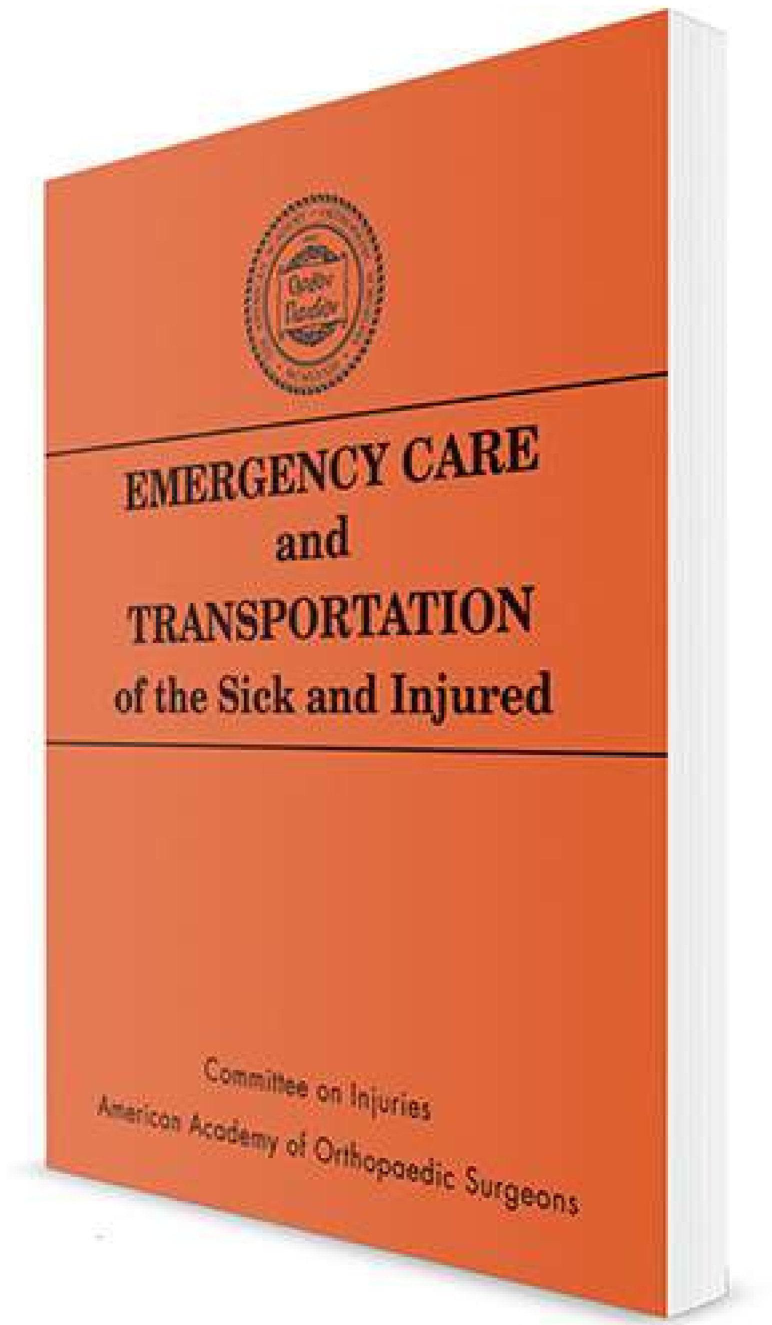
JONES & BARTLETT LEARNING

Celebrating 45 years of EMS education and innovation.



In 1971, the American Academy of Orthopaedic Surgeons (AAOS) published the first edition of ***Emergency Care and Transportation of the Sick and Injured*** with its now-familiar orange cover and laid the foundation of EMS training. Today, the AAOS's commitment and dedication to excellence has transformed how EMS education is delivered throughout the world and helped develop and train countless world-class EMS providers.

In 1997, the AAOS partnered with Jones & Bartlett Publishers (JB Learning) to release ***Emergency Care and Transportation of the Sick and Injured, Revised Sixth Edition***. Since the publication of that edition, the AAOS and JB Learning have worked together to transform all levels of EMS training, from emergency medical responder to paramedic. Our partnership has resulted in market-leading resources that go beyond initial training into assessment, continuing education, and professional resources to support EMS providers through every step of their education and career.

Today, the AAOS suite of EMS educational resources, from first aid and CPR to critical care transport, are the gold standard in training programs with exceptional content and instructional resources that meet the diverse needs of today's educators and students.

JB Learning is proud and honored to congratulate our esteemed partner, the American Academy of Orthopaedic Surgeons, on the 45th anniversary of their first publication of the Orange Book.

To explore other AAOS publications, programs, and products on orthopaedic trauma and other practice areas, please visit

www.aaos.org/Education.

Brief Contents

Section 1: Preparatory

Section 2: Patient Assessment

Section 3: Airway

Section 4: Pharmacology

Section 5: Shock and Resuscitation

Section 6: Medical

Section 7: Trauma

Section 8: Special Patient Populations

Section 9: EMS Operations

Section 10: The Team Approach to Health Care

CHAPTER 1

EMS Systems

National EMS Education Standard Competencies

Preparatory

Applies fundamental knowledge of the emergency medical services (EMS) system, safety/well-being of the emergency medical technician (EMT), medical/legal, and ethical issues to the provision of emergency care.

Emergency Medical Services (EMS) Systems

› EMS systems (pp 15–26)
› History of EMS (pp 9–10)
› Roles/responsibilities/professionalism of EMS personnel (pp 26–27)
› Quality improvement (pp 20–21)
› Patient safety (pp 7, 26)

Research

› Impact of research on emergency medical responder (EMR) care (pp 24–26)
› Data collection (p 25)
› Evidence-based decision making (pp 25–26)

Public Health

Uses simple knowledge of the principles of illness and injury prevention in emergency care.

Knowledge Objectives

1. Define emergency medical services (EMS) systems. (p 5)
2. Name the four levels of EMT training and licensure. (pp 6–8)
3. Describe EMT licensure criteria; include how the Americans with Disabilities Act (ADA) applies to employment as an EMT. (p 8)
4. Discuss the historical background of the development of the EMS system. (pp 9–10)
5. Describe the levels of EMT training in terms of skill sets needed for each of the following: EMR, EMT, AEMT, and paramedic. (pp 10–14)

6. Recognize the possible presence of other first responders at a scene with EMR training, some knowledge of first aid, or merely good intentions, and their need for direction. (pp 13–14)
7. Name the 14 components of the EMS system. (pp 15–26)
8. Describe how medical direction in an EMS system works, and the EMT's role in the process. (p 18)
9. Define mobile integrated healthcare and community paramedicine. (p 19)
10. Discuss the purpose of the EMS continuous quality improvement (CQI) process. (pp 20–21)
11. Characterize the EMS system's role in disease and injury prevention and public education in the community. (pp 23–24)
12. Describe the roles and responsibilities of the EMT. (p 26)
13. Describe the attributes an EMT is expected to possess. (p 27)
14. Explain the impact of the Health Insurance Portability and Accountability Act (HIPAA) on patient privacy. (p 27)

Skills Objectives

There are no skills objectives for this chapter.

Introduction

This textbook serves as the primary resource for the emergency medical technician (EMT) course. It discusses what will be expected of you during the course and what requirements you must meet to be licensed or certified as an EMT in most states. You will learn about the differences between first aid training, a Department of Transportation (DOT) emergency medical responder (EMR) training course, and the training courses for an EMT, advanced emergency medical technician (AEMT), and paramedic.

Emergency medical services (EMS) is a *system*. This system's key components and how they influence and affect the EMT and his or her delivery of emergency care are carefully discussed in this chapter. The administration, medical direction, quality control, and regulation of EMS are also presented. The chapter concludes with a detailed discussion of the roles and responsibilities of the EMT as a health care professional.

Course Description

You are about to enter an exciting field. The **emergency medical services (EMS)** system consists of a team of health care professionals who, in each area or jurisdiction, are responsible for and provide emergency care and transportation to the sick and injured **Figure 1-1**. Each emergency medical service is part of a local or regional EMS system that provides the many prehospital and hospital components required for the delivery of proper emergency medical care. The standards for prehospital emergency care and the people who provide it are governed by the laws of each state they serve and are typically regulated by a state office of EMS.

Figure 1-1 As an EMT, you are part of a larger team that responds to a variety of calls and provides a wide range of prehospital emergency care.

After you successfully complete this course, you should be eligible to take either the National Registry of EMTs exam or your state's certification exam. A **certification** exam is used to ensure all health care providers have at least the same basic level of knowledge and skill. After you pass this exam, you will be eligible to apply for state licensure. **Licensure** is the process by which states ensure applicant competency in an examination setting. This allows states to manage who can function as a health care provider. It is the same principle as taking a driving test to obtain a driver's license to certify you know how to operate a motor vehicle. Different states will refer to the authority granted to you to function as an EMT as licensure, certification, or credentialing. For the purposes of this textbook, the term *licensure* will be used.

YOU are the Provider — PART 1

You are working your first shift as an EMT. You are on duty with an experienced EMT and her paramedic partner. The crew is familiarizing you with the ambulance when the tone alert sounds, "EMS 4, respond to 325 Blossom Avenue for a woman with back pain." You and your crew proceed to the scene, which is located 4 miles from your station.

1. Do your roles and responsibilities as an EMT differ from those of a paramedic? If so, how?
2. What is the difference between what you learned in your EMT class and the care you provide in the field?

