? How will they affect your assessment of the patient?

Most pregnancy-related changes are observed in the respiratory and cardiovascular systems. As the uterus enlarges during pregnancy, it is displaced upward from the pelvic cavity, where it is normally protected, and is therefore exposed to potential injury. The enlarged uterus pushes upward on the diaphragm. This decreases the woman's ability to breathe deeply, so the respiratory rate increases slightly to maintain adequate minute volume. Pregnancy also increases maternal oxygen demand and consumption. Blood volume increases throughout pregnancy. To accommodate the increase in total blood volume, the woman's heart rate increases up to 20%, or about 20 beats/ min, by the third trimester of pregnancy.

Vital sign changes during pregnancy, such as an increase in heart rate and respiratory rate, should not be assumed to be pregnancy-related if the woman experiences an acute illness or injury. Instead, assume them to be signs of shock until proven otherwise.

2. How will you determine if delivery is imminent or if there is enough time to transport the pregnant patient?

Ask the patient how long she has been pregnant, when she is due to deliver, and if this is her first pregnancy. As a general rule, labor is longer in women who are pregnant for the first time (primigravida). If the patient is experiencing contractions, ask her how far apart they are and how long they last. Ask if her bag of water (amniotic sac) has ruptured. This typically occurs toward the end of the first stage of labor, but may not occur until the delivery itself. Ask her if she is experiencing any vaginal spotting or bleeding; during the first stage of labor a plug of mucus—sometimes mixed with blood (bloody show)—is expelled from the dilating cervix and discharged from the vagina. Ask the patient if she feels the urge to push or move her bowels. The presence of crowning is an obvious indicator that delivery is in progress. Perhaps one of the most reliable indicators of imminent delivery is when the patient states, "I'm having this baby now!" This is especially true in women who have given birth in the past.

3. What are gestational diabetes and preeclampsia? How can they affect this delivery?

Gestational diabetes, or diabetes of pregnancy, is a condition that develops during pregnancy and typically resolves on its own after delivery. Infants born to women with gestational diabetes are often large for their gestational age, which could lead to shoulder dystocia—a condition in which the fetus's shoulders are too broad to fit through the woman's pelvic opening—or other delivery complications caused by the fetus's size. In addition, many women experience nausea before labor and have not eaten recently—factors that could lead to hypoglycemia and weakness in the woman and fetus.

Preeclampsia, or pregnancy-induced hypertension, is characterized by hypertension; edema of the hands, feet, and face; and protein in the urine. Other symptoms may include visual disturbances (eg, seeing spots, blurred vision), headache, and anxiety.

Untreated preeclampsia may lead to eclampsia, which is characterized by life-threatening seizures. The

4. Is there time to transport this patient, or should you prepare for imminent delivery?

The patient is experiencing frequent (every 2 minutes) contractions that are lasting 45 seconds, and she has the urge to move her bowels, which indicates that the fetus is in the birth canal. On the basis of these factors, delivery will likely occur within the next few minutes; therefore, you and your partner should prepare for imminent delivery.

5. How should you manage the umbilical cord situation?

As soon as the head has delivered, you should assess for the umbilical cord. If present, an umbilical cord must be treated immediately because if the cord is wrapped tightly around the newborn's neck, the airway could be blocked. Usually, you can slip the cord gently over the head (or shoulders, if necessary). If not, clamp the cord about 2 inches (5 cm) apart and cut between the two clamps. In the rare event that the cord is wrapped more than once around the neck, clamp and cut only once and then unwrap it from around the neck. Handle the cord very carefully; it is fragile and easily torn. Do not let the clamps come off until the ends have been tied.

6. What would you do if the amniotic sac were still intact?

If you notice that the amniotic sac seems to be intact after the head delivers or as the head is crowning, immediately puncture the membrane and allow the fluid to drain. Avoid using sharp objects to puncture the membrane; first attempt to use your fingers. Once the membrane ruptures and the fluid drains, wipe the traces of the membrane away from the newborn's mouth and nose and continue with the delivery.

7. What is involved in the routine postdelivery care of a newborn?

Immediate postdelivery care of a newborn—regardless of his or her appearance—involves keeping the newborn dry and warm and facilitating effective breathing. The need for further treatment is based on assessment of the newborn's respiratory effort, heart rate, and skin color.