In most states, people who work on an ambulance are categorized into four training and licensure levels: **emergency medical responder (EMR)**, **emergency medical technician (EMT)**, **advanced EMT (AEMT)**, and **paramedic**. An EMR has very basic training and provides care before the ambulance arrives. EMRs may also perform in an assistant role within the ambulance. An EMT has training in basic life support (BLS), including automated external defibrillation, use of airway adjuncts, and assisting patients with certain medications. An AEMT has training in specific aspects of **advanced life support (ALS)**, such as **intravenous (IV) therapy** and the administration of certain emergency medications. A paramedic has extensive training in ALS, including endotracheal intubation, emergency pharmacology, cardiac monitoring, and other advanced assessment and treatment skills.

Although the specific training and licensure requirements vary from state to state, almost every state's requirements follow or exceed the guidelines recommended in the current National Highway Traffic Safety Administration (NHTSA) EMS Education Standards.

This textbook covers the practice and skills identified in the 2009 *National EMS Education Standards*. It also covers the information needed for EMTs to perform the skills outlined in the 2005 National EMS Scope of Practice Model. In the United States, NHTSA is the federal administrative source for education standards and related documents.

Like any introductory course, the EMT course covers a great deal of information and introduces many skills **Figure 1-2**. EMT courses include didactic instruction (knowledge), psychomotor instruction (skills laboratories), and clinical behavior/judgment (professionalism). Everything you learn in the course will be important to your ability to provide high-quality emergency care once you are licensed and ready to practice. In addition, the knowledge, understanding, and skills that you acquire in the EMT course will serve as a foundation for the additional knowledge and training you will receive in future years.

In addition to the required core content, this text includes additional information to help you understand and apply the knowledge and skills included in the EMT course. Your instructor will furnish you with reading assignments. It is essential that you complete the assigned reading before each class. Each class builds upon the previous; ensuring you complete the readings and assignments will help you understand subsequent lessons. This approach is pivotal to your success in this course.

Figure 1-2 In the classroom, you will learn both didactic and practical skills to prepare you for various types of calls.

In class, your instructor will review the key parts of the reading assignment and clarify and expand on them. He or she will answer any questions you have and clarify any points you or others find confusing. Unless you carefully read the assignment and made notes before coming to class, you will not fully understand or benefit from the classroom presentations and discussions. Creating your own tools such as flashcards, study questions, and outlines will help you retain important information. It will also help you take better notes during class **Table 1-1**.

The EMT course includes four types of learning activities:

1. Reading assignments from the textbook, lecture presentations, and classroom discussions provide you with the necessary knowledge base.
2. Step-by-step demonstrations teach you the hands-on skills you then need to practice repeatedly in supervised small group workshops.
3. Summary skills sheets help you memorize the sequence of steps in complex skills that contain a large number of steps or variations so you can perform the skill with no errors or omissions.
4. Case presentations and scenarios used in class help you learn how to apply the knowledge and skills acquired to situations you will find in the field.

Table 1-1 Study Tips for Using This Textbook

- Complete each assignment diligently and carefully.
- Reading a textbook is different from reading a newspaper, website, blog, or novel. Make sure you understand what you have read, and study difficult concepts.
- Read each chapter several times and underline key points. Take notes!
- Note the chapter's objectives so you can measure your knowledge effectively.
- Ask your instructor to clarify any questions you note in your reading or in class.
- Take additional notes when the assigned material is expanded upon in class.

Use supporting materials suggested by your instructor, such as digital assessments, animations, videos, and student workbooks.

- Remember: The only absurd question is the one that you fail to ask.

EMT Training: Focus and Requirements

What is an EMT? EMTs are the backbone of the EMS system in the United States. You provide emergency care to the sick and injured. Some of the patients you will treat are in life-threatening situations, whereas others require only supportive care.

The skills you need to safely deliver this care are found within this textbook. Some of the subjects discussed include:

- **Scene size-up:** Scene size-up involves both awareness of scene safety *and* a big-picture awareness of the overall situation at hand. EMS operates in a wide variety of environments that can create situations where EMS personnel can be injured—outside on a highway, inside a cluttered house, or anywhere in between. Your primary job is to ensure it is as safe as possible. During scene size-up you must gain a big-picture perspective of the call, determine whether it is safe to proceed, determine whether additional resources are needed, and identify the initial approach to mitigate the emergency.
- **Patient assessment:** Patient assessment is the foundation of any EMS call. You must determine what is wrong with the patient. Patients can have many complaints and you will learn to determine which complaints are life threatening.

Words of Wisdom

The Star of Life

The National Highway Transportation Safety Administration (NHTSA) recognized the need for a symbol that would represent EMS as a critical public service and created the *Star of Life*. NHTSA holds priority rights to the use of this registered certification mark.

Adapted from the personal Medical Identification Symbol of the American Medical Association, each bar on the Star of Life represents an EMS function. The functions include:

1. Detection
2. Reporting
3. Response
4. On-scene care
5. Care in transit
6. Transfer to definitive care

The serpent and staff in the symbol portray the staff of Asclepius, an ancient Greek physician deified as the god of medicine. Overall, the staff represents medicine and healing, with the skin-shedding serpent being indicative of renewal.

The Star of Life has become synonymous with emergency medical care around the globe. This symbol can be seen as a means of identification on ambulances, emergency medical equipment, patches or apparel worn by EMS providers, and materials such as books, pamphlets, manuals, reports, and publications that either have a direct application to EMS or were generated by an EMS organization. It also appears on road maps and highway signs indicating the location of or access to qualified emergency medical care.

Source: Adapted from US National Highway Traffic Safety Administration. www.ems.gov.

- **Treatment:** As an EMT, you will provide oxygenation and medication therapies. You will control bleeding and assist patients during childbirth. In addition to hands-on skills, you will learn how to manage patients who are in emotional crisis, and to calm patients and to relieve some of their anxiety.
- **Packaging:** Most patients need to be transported to a facility. This could mean a hospital, clinic, or other medical care facility. You will learn how to transport patients with a wide variety of illnesses and injuries.
- **EMS as a career:** Many of you are taking this course because you want to help people. To ensure all EMS providers have a long, healthy career, it is important for you to learn how to take care of yourself. We will discuss job stressors and successful ways to cope with them.

Licensure Requirements

To be recognized and function as an EMT, you must meet certain requirements. The specific requirements differ from state to state. Ask your instructor, learning institute, or your state EMS official about the requirements in your state. Generally, the criteria to be licensed and employed as an EMT will include the following:

- High school diploma or equivalent
- Proof of immunization against certain communicable diseases
- Successful completion of a background check and drug screening
- Valid driver's license
- Successful completion of a recognized health care provider basic life support (BLS)/ cardiopulmonary resuscitation (CPR) course
- Successful completion of a state-approved EMT course
- Successful completion of a state-recognized written certification examination
- Successful completion of a state-recognized practical certification examination
- Demonstrate the mental and physical ability necessary to safely and properly perform all the tasks and functions described in the defined role of an EMT
- Compliance with other state, local, and employer provisions

The **Americans With Disabilities Act (ADA)** of 1990 protects people who have a disability from being denied access to programs and services that are provided by state or local governments and prohibits employers from failing to provide full and equal employment to the disabled. In addition, Title I of the ADA protects EMTs with disabilities seeking gainful employment under many circumstances. Employers with a certain number of employees are required to adjust processes so that a candidate with a disability can be considered for the position, and when possible, modify the work environment or how the job is normally performed. This allows EMTs who can perform the functional job skills the opportunity to pursue a career in EMS.

YOU are the Provider — PART 2

You arrive at the scene, ensure it is safe to enter, and make contact with the patient, a 59-year-old woman. She is sitting on her couch, is in obvious pain, and states it has been ongoing for the past month. You assess the patient as your partner prepares to take her vital signs.

Recording Time: 0 Minutes	
Appearance	Grimacing; obvious pain
Level of consciousness	Conscious and alert
Airway	Open; clear of secretions or foreign bodies
Breathing	Adequate rate and depth
Circulation	Radial pulse, normal rate and rhythm; skin is pink, warm, and dry

3. How do you know if this patient is experiencing a "true emergency?"

One of the primary responsibilities of each state is to ensure the safety of its residents. As such, states have requirements prohibiting people with certain legal infractions from becoming EMS providers. The specific legal exclusions, either misdemeanors and/or felonies, are created on a state-by-state basis. Contact your state EMS office for more information.

Special Populations

EMS systems must be capable of handling many different situations, including obstetric, pediatric, and geriatric emergencies. Proper procedures, drug dosages, and even assessment techniques are often different in children, adults, and older people.

Overview of the EMS System

History of EMS

As an EMT, you will join a long tradition of people who provide emergency medical care to their fellow human beings. With the early use of motor vehicles in warfare, volunteer ambulances were organized and personnel went overseas to provide care for the wounded in World War I. During World War II, the military trained special corpsmen to provide care in the field and bring the casualties to aid stations staffed by nurses and physicians. In the Korean conflict, this evolved into the field medic and rapid helicopter evacuation to nearby Mobile Army Surgical Hospital units, where immediate surgical interventions could be performed. Many advances in the immediate care of trauma patients resulted from the casualty experiences in the Korean and Vietnam conflicts.

Unfortunately, emergency care of the injured and ill at home had not progressed to a similar level. As recently as the 1960s and early 1970s, emergency ambulance service and care varied widely across the United States. In some places, it was provided by well-trained advanced first aid personnel who had well-equipped, modern ambulances. In a few urban areas, it was provided by hospital-based ambulance services that were staffed with interns and early forms of prehospital care providers. In many areas, the only emergency care and ambulance service was provided by the local funeral home using a hearse that could be converted to carry a cot and serve as an ambulance. In other places, the police or fire department used a station wagon that carried a cot and a first aid kit. In most cases, these vehicles were staffed with a driver and an attendant who had some basic first aid training. In the few areas where a commercial ambulance was available to transport the ill, it was usually similarly staffed and served primarily as a means to transport the patient to the hospital.