8. What immediate treatment is indicated for this newborn?

The newborn is breathing; however, her heart rate is low (80 beats/min) and her trunk and extremities are cyanotic. These clinical signs indicate that she is hypoxemic and will require additional resuscitative measures. Begin positive-pressure ventilations with a BVM. Newborn bradycardia is almost always the result of hypoxemia.

Ventilate the newborn at a rate of 40 to 60 breaths/ min for 30 seconds, and then reassess the heart rate. In most cases, only a brief period of positive-pressure ventilation is needed to increase the newborn's heart rate. If the heart rate is still less than 100 beats/min after 30 seconds of positive-pressure ventilation, continue ventilations, keep the newborn warm, and transport at once.

9. What further treatment is indicated for the mother?

After delivery and before transport, place a sterile pad or sanitary pad over the vagina and straighten the mother's legs. *Never place any pads or dressings into the vagina.* Gently massage the mother's abdomen with a firm, circular motion to cause the uterus to contract and help control bleeding.

If severe bleeding occurs after placental delivery, transport immediately, and treat the mother for shock. Place a sterile pad or sanitary pad over the mother's vagina, administer high-flow oxygen if necessary, and keep her warm with blankets. Closely monitor her vital signs en route.

10. What Apgar score should you assign to this newborn?

This newborn has a pink body but cyanotic hands and feet; therefore, you should assign a score of 1 for appearance. Her heart rate is 130 beats/min; therefore, assign a score of 2 for the pulse. She moves her foot away when you flick the soles; therefore, assign a score of 2 for grimace. She resists your attempts to straighten her knees, which indicates good muscle tone; therefore, assign a score of 2 for activity. Finally, her respirations are rapid (40 to 60 breaths/min is a normal newborn respiratory rate); therefore, assign a score of 2 for respirations. On the basis of your assessment findings, you should assign the newborn an Apgar score of 9.

Narrative

Medic 44 is dispatched to a residence for a female in labor. Arrived on scene and found the patient, a 28-year-old female, lying supine in her bed. She was conscious and alert; her airway was patent, and her breathing, although increased in rate, was of adequate depth. Patient stated, "I am having my baby now!" She stated that this is her third baby. Her husband, who was present at the scene, advised that she has had gestational diabetes and preeclampsia with this pregnancy and has had regular prenatal care. The patient stated that her contractions were 2 minutes apart and lasting about 45 seconds each; she further stated that she had the urge to move her bowels and that her amniotic sac ruptured 5 hours ago. Initial visual inspection of the vaginal area did not reveal crowning. After initial set of vital signs were obtained, reassessment of vaginal area revealed crowning. Properly positioned patient, administered supplemental oxygen, and prepared for delivery. Husband remained present and provided emotional support and respiratory coaching to his wife. Delivery of head revealed nuchal cord, which was easily corrected by sliding the cord over the shoulders. Delivered the rest of the body without difficulty. After providing immediate postdelivery care to the newborn, a female, assessment revealed that she was breathing, had a heart rate of 80 beats/min, and had cyanosis of the trunk and extremities. Began assisted ventilation with a BVM at 40 breaths/min; reassessment after 30 seconds revealed marked improvement in newborn's heart rate and skin color; her hands and feet remained slightly cyanotic, but her body was pink. Allowed mother to hold the newborn while it was dried and wrapped. Clamped and cut the umbilical cord. Placental delivery occurred approximately 5 minutes after the birth of the baby. Reassessed mother's vital signs, and provided fundal massage for mild postpartum bleeding. Assigned 5-minute Apgar score of 9 (A, 1; P, 2; G, 2; A, 2; R, 2). Packaged mother and newborn and began transport to the hospital. En route, continued to assess mother and newborn; they both remained stable. Reassessment of vaginal bleeding revealed that it had stopped. Continued oxygen therapy for the mother, and delivered her and her baby to the hospital without incident. Provided verbal report to attending physician. Medic 44 returned to service at 0753.**End of report**

Prep Kit

Ready for Review

- Inside the uterus, the developing fetus is within the amniotic sac. The umbilical cord connects the woman and fetus through the placenta. Eventually, contractions of the uterus will propel the fetus through the birth canal.
- Throughout pregnancy, the body changes to accommodate the fetus. The primary systems involved with these changes are the respiratory, cardiovascular, and musculoskeletal systems.
- As a result of enlargement of the uterus, a pregnant patient's respiratory capacity changes with increased respiratory rates and decreasing minute volumes.
- A pregnant woman's blood volume increases by as much as 50%, and the heart rate increases by 20%.
- Increased hormone levels affect the musculoskeletal system by making the joints looser, or less stable.
- Complications of pregnancy include hypertensive disorders, bleeding, and diabetes.
- During a trauma call that involves a pregnant woman, you have two patients to consider—the woman and the unborn fetus. Trauma to the woman may have a direct effect on the condition of the fetus.
- The first stage of labor, dilation, begins with the onset of contractions and ends when the cervix is fully dilated. The second stage of labor, expulsion of the fetus, begins when the cervix is fully dilated and the fetus enters the birth canal; it ends with delivery of the newborn. The third stage of labor, delivery of the placenta, begins with the delivery of the newborn and ends with the delivery of the placenta.
- Once labor has begun, it cannot be slowed or stopped; however, there is usually time to transport the patient to the hospital during the first stage of labor. During the second stage of labor, you must decide whether to deliver at the scene or transport the patient. During the third stage of labor, after delivery of the newborn, you will probably not transport the patient until the placenta has delivered. Warm, dry, and stimulate the infant after birth.
- Abnormal or complicated deliveries include breech deliveries (buttocks first), limb presentations (arm or leg first), and prolapse of the umbilical cord (umbilical cord first). Quickly transport the patient with a limb presentation or prolapsed umbilical cord to the hospital.
- You should place a finger or hand into the vagina for only two reasons: to keep the walls of the vagina from compressing the fetus's airway during a breech presentation or to push the fetus's head away from the cord when the cord is prolapsed.
- Assess a newborn for term gestation, good muscle tone, and breathing/crying to determine whether he or she requires resuscitation. Also obtain an Apgar score one minute after birth as part of the initial evaluation.
- Excessive bleeding is a serious emergency. Cover the vagina with a sterile pad. Change the pad as often as necessary, and take all used pads to the hospital for examination.

Vital Vocabulary

abruptio placenta Premature separation of the placenta from the wall of the uterus.

amniotic sac The fluid-filled, baglike membrane in which the fetus develops.

anemic Describes a condition in which the patient has too few red blood cells, resulting in a decreased ability to transport oxygen throughout the body via the bloodstream.

Apgar score A scoring system for assessing the status of a newborn that assigns a number value to each of five areas.

birth canal The vagina and cervix.

bloody show A small amount of blood in the vagina that appears at the beginning of labor and may include a plug of pink-tinged mucus that is discharged when the cervix begins to dilate.

breech presentation A delivery in which the buttocks come out first.

cervix Narrowest portion of the uterus that opens into the vagina.

crowning The appearance of the fetus's head at the vaginal opening during labor.

eclampsia Severe hypertension in a pregnant woman, resulting in seizures (convulsions).

ectopic pregnancy A pregnancy that develops outside the uterus, typically in a fallopian tube.

embryo The early stage of development after the fertilization of the egg (first 10 weeks).

endometrium The lining of the inside of the uterus.

fetal alcohol syndrome A condition caused by the consumption of alcohol by a pregnant woman; characterized by growth and physical problems, mental retardation, and a variety of congenital abnormalities.

fetus The developing, unborn infant inside the uterus, from 10 weeks after fertilization until birth.

fundus The dome-shaped top of the uterus.

gestational diabetes Diabetes that develops during pregnancy in women who did not have diabetes before pregnancy.

lightening The movement of the fetus down into the pelvis late in pregnancy.

limb presentation A delivery in which the presenting part is a single arm or leg.

meconium Fetal stool. When appearing as a dark green material in the amniotic fluid, it can indicate distress or disease in the newborn; it can be aspirated into the fetus's lungs during delivery.

miscarriage The spontaneous passage of the fetus and placenta before 20 weeks; also called spontaneous abortion.

multigravida A woman who has had previous pregnancies.

nuchal cord An umbilical cord that is wrapped around the fetus's neck.

perineum In a woman, the area between the vagina and the anus.

placenta The tissue attached to the uterine wall that nourishes the fetus through the umbilical cord.

placenta previa A condition in which the placenta develops over and covers the cervix.