Many communities did not have formal provisions for prehospital emergency care or transportation. Injured people were given basic first aid by police or fire personnel at the scene and were transported to the hospital in a police or fire officer's car. Customarily, patients with an acute illness were transported to the hospital by a relative or neighbor and were met by their family physician or an on-call hospital physician, who assessed them and then summoned any specialists and operating room staff that were needed. Except in large urban centers, most hospitals did not have the emergency department (ED) staff available today.

EMS as we know it today had its origins in 1966 with the publication of *Accidental Death and Disability: The Neglected Disease of Modern Society*, known more commonly as The White Paper. This report, prepared jointly by the Committees on Trauma and Shock of the National Academy of Sciences/National Research Council, revealed to the public and Congress the serious inadequacy of prehospital emergency care and transportation in many areas. As a result, Congress mandated that two federal agencies address these issues. The NHTSA of the DOT, through the Highway Safety Act of 1966, and the Department of Health, Education, and Welfare (now known as the Department of Health and Human Services), through the Emergency Medical Services Development Act of 1973, created funding sources and programs to develop improved systems of prehospital emergency care. This explains why EMS is administrated at the federal level through the DOT and not the Department of Health.

In the early 1970s, the DOT developed and published the first curriculum to serve as the guideline for EMT training. To support the EMT course, the American Academy of Orthopaedic Surgeons prepared and published the first EMT textbook—*Emergency Care and Transportation of the Sick and Injured*—in 1971, often called the Orange Book for its original trademark orange cover. Through the 1970s, following the recommended guidelines, each state developed the necessary legislation, and the EMS system expanded throughout the United States. During the same period, emergency medicine became a recognized medical specialty, and the fully staffed EDs that we know today became the accepted standard of care.

In the late 1970s, the DOT developed a recommended National Standard Curriculum for the training of paramedics and identified a part of the course to serve as training for EMTs.

During the 1980s, many areas enhanced the EMT National Standard Curriculum by adding EMTs with advanced levels of training who could provide key components of ALS care and advanced lifesaving procedures. The availability of paramedics and ALS-level care on calls that require or benefit from advanced care has grown steadily in recent years. In addition, with the evolution in training and technology, the EMT and AEMT can now perform a number of important advanced skills in the field that were formerly reserved for only the paramedic.

This growth and sophistication of the EMS system did not come without its drawbacks. As each state sought to create a system that would meet the needs of its citizens, the definitions of EMS providers began to vary from state to state. For example, in some states EMTs were allowed to administer medications, while in other states they were not.

In the 1990s NHTSA began an examination of EMS from a national perspective. With the counsel of EMS providers, physicians, fire chiefs, nurses, state administrators, educators, and other interested professionals, NHTSA created the *EMS Agenda for the Future*. This important document created a plan to standardize the levels of EMS education and EMS providers in an effort to ensure a more seamless delivery of EMS care across the country.

The skills you learn and the scope of practice EMTs now enjoy are part of this national movement toward an EMS system that meets the needs of an ever-changing health care industry and meets those needs through a safe and efficient method.

Levels of Training

As discussed earlier, licensure of EMTs is a state function subject to the laws and regulations of the state in which the EMT practices. Each state is granted the ability to control the functions of its licensed providers. For this reason there remains some variation from state to state on the scope of EMT practice, as well as training and recertification requirements. Here is how the system is supposed to work from the federal level down to the local level.

At the federal level, NHTSA brings in experts from around the country to create the **National EMS Scope of Practice Model**. This document provides overarching guidelines for the minimum skills each level of EMS provider should be able to accomplish. **Table 1-2** shows the guidelines from that model. Some items in the table are flagged and corresponding notes are provided to show areas where current practice has evolved. For example, certain skills listed in the table are no longer practiced or have been aligned with a different skill level. Because licensure is a state function, at the state level laws are enacted to regulate how EMS providers will operate and are then executed by the state level EMS administrative offices that control licensure. Finally, the local medical director provides daily oversight and support to EMS personnel **Figure 1-3**. For example, the medications that will be carried on an ambulance or where patients are transported are the day-to-day operational concerns on which the medical director will have direct input.

The national guidelines are intended to ensure consistent delivery of EMS across the country. The only way a medical director can allow an EMT to perform a skill is if the state has already approved that skill. The medical director can limit scope of practice but cannot expand it beyond state law. Expanding the scope of practice requires state approval.

You can download the EMR, EMT, AEMT, and paramedic education standards and instructional guidelines at www.ems.gov. In addition, the National Registry of Emergency Medical Technicians (NREMT) is a nongovernmental agency that provides national standardized EMS testing and certification in much of the United States. Many states use the National Registry standards to certify their EMTs and grant licensing reciprocity to NREMT-certified EMTs. It is important to remember EMS is regulated entirely by the state in which you are licensed.

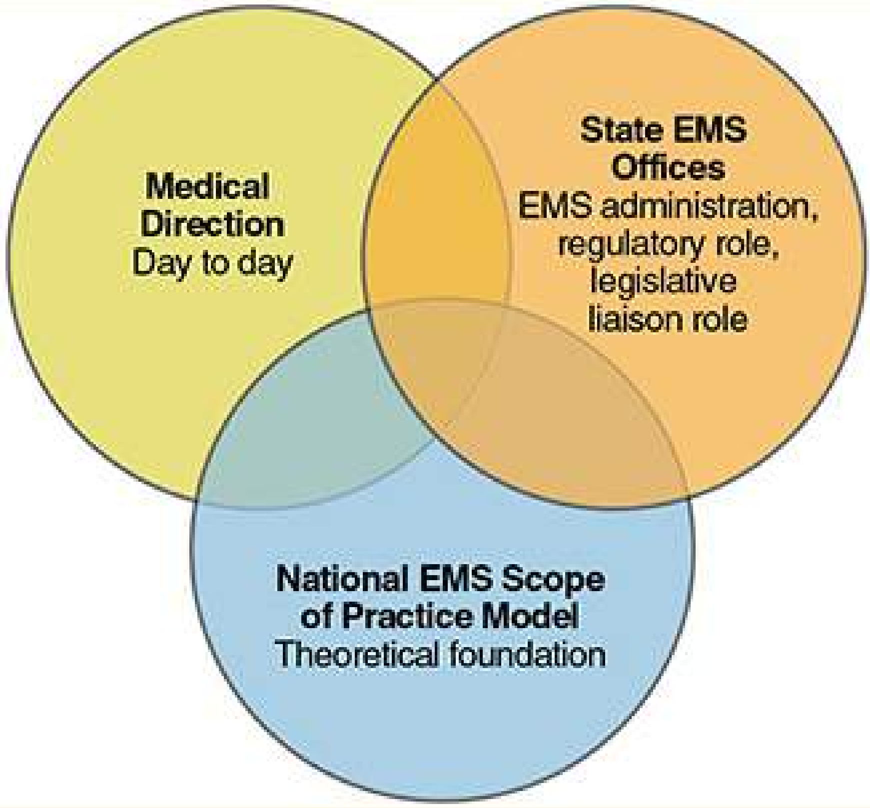

Figure 1-3 Hierarchies of the National EMS Scope of Practice Model.

Table 1-2 The Interpretive Guidelines: National EMS Scope of Practice Model

Note:
An EMT also provides the skills listed in the EMR level.
An AEMT also provides the skills listed in the EMR and EMT levels.
A paramedic also provides the skills listed in the EMR, EMT, and AEMT levels.

Airway and Breathing Minimum Psychomotor Skill Set			
EMR	**EMT**	**AEMT**	**Paramedic**
Oral airway	Humidifiers	Supraglottic airway	BiPAP/CPAP
Bag mask device	Partial rebreathing mask		Needle chest decompression
Sellick maneuver[a]	Venturi mask		Chest tube monitoring
Head tilt–chin lift	Manually triggered ventilators		Percutaneous cricothyrotomy
Jaw-thrust	Automatic transport ventilators		$ETCO_2$/capnography
Modified chin lift	Oral and nasal airways		NG/OG tube
Obstruction, manual			Nasal and oral endotracheal intubation
Oxygen therapy			Airway obstruction removal by direct laryngoscopy
Nasal cannula			Positive end-expiratory pressure
Nonrebreathing mask			
Upper airway suctioning			
Assessment Minimum Psychomotor Skill Set			
Manual BP	Pulse oximetry	Blood glucose monitoring[b]	ECG interpretation
	Manual and auto BP		Interpretive 12-lead
			Blood chemistry analysis
Pharmacologic Intervention Minimum Psychomotor Skill Set			
Medication Administration Routes ▪ Unit dose auto-injector for self or peer care (MARK 1)[c]	*Assisted Medications* ▪ Assisting a patient in administering his/her own prescribed medications, including auto-injector	▪ Peripheral IV insertion ▪ IV fluid infusion ▪ Pediatric IO insertion	▪ Central line monitoring ▪ IO insertion ▪ Venous blood sampling

Pharmacologic Intervention Minimum Psychomotor Skill Set

	Medication Administration Routes ▪ Buccal ▪ Oral	*Medication Administration Routes* ▪ Aerosolized ▪ SC ▪ IM ▪ Nebulized ▪ SL ▪ Intranasal (IN) ▪ IV push for D_{50} and narcotic antagonist only	*Medication Administration Routes* ▪ Endotracheal ▪ IV (push and infusion) ▪ Nasogastric (NG) ▪ Rectal ▪ IO ▪ Topical ▪ Accessing implanted central IV port
	Medications To Be Administered ▪ Physician-approved over-the-counter medications (oral glucose, aspirin for chest pain or suspected ischemic origin)	*Medications To Be Administered* ▪ SL nitroglycerin for chest pain of suspected ischemic origin ▪ SC[d] and IM epinephrine for anaphylaxis	*Medications To Be Administered* ▪ Physician-approved medications ▪ Maintenance of blood administration