preeclampsia A pregnancy complication that is characterized by high blood pressure, headache, visual changes, and swelling of the hands and feet; also called pregnancy-induced hypertension or toxemia of pregnancy.

pregnancy-induced hypertension A condition of late pregnancy that is characterized by headache, visual changes, and swelling of the hands and feet; also called preeclampsia or toxemia of pregnancy.

presentation The position in which an infant is born; defined by the part of the body that appears first.

primigravida A woman who is experiencing her first pregnancy.

prolapse of the umbilical cord A situation in which the umbilical cord comes out of the vagina before the fetus.

spina bifida A developmental defect in which a portion of the spinal cord or meninges may protrude outside of the vertebrae and possibly even outside of the body, usually at the lower third of the spine in the lumbar area.

supine hypotensive syndrome Low blood pressure resulting from compression of the inferior vena cava by the weight of the pregnant uterus when the woman is supine.

term gestation A pregnancy that has reached full term, between 39 weeks and 40 weeks, 6 days.

umbilical cord The structure that connects the pregnant woman to the fetus via the placenta; contains two arteries and one vein.

vernix caseosa A white, cheesy substance that covers the body of the fetus.

vertex presentation A delivery in which the head of the newborn comes out first.

Assessment *in Action*

You and your partner are called to a private residence for a woman in labor. On arrival, you find a 27-year-old woman lying on the living room couch, and she appears to be having a contraction.

1. The patient tells you that she is 38 weeks pregnant and her water broke when she was walking to the kitchen to get a drink. She says that she began experiencing contractions shortly afterward. The onset of her labor began when the:

   A. amniotic sac ruptured.
   B. fetus entered the birth canal.
   C. uterine contractions began.
   D. woman had the urge to push.

2. When your partner asks the patient about any complications related to this pregnancy, she tells her that she has been on bed rest for the past 7 weeks because she was diagnosed with preeclampsia. Preeclampsia is dangerous because:

   A. the headache can be a sign of a stroke.
   B. it causes swelling of the hands and feet.
   C. the high blood pressure can hide signs of shock.
   D. it can lead to eclampsia and seizures.

3. The answer to which of the following questions will help you determine whether delivery for this patient is imminent?

   A. Have you had a previous complicated pregnancy?
   B. Do you know if there is a chance of multiple deliveries?
   C. Is this your first baby?
   D. Do you use drugs or drink alcohol?

4. The patient informs you that her amniotic fluid was green and she is concerned. The green color is caused by:

   A. premature rupture of the membranes.
   B. the presence of meconium.
   C. prolonged gestation.

D. maternal infection.

5. As you deliver the head, you observe the umbilical cord is wrapped once around the neck. What should you do?

   A. Ask the patient not to push, and prepare for immediate transport.
   B. Clamp and cut the cord, and remove the cord from around the neck.
   C. Pull on the cord to speed the delivery.
   D. Try to slip the cord gently over the head.

6. Following delivery, what is the correct way to stimulate this newborn to breathe?

   A. Gently rub the newborn's back.
   B. Blow oxygen into the newborn's face.
   C. Smack the newborn on the buttocks.
   D. Begin chest compressions.

7. The best way to assess this newborn's circulation is:

   A. palpate the carotid pulse.
   B. assess for cyanosis in the extremities.
   C. palpate the brachial pulse.
   D. check for capillary refill on the sole of the foot.

8. Once an appropriate respiratory effort is present in the newborn after delivery, what is the next most important measure in determining the newborn's need for resuscitation?

   A. Heart rate
   B. Blood pressure
   C. Pulse oximetry
   D. Apgar score

9. Discuss the proper management for a newborn who needs ventilatory assistance.

10. What is the significance of meconium in the amniotic fluid?

CHAPTER
34

Pediatric Emergencies

National EMS Education Standard Competencies

Special Patient Populations

Applies a fundamental knowledge of the growth, development, and aging and assessment findings to provide basic emergency care and transportation for a patient with special needs.