Pharmacologic Intervention Minimum Psychomotor Skill Set

EMR	EMT	AEMT	Paramedic
		▪ Glucagon and IV D_{50} for hypoglycemia ▪ Inhaled beta-agonist for dyspnea and wheezing ▪ Narcotic antagonist ▪ Nitrous oxide for pain relief	▪ Initiation of thrombolytics

Emergency Trauma Care Minimum Psychomotor Skill Set

Manual cervical stabilization	Spinal immobilization		Morgan lens
Manual extremity stabilization	Seated spinal immobilization		
Eye irrigation	Long board		
Direct pressure	Extremity splinting		
Hemorrhage control	Traction splinting		
Emergency moves for endangered patients	Mechanical patient restraint		
	Tourniquet[e]		

Emergency Trauma Care Minimum Psychomotor Skill Set		
	MAST/PASG*	
	Cervical collar	
	Rapid extrication	
Medical/Cardiac Care Minimum Psychomotor Skill Set		
CPR	Mechanical CPR	Cardioversion
AED	Assisted complicated delivery of an infant	Carotid massage
Assisted normal delivery of an infant		Manual defibrillation
		TC pacing

Abbreviations: AED, automated external defibrillator; BiPAP/CPAP, bilevel positive airway pressure/continuous positive airway pressure; BP, blood pressure; CPR, cardiopulmonary resuscitation; D_{50}, 50% dextrose in water; ECG, electrocardiogram; IM, intramuscular; IO, intraosseous; IV, intravenous; MAST/PASG, military antishock trousers/pneumatic antishock garments; NG, nasogastric; OG, orogastric; SL, sublingual; SC, subcutaneous; TC, transcutaneous.

Note: The 2005 National EMS Scope of Practice Model serves as a foundation for states to build their own model. It is intended to illustrate the operation of each level of EMS provider and the progression from one level to another. It is not inclusive of every skill a state may allow.

[a] The Sellick maneuver is no longer routinely recommended.
[b] Blood glucose monitoring is now considered an EMT-level skill.
[c] Mark I has been replaced by the DuoDote and the Antidote Treatment Nerve Agent Auto-Injector (ATNAA).
[d] Subcutaneous epinephrine administration is typically considered a paramedic-level skill now.
[e] Tourniquet use has evolved to be practiced by all providers including the EMR level.

Public Basic Life Support and Immediate Aid

With the development of EMS and increased awareness of the need for immediate emergency care, millions of laypeople have been trained in BLS/CPR. In addition to CPR, many people take first aid courses that include bleeding control and other simple skills that may be required to provide immediate essential care. These courses are designed to train people so those in the workplace—teachers, coaches, child care providers, and others—can provide the necessary critical care in the minutes before EMTs or other responders arrive at the scene.

In addition, many people, such as those who regularly accompany groups on camping trips or are in other situations where the arrival of EMS may be delayed because of remote location, are trained in advanced first aid. This course includes BLS and the essential additional care and packaging that may be necessary until the help of rescuers and EMTs can be obtained at a remote location.

One of the most dramatic recent developments in prehospital emergency care is the use of an **automated external defibrillator (AED)**. These remarkable devices, some no larger than a cell phone, detect treatable life-threatening cardiac dysrhythmias (ventricular fibrillation and ventricular tachycardia) and deliver the appropriate electrical shock to the patient. Designed to be used by the untrained layperson, these devices are now included at every level of prehospital emergency training.

Emergency Medical Responders

Because the presence of a person who is trained to initiate BLS and other urgent care cannot be ensured, the EMS system includes immediate care by EMRs, such as law enforcement officers, firefighters, park rangers, ski patrollers, or other organized rescuers who often arrive at the scene before the ambulance and EMTs **Figure 1-4**. EMR training provides these people with the skills necessary to initiate immediate care and assist the EMTs on their arrival. The course focuses on providing immediate BLS and urgent care with limited equipment. It also familiarizes students with the additional procedures, equipment, and packaging techniques that EMTs may use and the EMR may be called on to assist.

In addition to professional EMRs, EMTs often encounter a variety of people on the scene eager to help. You will encounter Good Samaritans trained in first aid and CPR, physicians and nurses, and other well-meaning people with or without prior training and experience. Identified and used properly, these people can provide valuable assistance when you are shorthanded. At other times, they can interfere with operations and even create problems or danger for themselves or others. It will be your task in your initial scene size-up to identify the various people on the scene and orchestrate well-meaning attempts to assist.

Emergency Medical Technician

The EMT course requires approximately 150 hours (more in some states) and provides the essential knowledge and skills required to provide basic emergency care in the field. The course serves as the foundation on which additional knowledge and skills are built in AEMT training. On arrival at the scene, you and any other EMTs who have responded should assume responsibility for the assessment and care of the patient and follow the proper packaging and transport of the patient to the ED if appropriate.

Figure 1-4 Emergency medical responders, such as law enforcement officers, are trained to provide immediate basic life support until EMTs arrive on the scene.

Advanced Emergency Medical Technician

The AEMT course and training are designed to add knowledge and skills in specific aspects of ALS to providers who have been trained and have experience in providing emergency care as EMTs. These additional skills include IV therapy, use of advanced airway adjuncts, and the knowledge and skills necessary to administer a limited number of medications. The AEMT course ranges between 200 and 400 hours. The purpose of this level of EMS provider is to deliver an expanded range of skills beyond the EMT. In some parts of the United States, the availability of paramedics is limited. AEMTs help to fill the gap by providing limited ALS care to regions where paramedics are not available.

Paramedic

The paramedic completes an extensive course of training that significantly increases knowledge and mastery of basic skills and covers a wide range of ALS skills **Figure 1-5**. This course ranges from 1,000 to more than 1,300 hours, divided between classroom and internship training. Increasingly, this training is offered within the context of an associate's degree or bachelor's degree college program.

Figure 1-5 Paramedic training covers a wide range of ALS skills.

Words of Wisdom

There are many directions you can take your EMS career. Specialty certifications include technical rescue, tactical EMS, critical care transport, disaster management, and much more. Other career paths include serving as an instructor or administrator. Advancement into positions such as EMS directors, administrators, and educators frequently requires formal education or degrees related to EMS.

Components of the EMS System

The *EMS Agenda for the Future* is a multidisciplinary, national review of all aspects of EMS delivery. The goal is to develop a more cohesive and consistent system across the country. In the document, there are 14 components of an EMS system as outlined in **Table 1-3**. NHTSA has taken these components and organized them in such a way to understand some of the interrelationships between the components.

Figure 1-6 demonstrates how the components interact. The tabs on the right side show the primary 9-1-1 components of EMS. Someone recognizes an emergency, 9-1-1 is activated, an ambulance is dispatched, and emergency care and transportation are administered. In the center are the essential aspects needed to allow the primary 9-1-1 components to function—finances, radios, computers, and people. The left side demonstrates the continuum of care from the prehospital environment to the ED and beyond. Finally, as patients leave the health care system, there are strategies of prevention and education to help ensure people live long and healthy lives. Understanding the 14 components will help you better understand how the EMS system works.

Table 1-3 ***EMS Agenda for the Future Components of an EMS System***

EMS System	
1. Public Access	8. Communication Systems
2. Clinical Care	9. Human Resources
3. Medical Direction	10. Legislation and Regulation
4. Integration of Health Services	11. Evaluation
5. Information Systems	12. System Finance
6. Prevention	13. Public Education
7. EMS Research	14. Education Systems

YOU are the Provider — PART 3

Your partner records the patient's vital signs on the patient care report as you ask the patient additional questions regarding her back pain. She tells you her lower back began hurting about a month ago; however, she has never been evaluated by a physician. She denies injuring her back. She further denies any other symptoms or past medical history.

Recording Time: 4 Minutes	
Respirations	16 breaths/min; regular and unlabored
Pulse	88 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	126/66 mm Hg
Oxygen saturation (Spo_2)	99% (on room air)

Your assessment of the patient's back does not reveal any obvious deformities, swelling, or bruising, and her vital signs are stable. The patient requests you take her to the hospital.

4. The patient has requested you transport her to the hospital, but does not appear to be experiencing any life-threatening conditions. Should you transport her to the hospital?

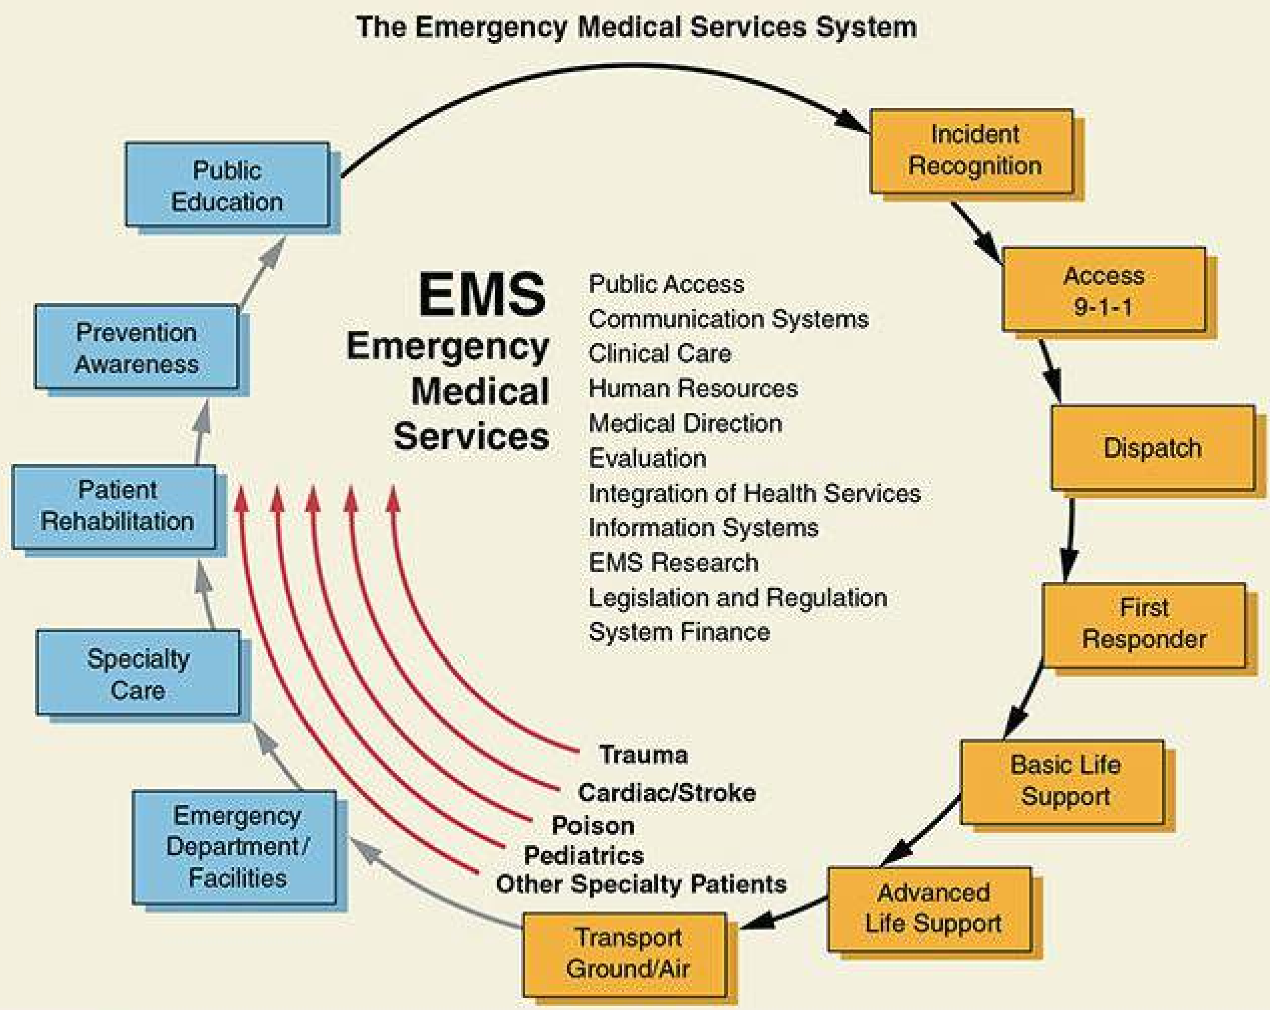

Figure 1-6 Interaction of the components of the National Highway Traffic Safety Administration's emergency medical services system.

Public Access

Easy access to help in an emergency is essential. In most of the country, an emergency communication center that dispatches fire, police, rescue, and EMS units can be reached by dialing 9-1-1. At the communication center, trained dispatchers obtain the necessary information from the caller and, following dispatch protocols, dispatch the ambulance crew and other equipment and responders that may be needed **Figure 1-7**. This communication center is called a **public safety access point**.

In an enhanced 9-1-1 system, the address of the caller is displayed on a screen. The address remains on the screen until the dispatcher removes it. Therefore, if the caller is unable to speak or hangs up, the location remains displayed. However, not all cell phones have this capability. Most emergency communication centers are equipped with special equipment allowing people with speech or hearing disabilities to communicate with the dispatcher via a keyboard and printed messages. In some areas, rather than 9-1-1, a different special published emergency number may be used to call for EMS. Social media may play an evolving role in allowing lay people trained in CPR to be alerted of a cardiac arrest in their area. Training the public how to summon an EMS unit is an important part of the public education responsibility of each EMS service. Enhanced 9-1-1 systems are now available that can identify not only the cell phone number from which an emergency call is being placed, but also the exact geographic coordinates of the cell phone at the time the call is made. Such systems use global positioning system (GPS) technology. Because cell phones capable of transmitting a GPS signal and a system capable of receiving that signal are both required, the technology requires additional time and resources to implement.

Figure 1-7 Trained dispatchers obtain information about the call and then send responders to the scene as needed.

A system called **emergency medical dispatch (EMD)** was developed to assist dispatchers in providing callers with vital instructions to help them deal with a medical emergency until EMS crews arrive. Dispatchers are trained and provided scripts to help them relay relevant instructions to the callers. The system helps dispatchers select appropriately resourced units to respond to a request for assistance. It is the dispatcher's duty to relay all relevant and available information to the responding crews in a timely manner. Keep in mind current technology does not allow the dispatcher to "see" what is actually going on at the scene; however, it is not uncommon for you to find the reality of the call quite different from the dispatch information.

Communication Systems

Using the information provided by the caller, the dispatcher will select the appropriate parts of the emergency system that need to be activated. Over half of EMS support is provided by a governmental entity such as a fire agency (about 45%) or other non-fire governmental agency (20%). Private services deliver about one-fourth of EMS support. Other models seen less frequently include hospital-based programs and Native American tribal services.

New technologies are constantly being developed to assist responders in locating their patients. As previously described, cell phones can be linked to GPS units to display their location. Responding units can transmit their position to a dispatcher who can transmit the location of a call to a moving digital map in the unit, complete with turn-by-turn directions. Medical databases can be queried and patient information can be directly downloaded to the EMT's computer or uploaded from the EMT's laptop to the database. Familiarize yourself with mobile phone dispatch systems in your jurisdiction so you are aware of who will potentially be on-scene when you arrive to a cardiac arrest. Constant training and education are required to keep the EMT's knowledge of technological developments up-to date.

Safety Tips

As an EMT, you are responsible for checking the ambulance and making sure equipment is completely functional. If equipment is not functioning properly, you should notify a supervisor immediately and either take the ambulance out of service or replace the nonfunctioning piece of equipment. Remember, safety first.

Clinical Care

Clinical care describes the various pieces of equipment and scope of practice for using that equipment. As an EMT, you will use a wide range of different emergency equipment. During the EMT course, you will be introduced to, and learn how to use, a variety of appliances and devices that you may need on a call. You will learn when the use of each is indicated and when it is of no benefit or may cause harm. Although the use of different models and brands of a given device will follow the same basic principles and methods, some variation and peculiarities may exist from one model to another. When you join a service, check each key piece of equipment before going on duty to ensure that it is in its assigned place, that it is working properly, and that you are familiar with the specific model carried on your ambulance.

Each EMT may be called on to drive the ambulance. Therefore, you must familiarize yourself with the roads in your **primary service area (PSA)** or sector. The PSA is the main area in which an EMS agency operates. Before going on duty, check all the equipment and supplies and communication equipment that the ambulance carries. It is your responsibility to ensure the ambulance is fully fueled, has sufficient oil and other key fluids, and that the tires are in good condition and properly inflated **Figure 1-8**. You should also test each of the driver's controls and each built-in unit and control in the patient compartment. If you have not driven the specific ambulance before, it is a good idea to take it out and become familiar with it before you respond to a call. Maintenance and safe driving of the ambulance are discussed in detail in Chapter 37, *Transport Operations*.

Figure 1-8 Making sure the ambulance is fueled is part of an EMT's responsibility.

Human Resources

The human resources component deals with people. Who delivers the care? How are these people compensated for their time and energy? How do other members of the medical community interact and participate within the EMS world? These are some of the questions discussed within the component of human resources.

EMS in this component is examined as a profession. The overarching concept is to encourage the creation of EMS systems that provide an environment where talented people want to work and can turn their passion into a rewarding career.

Several objectives need to be accomplished to help make a career in EMS a lasting one. Efforts are being made to ensure that EMS providers can move from one state to another more seamlessly. From a global point of view, one of the core functions of a state is to provide and protect its citizens. This obligation has led to the creation of EMS levels that are unique to a particular state. Though effective for any one state, these idiosyncratic EMS levels make movement from one state to another complicated. One of the functions of the National Scope of Practice Model is to create stable foundations on which each level of EMS provider is grounded. The net effect is to encourage a more consistent definition of "what is an EMT" so providers can move more freely about the country.

The *EMS Agenda for the Future* encourages the creation of systems that help to protect the well-being of EMS providers. It also encourages systems to develop career ladders, allowing talented EMS providers ways to use their talent for many years.

Medical Direction

Each EMS system has a physician **medical director** who authorizes the EMTs in the service to provide medical care in the field. The appropriate care for each injury, condition, or illness that you will encounter in the field is determined by the medical director and is described in a set of written standing orders and protocols. Protocols are described in a comprehensive guide delineating the EMT's scope of practice. Standing orders are part of protocols and designate what the EMT is required to do for a specific complaint or condition. Providers are not required to consult medical direction before implementing standing orders.

The medical director is the ongoing working liaison between the medical community, hospitals, and the EMTs in the service. If treatment problems arise or different procedures should be considered, they are referred to the medical director for his or her decision and action. To ensure the proper training standards are met, the medical director determines and approves the continuing education and training that are required of each EMT in the service.