Patients With Special Challenges

› Recognizing and reporting abuse and neglect (pp 1268–1271 and Chapter 35, *Geriatric Emergencies*)

Health care implications of

› Abuse (pp 1268–1271 and Chapter 35, *Geriatric Emergencies*)
› Neglect (pp 1268, 1270 and Chapter 35, *Geriatric Emergencies*)
› Homelessness (Chapter 36, *Patients With Special Challenges*)
› Poverty (Chapter 36, *Patients With Special Challenges*)
› Bariatrics (Chapter 36, *Patients With Special Challenges*)
› Technology dependent (Chapter 36, *Patients With Special Challenges*)
› Hospice/terminally ill (Chapter 36, *Patients With Special Challenges*)
› Tracheostomy care/dysfunction (Chapter 36, *Patients With Special Challenges*)
› Home care (Chapter 36, *Patients With Special Challenges*)
› Sensory deficit/loss (Chapter 36, *Patients With Special Challenges*)
› Developmental disability (Chapter 36, Patients With Special Challenges)

Pediatrics

Age-related assessment findings, and age-related assessment and treatment modifications for pediatric-specific major diseases and/or emergencies

› Upper airway obstruction (pp 1228–1232, 1240–1243)
› Lower airway reactive disease (pp 1228–1232, 1240–1245)

› Respiratory distress/failure/arrest (pp 1232, 1240–1253)
› Shock (pp 1230, 1232, 1253–1255)
› Seizures (pp 1255–1256, 1260–1261)
› Sudden infant death syndrome (pp 1271–1274)

Age-related assessment findings, and developmental stage related assessment and treatment modifications for pediatric-specific major diseases and/or emergencies

› Upper airway obstruction (pp 1228–1232, 1240–1243)
› Lower airway reactive disease (pp 1228–1232, 1240–1245)
› Respiratory distress/failure/arrest (pp 1232, 1240–1253)
› Shock (pp 1230, 1232, 1253–1255)
› Seizures (pp 1255–1256, 1260–1261)
› Sudden infant death syndrome (pp 1271–1274)
› Gastrointestinal disease (pp 1257–1258)

Trauma

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

Special Considerations in Trauma

Recognition and management of trauma in

› Pregnant patient (Chapter 33, *Obstetrics and Neonatal Care*)
› Pediatric patient (pp 1226–1240, 1261–1267)
› Geriatric patient (Chapter 35, *Geriatric Emergencies*)

Pathophysiology, assessment, and management of trauma in the

› Pregnant patient (Chapter 33, *Obstetrics and Neonatal Care*)
› Pediatric patient (pp 1226–1240, 1261–1267)
› Geriatric patient (Chapter 35, *Geriatric Emergencies*)
› Cognitively impaired patient (Chapter 36, *Patients With Special Challenges*)

Knowledge Objectives

1. Explain some of the challenges inherent in providing emergency care to pediatric patients and why effective communication with both the patient and his or her family members is critical to a successful outcome. (p 1218)
2. Discuss the physical and cognitive developmental stages of an infant, including health risks, signs that may indicate illness, and patient assessment. (pp 1219–1220)
3. Discuss the physical and cognitive developmental stages of a toddler, including health risks, signs that may indicate illness, and patient assessment. (pp 1220–1221)
4. Discuss the physical and cognitive developmental stages of a preschool-age child, including health risks, signs that may indicate illness, and patient assessment. (pp 1221–1222)
5. Discuss the physical and cognitive developmental stages of a school-age child, including health risks, signs that may indicate illness, and patient assessment. (p 1222)
6. Discuss the physical and cognitive developmental stages of an adolescent, including health risks, patient assessment, and privacy issues. (pp 1222–1223)
7. Describe differences in the anatomy and physiology of the pediatric patient compared to the adult patient and their implications for EMTs, with a focus on the following body systems: respiratory, circulatory, nervous, gastrointestinal, musculoskeletal, and integumentary. (pp 1223–1226)
8. Describe differences in the pathophysiology of the pediatric patient compared to the adult patient and their implications for EMTs, with a focus on the following body systems: respiratory, circulatory, nervous, gastrointestinal, musculoskeletal, and integumentary. (pp 1224–1226)
9. Explain the steps in the primary assessment of a pediatric patient, including the elements of the pediatric assessment triangle (PAT), hands-on ABCs, transport decision considerations, and privacy issues. (pp 1227–1236)
10. Explain the steps in the secondary assessment of a pediatric patient, including what EMTs should look for related to different body areas and the method of injury. (pp 1236–1240)