Medical control is provided either off-line (indirect) or online (direct), as authorized by the medical director. Online medical control consists of direction given over the phone or radio directly from the medical director or designated physician. The medical direction can be transferred by the physician's designee; it does not have to be transferred by the physician himself or herself. Off-line medical control consists of standing orders, training, and supervision authorized by the medical director. Each EMT must know and follow the protocols developed by his or her medical director.

The service's protocols will identify an EMS physician, usually at a local hospital, who can be reached by radio or telephone for medical control during a call. This is a type of direct online medical control. On some calls, once the ambulance crew has initiated any immediate urgent care and gives their radio report, the online medical control physician may either confirm or modify the proposed treatment plan or may prescribe any additional special orders that the EMTs are to follow for that patient. The point at which the EMTs should give their radio report or obtain online medical direction will vary.

Legislation and Regulation

Although each EMS system, medical director, and training program has latitude, their training, protocols, and practices must conform to the EMS legislation, rules, regulations, and guidelines adopted by each state. The state EMS office is responsible for authorizing, auditing, and regulating all emergency medical services, training institutions, courses, instructors, and providers within the state. In most states, the state EMS office obtains input from an advisory committee made up of representatives of the services, service medical directors, medical associations, hospitals, training programs, instructors' associations, EMT associations, and the public in that state.

At the local level, each EMS system operates in a designated PSA in which it is responsible for the provision of prehospital emergency care and the transportation of the sick and injured to the hospital.

EMS is usually administered by a senior EMS official. Daily operations and overall direction of the service are provided by an appointed chief executive officer and several other officers who serve under him or her. When EMS is a part of a fire or police department, the department chief will usually delegate the responsibility for directing EMS to an assistant chief or other officer whose sole responsibility is to manage the EMS activities of the department. To provide clear guidelines, most services have written operating procedures and policies. When you join a service, you are expected to learn and follow them.

The chief executive of the service is in charge of both the necessary administrative tasks (eg, scheduling, personnel, budgets, purchasing, vehicle maintenance) and the daily operations of the ambulances and crews. Except for medical matters, he or she operates as the chief (similar to a fire chief or police chief) of EMS for the service and the PSA that it covers.

Integration of Health Services

EMS does not work in a vacuum. EMS personnel travel to people's homes and to vehicle crashes. Once on scene, they deliver care and transport the patient to a care facility. Integration of health services means that the prehospital care you administer is coordinated with the care administered at the hospital. When you deliver a patient to the ED you are simply transferring that patient to another care provider. The excellent care that you began should be continued in the ED. This component helps to decrease errors, to increase efficiencies, and, most of all, to ensure the patient receives comprehensive continuity of care.

Words of Wisdom

A patient may experience only once what you may experience hundreds of times. Understand and be empathetic to the patient's anxiety.

Although it may not appear like an emergency to you, it is considered an emergency by your patient and his or her family members. Treat them with respect. Your patients and their family members will always remember how you acted when you were with them.

Some EMS systems have collaborated with local hospitals to improve patient outcomes associated with time sensitive treatment like heart attacks, trauma, and stroke. This is accomplished through special training in the EMS system and certain hospital departments. For example, when paramedics determine a patient is having a heart attack, they alert the ED. In turn, the personnel in the ED notify the cardiac catheterization team, or you may be directed to transport the patient to a cardiac specialty center. As a result, the key personnel are ready to begin critical treatments as soon as the patient arrives at the hospital. Similar activities take place for stroke and trauma patients.

Mobile Integrated Healthcare

Mobile integrated healthcare (MIH) is a new method of delivering health care that utilizes the prehospital spectrum. It has evolved as a result of the Patient Protection and Affordable Care Act, with the goal to facilitate improved access to health care at an affordable price. In the MIH model, health care is provided within the community, rather than at a physician's office or hospital. An integrated team of health care professionals, including EMS providers, delivers health care services in the community, and connects patients with other valuable resources such as social services. An advantage of this model is that it offers access for care to patients within communities with limited medical resources, and leads to better service for those who are home-bound or disabled.

This new branch of health care is causing the evolution of additional training levels for EMS providers. One new aspect is **community paramedicine**, in which experienced paramedics receive advanced training to equip them to provide services within a community. In addition to the patient care services a paramedic would typically provide, services provided by community paramedics may include performing health evaluations, monitoring chronic illnesses or conditions, obtaining laboratory samples, administering immunizations, and serving as a patient advocate.

Evaluation

The medical director is responsible for maintaining **quality control**, ensuring that all staff members who are involved in caring for patients meet appropriate medical care standards on each call. To provide the necessary quality control, the medical director and other involved staff review patient care reports (PCR), audit administrative records, and survey patients.

Continuous quality improvement (CQI) is a circular system of continuous internal and external reviews and audits of all aspects of an EMS system. To provide CQI, periodic run review meetings are held with those involved in patient care to review the run reports and then discuss any areas of care that appear to need change or improvement. Positive feedback is also discussed. If a problem appears to be repeated by a single EMT or crew, the medical director will discuss the details with those involved. The CQI process is designed to identify areas of improvement and, if necessary, assign remedial training or develop some other educational activity. The medical director is also responsible for ensuring that appropriate continuing education and training are available.

Information and skills in emergency medical care change constantly. You need refresher training or continuing education as new modalities of care, equipment, and understanding of critical illnesses and trauma develop. Equally, when you have not used a particular procedure for some time, skill decay may occur. Therefore, your medical director may establish a training program to correct the deficit. For example, an ED physician noted that despite their assessments, many EMTs were missing a high number of closed long bone fractures, resulting in poor prehospital care. A subsequent audit of calls led to a review and retraining session for assessment and care of fractures. This same process can apply to CPR or any other type of skill you do not use often. Ensuring your skills and knowledge are current is one of the ongoing commitments of being an EMT.

YOU are the Provider — PART 4

The patient is placed onto the stretcher, placed in a position of comfort, and loaded into the ambulance. You and the paramedic are in the back with the patient as your EMT partner drives to the hospital. En route, the paramedic starts an intravenous (IV) line and administers pain medication to the patient. Shortly after the medication has been administered, you reassess the patient.

Recording Time: 12 Minutes	
Level of consciousness	Conscious and alert
Respirations	16 breaths/min; regular and unlabored
Pulse	90 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	120/62 mm Hg
Spo_2	97% (on room air)

Within a few minutes, the patient tells you her back pain has subsided. She asks you if you think her back pain could be a sign of a serious problem.

5. Is the paramedic required to contact medical control prior to administering any medications?
6. How should you answer the patient's question regarding her concern that she may have a serious condition?

Another function of the evaluation process is to determine ways to limit or eliminate human error. During the delivery of EMS, as with any occupation, there are times when errors can happen. Driving to the scene can be hazardous. As you are lifting and moving a patient, the patient can be dropped. Communicating with other EMTs or transferring the patient to the ED presents circumstances where errors can happen. Remember, errors can occur at any point during the call that can result in harm to the patient, public, and you.

Errors are not inevitable, though. If the circumstances of the errors are understood, it may be possible to eliminate or at least minimize them. There are many ways to examine medical errors. This textbook focuses on errors from three possible sources. They can occur as a result of a rules-based failure, a knowledge-based failure, or a skills-based failure (or any combination of these). For example, does the EMT have the legal right to administer the particular medication the patient needs? Has the medical director given permission to administer the drug? If not, a rules-based failure has occurred if the EMT assists with the administration. Does the EMT know all of the pertinent information about the medication being delivered? If not, a breakdown at this point, such as the administration of the wrong medication, would be referred to as a knowledge-based failure. Finally, is the equipment operating and being used properly? If not, a skills-based error has occurred. Any error can come from multiple sources.

Limiting errors requires the efforts of both the EMS agency and EMS personnel. Agencies need to have clear protocols, which are detailed plans that describe how certain patient issues, such as chest pain or shortness of breath, are to be managed. These protocols need to be understood by all EMTs within the service.

The environment can also contribute to errors. Are there ways to limit distractions? How do we improve lighting so EMTs can see well? How organized is the equipment? Can the EMT find what he or she needs in a timely manner? Environmental considerations can be managed using many approaches. Sometimes the solution is as easy as ensuring flashlights are available on all ambulances. Consider having police assistance on certain types of EMS calls or getting the assistance of an EMS supervisor. Perhaps a new type of equipment bag will provide better organization. Typically, when trying to reduce environmental factors regarding errors, this means having the right people with the right equipment in place.

EMTs can also help to reduce errors. Your job is to protect the patient from harm and to deliver high-quality medical care. This is one of your most important responsibilities. You are a patient care advocate—you speak for patients on their behalf. Keeping this responsibility in mind will help you to limit errors.

There are other ways errors can be reduced. When you are about to perform a skill, ask yourself, "Why am I doing this?" Knowing the reason for your actions gives you time to reflect and make a more informed decision. Even within EMS, rarely do you have to act so quickly that you do not have a moment to consider what it is you are doing and why. If you have considered what to do and cannot come up with a solution, ask for help. Talk with your partner, contact medical control, or call your EMS supervisor.

Another way to help limit medical errors is to use “cheat sheets.” Keep a copy of your protocol book with you. Emergency physicians have many reference materials available to them. Physicians recognize they cannot memorize everything, so referencing a book or an Internet resource helps ensure the accuracy of their memory.

Finally, after a troublesome call, sit down and talk. Talk with your partner and/or your supervisor. Discussing the events that just happened provides an excellent avenue for learning. Your discussions can help lead to changes in protocol, how equipment is stocked, or even the purchase of new equipment.

Information Systems

EMS is not unlike any other profession in today’s world. Without computers, the job would be much more difficult. An information system allows EMS providers to efficiently document the care that has been delivered. Once that information is stored electronically, it can be used to improve care. For example, how many times has a department seen patients with chest pain? What is the average on-scene time for major trauma patients? How many AED runs has the department had? These questions and many more can be answered using the information gathered from computerized medical records.

This information is used for a variety of purposes. It is used to construct educational sessions for the department. Data from ambulance activity logs is used to justify hiring more personnel. Examining the types of patients and their frequency can provide the foundation for the purchase of new equipment and guide continuing education sessions. This information can also be combined with other database resources, such as from a hospital, to determine patient outcome. Departments from around the country are sending information to Washington, DC, so a national snapshot of EMS activities can be obtained. Information gathered by the National EMS Information System (NEMSIS) can be found at http://www.nemsis.org. This information will be used to better plan for the needs of EMS systems today and in the future.

System Finance

All EMS departments need a funding system that allows them to continue to provide care; however, the type of system needed depends on many variables. There are several types of EMS departments around the country. The *Journal of Emergency Medical Services* annually reports on how EMS is delivered in the 200 largest cities within the United States. See **Table 1-4** for the breakdown of types of EMS services within the United States for the year 2012.

These departments may have paid or volunteer personnel, or a mix of both. Financial resources are available for EMS departments through taxation, fee for service, paid subscription, donations, federal/ state/local grants, fund-raisers, or combinations of same. Which financial system is used depends on the needs and makeup of each EMS department.

How are EMTs involved with the financial side of EMS? You may think the financial activities belong to those who work in the office. However, you may be asked to gather insurance information from patients, secure signatures on certain documents such as HIPAA notifications, or obtain written permission from patients to bill their health insurance company. All of these steps are important to the health care process. When you do not provide needed information, the patient may be billed, rather than the insurance company.

EMTs are also involved in helping with fund-raisers, stuffing envelopes, or just making calls to potential subscribers to the service. Regardless of what type of system you work, you will help the department secure its financial resources.

Table 1-4 Types of EMS Services that Transport Patients in the 200 Largest Cities Within the United States

Type of Organization Providing EMS Transport Services	
Private organization	39.6%
Fire department	37.4%
Third service and hospital	23.0%

Data from: Ragone, MG. JEMS Surveys 200 Most Populous Cities. February 1, 2012. Accessed 11/4/14 at http://www.jems.com/article/administration-and-leadership/jems-surveys-200-most-populous-cities.

Education Systems

Your training will be conducted by many knowledgeable EMS educators. In most states, the instructors who are responsible for coordinating and teaching the EMT course and continuing education courses are approved and licensed by the state EMS office or agency. Most EMS training programs must adhere to national standards established by the accrediting organizations CoAEMSP (Committee on Accreditation of Educational Programs for the Emergency Medical Services Professions) and CAAHEP (Commission on Accreditation of Allied Health Education Programs). To be licensed in some states, an instructor must have extensive medical and educational training and teach for a designated period while being observed and supervised by an experienced instructor. ALS-level instructors and directors must hold a four-year degree.

Generally, ALS training is provided either in a college, adult career center, or hospital setting. In most states, educational programs that provide ALS training must be approved by the state and have their own medical director. In these courses, many of the lectures and small group sessions are presented by the medical director or other physicians, nurses, and EMS instructors. In clinical sessions in which supervised practice is obtained in the ED or other in-hospital settings, students are also supervised directly by physicians and nurses.

The quality of care you provide depends on your ability and the quality of your training. Therefore, your instructor and the many others who develop and participate in your training program are key members of the emergency care team.

When you no longer have the structured learning environment that is provided in your initial training course, you must assume responsibility for directing your own study and learning. As an EMT, you are required to attend a certain number of hours of continuing education approved for EMTs each year to maintain, update, and expand your knowledge and skills. In many services, the required hours are provided by the training officer and medical director. In addition, most EMS education programs and hospitals offer a number of regular continuing education opportunities in each region. You may also attend state and national EMS conferences to help keep you current about local, state, and national issues affecting EMS. Because there are many levels of licensing, you should ensure that the continuing education you receive is approved for the EMT. Whether you take advantage of these opportunities depends on you. You may decide to remain an EMT or you may want to achieve a higher level of training and certification, but whatever you choose, the key to being a good EMT and providing high-quality care is your commitment to continual learning and increasing your knowledge and skills.

EMTs possess special knowledge and skills that are directed to the care of patients in emergency situations. The authority that is delegated to you to care for patients is a very special one. Maintaining your knowledge and skills is a substantial responsibility. Knowledge and skills that are learned in any profession weaken when they are not used on a continual basis. Consider the steps involved in CPR, for example. If you have not used these skills since your original training, it is unlikely you will perform CPR proficiently. Frequent continuing education, refresher courses, and computer-based or manikin-based self-education exercises are measures you can take to maintain your skills and knowledge.

Prevention and Public Education

The next two components of the EMS system are often closely associated with each other. Prevention and public education are aspects of EMS where the focus is on public health. **Public health** examines the health needs of entire populations with the goal of preventing health problems. Although there are many definitions possible for public health, the prevention of health problems seems to provide a good overarching framework.

Health care in the United States is currently in a state of flux. The high-tech, on-demand style of care that is prevalent has two major drawbacks. One, it is very expensive. In the United States, more than 17.9% of the gross domestic product is accounted for by health care. Two, it may not deliver a better product. The US government reports people born in the United States have an average life expectancy of 79 years. There are 35 other countries where people are living longer. If we are spending such large sums on health care, shouldn't we be living longer?

What needs to be addressed is the concept of prevention. Is it more expensive to treat a patient with a heart attack or to work with communities to help prevent the heart attack from ever happening? Or consider the scenario of an EMS provider working with a community to help get new traffic lights installed, thereby decreasing the incidence of vehicle collisions and subsequent injuries. The concept of prevention applies to both the patient and the EMS provider. Eating right, exercising, and using other stress management techniques can help prevent medical emergencies. It may seem strange, but the goal of education should be to create an environment where the need for EMS is decreased.

The focus of the public health arm of health care is prevention. Public health works to prevent illness and injury, meaning being proactive. A good example of public health at work is the common product, salt. The next time you buy salt, look at the contents. In the United States, salt is sold with the additive iodine. It was discovered years ago that a condition known as goiter (abnormally large thyroid gland) is caused by a decrease in iodine levels within people's diets. The solution was to add this important element into a commonly used food source. Today, goiters are rare within the United States. Table 1-5 demonstrates other significant accomplishments of the public health system.

EMS is able to work with public health agencies on both primary and secondary prevention strategies. **Primary prevention** focuses on strategies that will prevent the event from ever happening. Polio was a devastating disease that caused death and disability for thousands of Americans in the early 1900s. A vaccine was developed to prevent the disease. In the span of one generation, the disease was virtually eliminated. Vaccinations are a good example of primary prevention within public health.

Table 1-5 Examples of Public Health Accomplishments

Vaccination programs	Clean drinking water
Fluoridation of water supplies	Seat belt laws
Helmet laws	Tobacco use laws
Sewage systems	Restaurant inspections
Formation of the Food and Drug Administration	Prenatal screenings

In 2009, the World Health Organization declared the swine flu (H1N1) virus to be at pandemic levels, which meant that the virus had spread throughout the world. The Centers for Disease Control and Prevention estimated that between 2009 and 2010 there were approximately 60.8 million cases and 12,469 deaths in the United States. If a major outbreak were to occur in the United States, EMTs may be called on to assist in the administration of vaccinations. Other examples of primary prevention include ensuring people know the dangers of drinking and driving and the harmful effects of using tobacco and other drugs. There are several ways EMTs can contribute to primary prevention efforts. You can become involved in programs that educate the community about pool safety and car seat installation or in home safety and fall prevention programs for senior adults. Other opportunities include teaching first aid and CPR to various groups within your area. Remember, small actions can lead to big differences!

In a **secondary prevention** strategy, the event has already happened. The question is how can we decrease the effects of the event? Helmets and seat belts do not prevent the accident from happening, yet they do prevent serious injuries from occurring due to the accident. The next time you drive down a major roadway, take note of the construction of the guardrails. There have been significant changes in guardrail construction over the years as more information has become available on what happens during a vehicle collision.

As an EMT, you may also be involved in the surveillance of illnesses and injuries. The PCRs that are generated by EMS personnel can be used to determine if a serious, widespread condition exists. For example, EMS is in a perfect position to provide statistical information to the local government about collisions. Injury surveillance data can be used to determine ways to improve a dangerous intersection, to prevent accidents from ever happening, or to limit the severity of injuries to drivers.

As discussed earlier, you can help educate the public. People may not understand why an accident has happened. A parent allows her 15-month-old child to play outside with other children unsupervised. The child falls and cuts her hand. EMS arrives and the cause of the injury is obvious. You can work with the parents professionally, respectfully, and kindly to help educate them on how to prevent this injury from occurring in the future.

The public may not understand the education that EMS providers have, and what services you can provide. You can go to local schools and teach children to call 9-1-1 when there is a medical emergency. You can work with local health care institutions to inform local residents when to call for an ambulance and when other transportation methods are more appropriate. Also, efforts to use social media to alert the public of a cardiac arrest are developing. You should consider advocating for social-media-directed or mobile phone dispatch systems that encourage lay people trained in CPR to respond to episodes of cardiac arrest that occur in close proximity to them.

Teaching people how to perform CPR, how to help a choking victim, or even how to assist in the delivery of a baby are all aspects of public education. Educating the public on the benefits of compression-only CPR is another example. One of the important effects of public education is an increase in public respect for EMS. When people understand what it means to work on an ambulance and provide care to the sick and injured, they are more likely to consider EMS a vital part of the public health care system. This change in attitude can be powerful and lead to increased EMS funding and greater respect for EMS as a profession.