11. Describe the emergency care of a pediatric patient in respiratory distress, including the different causes of pediatric respiratory emergencies, the signs and symptoms of increased work of breathing, and the difference between respiratory distress and respiratory failure. (pp 1228–1229, 1240–1253)
12. List the possible causes of an upper and a lower airway obstruction in a pediatric patient and the steps in the management of foreign body airway obstruction. (pp 1241–1243)
13. Describe asthma, its possible causes, signs and symptoms, and steps in the management of a pediatric patient who is experiencing an asthma attack. (pp 1243–1244)
14. Explain how to determine the correct size of an airway adjunct intended for a pediatric patient during an emergency. (pp 1245–1249)
15. List the different oxygen delivery devices that are available for providing oxygen to a pediatric patient, including the indications for the use of each and precautions EMTs must take to ensure the patient's safety. (pp 1249–1253)
16. Describe the emergency care of a pediatric patient who is in shock (hypoperfusion), including common causes, signs, and symptoms. (pp 1253–1255)
17. Describe the emergency care of a pediatric patient with an altered mental status, including common causes, signs, and symptoms. (p 1255)
18. Describe the emergency care of a pediatric patient who has experienced a seizure, including the different types of seizures, common causes, signs, and symptoms. (pp 1255–1256)
19. Describe the emergency care of a pediatric patient with meningitis, including common causes, signs, symptoms, and special precautions. (pp 1256–1257)
20. Describe the emergency care of a pediatric patient who is experiencing a gastrointestinal emergency, including common causes, signs, and symptoms. (pp 1257–1258)
21. Describe the emergency care of a pediatric patient who has been poisoned, including common sources of poisoning, signs, and symptoms. (pp 1258–1259)
22. Describe the emergency care of a pediatric patient who is dehydrated, including how to gauge the severity of dehydration based on key signs and symptoms. (pp 1259–1260)
23. Describe the emergency care of a pediatric patient who is experiencing a fever emergency, including common causes. (pp 1260–1261)
24. Describe the emergency care of a pediatric patient who has experienced a drowning emergency, including common causes, signs, and symptoms. (p 1261)
25. Discuss the common causes of pediatric trauma emergencies; include how to differentiate between injury patterns in adults, infants, and children. (pp 1261–1267)
26. Discuss the significance of burns in pediatric patients, their most common causes, and general guidelines EMTs should follow when assessing patients who have sustained burns. (pp 1266–1267)
27. Explain the four triage categories used in the JumpSTART system for pediatric patients during disaster management. (pp 1267–1268)
28. Describe child abuse and neglect and its possible indicators, including the medical and legal responsibilities of EMTs when caring for a pediatric patient who is a possible victim of child abuse. (pp 1268–1271)
29. Discuss sudden infant death syndrome (SIDS), including its risk factors, patient assessment, and special management considerations related to the death of an infant patient. (pp 1271–1272)
30. Discuss the responsibilities of EMTs when communicating with a family or loved ones following the death of a child. (pp 1272–1273)
31. Discuss some positive ways EMTs may cope with the death of a pediatric patient and why managing posttraumatic stress is important for all health care professionals. (p 1273)

Skills Objectives

1. Demonstrate how to position the airway in a pediatric patient. (p 1231, Skill Drill 34-1)
2. Demonstrate how to palpate the pulse and estimate the capillary refill time in a pediatric patient. (pp 1232–1233)
3. Demonstrate how to use a length-based resuscitation tape to size equipment appropriately for a pediatric patient. (p 1246)
4. Demonstrate how to insert an oropharyngeal airway in a pediatric patient. (pp 1245–1247, Skill Drill 34-2)
5. Demonstrate how to insert a nasopharyngeal airway in a pediatric patient. (pp 1247–1249, Skill Drill 34-3)
6. Demonstrate how to administer blow-by oxygen to a pediatric patient. (p 1249)
7. Demonstrate how to apply a nasal cannula to a pediatric patient. (pp 1249–1250)
8. Demonstrate how to apply a nonrebreathing mask to a pediatric patient. (p 1250)

9. Demonstrate how to assist ventilation of an infant or child using a bag-valve mask (BVM). (pp 1250–1251)
10. Demonstrate how to perform one-person BVM ventilation on a pediatric patient. (pp 1251–1252, Skill Drill 34-4)
11. Demonstrate how to perform two-person BVM ventilation on a pediatric patient. (p 1253)
12. Demonstrate how to immobilize a pediatric patient who has been involved in a trauma emergency. (pp 1263–1264, Skill Drill 34-5)
13. Demonstrate how to immobilize a pediatric patient in a car seat who has been involved in a trauma emergency. (pp 1264–1265, Skill Drill 34-6)

Introduction

Children differ anatomically, physically, and emotionally from adults. The illnesses and injuries that children sustain, and their responses to them, vary based on age or developmental level. Children are not small adults; therefore, you must tailor your approach to accommodate the unique needs of pediatric patients. Depending on his or her age, the child may not be able to tell you what is wrong. Fear of EMS providers and pain can make the child difficult to assess. In addition, the child's parents or primary caregivers may be stressed, frightened, or behaving irrationally. For these reasons, **pediatrics**, the specialized medical practice devoted to the care of young patients, can be extremely challenging.

With the proper training and an understanding of this patient population, you will learn the tools necessary to form a baseline assessment and plan of care. Once you learn how to approach children of different ages and what to expect while caring for them, you will find that treating children also offers some very special rewards. Not only are their innocence and openness appealing, they often respond to treatment much more rapidly than adults do.

Communication With the Patient and the Family

In most situations, caring for an infant or child means that you must care for the parents or caregivers as well **Figure 34-1**. Family members often need emotional support when medical emergencies or problems develop. A calm parent or caregiver usually results in a calm child; he or she can often assist you with the child's care. An agitated parent or caregiver usually means that the child will act the same way, which often will make the child's care more difficult. Make sure that you are calm, efficient, professional, and sensitive as you deal with pediatric patients and their families.

Figure 34-1 Treating a sick or injured child can be extremely challenging. It is important to maintain a calm, professional demeanor as you care for both the child and the parents or caregivers.

Growth and Development

Recall from Chapter 7, *Life Span Development*, that many physical and emotional changes occur during childhood, which extends from birth until age 18 years. These changes will impact the care you provide to pediatric patients and can create difficulties during your assessment and treatment of the child if you do not expect them. For example, a child's head is proportionally larger than an adult's head, which predisposes the child to heat loss and head injuries from falls and other forms of trauma.

Whereas each child is unique, the thoughts and behaviors of children as a whole are often grouped into five stages: infancy, the toddler years, preschool years, school-age years, and adolescence. Children in each stage grapple with different developmental issues. Even though there are specific issues that are important to different age groups, there are also some general rules that apply when you care for children of any age.

YOU are the Provider — PART 1

At 2323 hours, you are dispatched to 545 West San Antonio Street for a 4-year-old girl with respiratory distress. You and your partner proceed to the scene; your response time is 6 minutes. It is a clear autumn day. The temperature is 58°F (14.4°C), and the traffic is light.

1. How does a child's airway and respiratory system differ from an adult's?
2. What are some airway and breathing problems that are unique to pediatric patients?

The Infant

Infancy is usually defined as the first year of life; the first month after birth is called the neonatal or newborn period.

0 to 2 Months

Infants younger than 2 months spend most of their time sleeping or eating. They experience the world through their bodies and respond mainly to physical stimuli such as light, warmth, hunger, and sound. Infants sleep for up to 16 hours a day between feeding times and parent or caregiver interactions. An infant should be aroused easily from a sleeping state, and it should be considered an emergency if this is not the case.

Infants are unable to tell the difference between parents or caregivers and strangers. Other than crying, infants have a limited ability to communicate pain or discomfort. Infants may cry if certain basic physical needs must be met, such as food, warmth, and comfort. Soothing an infant should be relatively easy for the parent or caregiver, such as by holding, cuddling, or rocking the infant. Hearing is generally well developed at birth, so calm and reassuring talk is often helpful as well. Every reasonable attempt should be made to identify why the infant is crying. If all obvious needs have been addressed and the infant is still inconsolable, then this could be a sign of significant illness.

Infants at this stage have a sucking reflex for feeding. Head control is limited, but infants can turn their heads and focus on faces. Infants have poor thermoregulation (the body's ability to maintain normal temperature). Their heads also have a relatively large surface area. These factors predispose them to hypothermia, so parents or caregivers will often bundle infants in an attempt to keep them warm. With this in mind, it is often necessary to unbundle the infant during your assessment.

2 to 6 Months