EMS Research

Why do EMTs perform the skills they do? How many ambulances does a city need? Should we remain on the scene and stabilize the patient or should we rapidly transport the patient? These questions and thousands more like them help determine the shape and impact of EMS on the community. The answers to these questions are derived from research. Unfortunately, many of the tools and techniques that EMS providers use are borrowed from other health care settings without any research proving their effectiveness in EMS.

In the early days of EMS, it was believed major trauma patients needed to be stabilized on the scene before they were transported. Paramedics would start IV lines and use advanced airways. There was no foundation to support this behavior; it was assumed that this care needed to be done. After compiling significant amounts of prehospital EMS research, it was determined that major trauma patients needed to be transported to an operating room more than they needed IV fluids. Now EMS providers provide rapid transport of major trauma patients to trauma centers where they can get the surgical care they need. This is the power of EMS research.

Applying evidence-based practice is becoming an integral part of functioning as an EMS provider. Patient care should be focused on procedures that have proven useful in improving patient outcomes. There is a limited amount of prehospital EMS research relative to other areas of medical research; however, as EMS research continues, evidence-based practice will have a correspondingly greater role in EMS. All aspects of the EMT role are currently being researched, not only within the academic community, but in growing numbers of the practitioner community, as every EMT has something to contribute to improving the role.

As an EMT, you will be involved in research typically through gathering data. You may be part of a study to determine how much oxygen should be given to patients with shortness of breath. You may be involved in a study to track the time it takes to get serious trauma patients to the ED. Your job is to ensure you carefully record all of the information about these patients. The information gathered is analyzed by others to answer these questions and the results are shared with the rest of the EMS community to change patient care practices. Traditional medical practice is based on such research.

Research can also be done at each EMS facility. EMS personnel can examine patient care records to determine where the department can improve. This information can be used to generate educational sessions for the EMTs or it can be used to plan public education/public prevention strategies. High-quality patient care should focus on procedures useful in improving patient outcomes through sound research.

It is important to stay current on the latest advances in health care. On a regular basis, the International Liaison Committee on Resuscitation (ILCOR), along with its member the American Heart Association, update guidelines based on current medical evidence. The ILCOR guidelines are an excellent example of evidence-based medical decision-making in progress. These changes occur because more information is known.

One word of caution: When reading new research, make sure you understand what the results mean. Research information can be powerful, but it is often powerful within a very limited setting. A manufacturer of a defibrillator boasts their new machine will terminate ventricular fibrillation on the first shock 95% of the time. On the basis of this information, you may immediately want to buy this new product. Terminating ventricular fibrillation is certainly a positive result, but does this defibrillator save more lives than other defibrillators? In this example, the manufacturer is reporting the defibrillator is able to terminate ventricular fibrillation, not that the defibrillator is able to save more lives. People who do not examine the research will often make that hasty conclusion.

YOU are the Provider **PART 5**

The patient's condition has remained stable throughout transport. She is now pain free. After reassessing her, the paramedic asks you to call in your patient report to the receiving facility. Your estimated time of arrival is 8 minutes.

Recording Time: 19 Minutes	
Level of consciousness	Conscious and alert
Respirations	14 breaths/min; regular and unlabored
Pulse	70 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	118/60 mm Hg
Spo_2	98% (on room air)

You deliver the patient to the emergency department (ED) in stable condition and give your verbal report to a staff nurse. The patient thanks you and your crew for taking such good care of her. You depart the hospital and return to service. On the way back to the station, the paramedic critiques your performance.

7. What is the purpose of an EMS call critique?

Be skeptical when reading research. Ask questions and conduct your own research. Conclusions that seem too good to be true are usually not true.

Roles and Responsibilities of the EMT

As an EMT, you will often be the first health care professional to assess and treat the patient; as such, you have certain roles and responsibilities Table 1-6 and are expected to possess certain attributes Table 1-7. The guiding principle for EMS personnel is "everything you do needs to be done with the patient in mind." What is in the best interest of the patient? This is referred to as being a patient advocate.

Often, patient outcomes are determined by the care you provide in the field and your identification of patients who need prompt transport. You are responsible for all aspects of EMS, from the preparation of the equipment to the delivery of care to providing a good example for others within the community.

Table 1-6 Roles and Responsibilities of the EMT

- Keep vehicles and equipment ready for an emergency.
- Ensure the safety of yourself, your partner, the patient, and bystanders.
- Emergency vehicle operation.
- Be an on-scene leader.
- Perform an evaluation of the scene.
- Call for additional resources as needed.
- Gain patient access.
- Perform a patient assessment.
- Give emergency medical care to the patient while awaiting the arrival of additional medical resources.
- Give emotional support to the patient, the patient's family, and other responders.
- Maintain continuity of care by working with other medical professionals.
- Resolve emergency incidents.
- Uphold medical and legal standards.
- Ensure and protect patient privacy.
- Give administrative support.
- Constantly continue your professional development.
- Cultivate and sustain community relations.
- Give back to the profession.

Table 1-7 Professional Attributes of EMTs

Attribute	Description
Integrity	Consistent actions, a firm adherence to a code of honest behavior
Empathy	Aware of and thoughtful toward the needs of others
Self-motivation	Able to discover problems and solve them without someone directing you
Appearance and hygiene	Uses persona to project a sense of trust, professionalism, knowledge, and compassion
Self-confidence	A state of being where you know what you know AND know what you not know; able to ask for help
Time management	Able to perform or delegate multiple tasks ensuring efficiency and safety
Communications	Able to understand others and have them understand you
Teamwork and diplomacy	Able to work with others; to know your place within a team; able to communicate while giving respect to the listener
Respect	Places others in high regard or importance; understands others are more important than self
Patient advocacy	Constantly keeping the needs of the patient at the center of care
Careful delivery of care	Pays attention to detail; makes sure what is being done for the patient is done as safely as possible

Professional Attributes

As an EMT, whether you are paid or a volunteer, you are a health care professional. Part of your responsibility is to make sure patient care is given a high priority without endangering your own safety or the safety of others. Another part of your responsibility to yourself, other EMTs, the patient, and other health care professionals is to maintain a professional appearance and manner at all times. Appearance, including uniforms, hair length, and tattoos, are usually regulated by the policies of your department **Figure 1-9**. Your attitude and behavior must reflect that you are knowledgeable and sincerely dedicated to serving anyone who is injured or in an acute medical emergency. A professional appearance and manner help to build confidence and ease the patient’s anxiety. You are expected to perform under pressure with composure and self-confidence. Patients and families who are under stress need to be treated with understanding, respect, and compassion.

Most patients will treat you with respect and appreciation, but some will not. Some patients are uncooperative, demanding, unpleasant, ungrateful, and verbally abusive. You must be nonjudgmental and overcome your instincts to react poorly to such behavior. Remember, when people are hurt, ill, under stress, frightened, despondent, under the influence of alcohol or drugs, or feel threatened, they will often react with inappropriate behavior, even toward those who are trying to help and care for them. Every patient, regardless of his or her attitude, is entitled to compassion, respect, and the best care that you can provide.

Figure 1-9 **A.** A professional appearance and demeanor help build confidence and ease patient anxiety. **B.** An unprofessional appearance may promote distrust and incompetence.

Words of Wisdom

Professionalism extends beyond appearance and the activities you perform on a daily basis. As a professional, you have a responsibility to your partner, colleagues, patients, and profession to maintain a current level of knowledge.

Most people in this country can obtain proper routine medical care when they are ill and are surrounded by relatives and friends who will help to take care of them. However, when you are called to a home for a medical problem that is clearly not an emergency, remember that for some patients, calling an ambulance and being transported to the ED is the only way to obtain medical care.

As a new EMT, you will be given a lot of advice and training from the more experienced EMTs with whom you serve. Some may voice a callous disregard for some types of patients. Do not be influenced by the unprofessional attitude of these providers, regardless of how experienced or skilled they appear.

As a health care professional and an extension of physician care, you are bound by patient confidentiality. You should not discuss your findings or any disclosures made by the patient with anyone but those who are treating the patient or in limited situations, as required by law, the police or other social agencies. When discussing a call with others, you should be careful to avoid revealing any information that might disclose the name or identity of patients you have treated. Be careful not to gossip about calls and patients with others, even in your own home. The protection of patient privacy has drawn national attention with the passage of the **Health Insurance Portability and Accountability Act (HIPAA)**. You should be familiar with the requirements of this legislation, especially as it applies to your particular practice.

YOU are the Provider SUMMARY

1. Do your roles and responsibilities as an EMT differ from those of a paramedic? If so, how?

The fundamental roles and responsibilities—providing *safe and effective* emergency medical care to the sick and injured, and transporting patients to an appropriate medical facility—are the same for the EMT, AEMT and paramedic provider.

The only difference between the EMT and the paramedic is the level of care that is provided to the patient. EMTs have a fundamental knowledge of emergency care and provide basic life support (BLS), such as cardiopulmonary resuscitation, bleeding control, bandaging and splinting, and basic airway management. Paramedics have a comprehensive knowledge of emergency medical care, which is built on a solid knowledge of BLS, and provide advanced life support interventions, such as advanced airway management, cardiac monitoring, and medication administration.

2. What is the difference between what you learned in your EMT class and the care you provide in the field?

Your education and training is intended to prepare you to function as an entry-level competent EMT; therefore, your education should reflect the current practice of prehospital emergency medical care. The cognitive knowledge and psychomotor skills learned in the classroom are concepts that you will apply when caring for patients in the field. With experience and contact with many patients experiencing a variety of injuries and illnesses, your ability to apply the concepts learned in the classroom will be enhanced. You will develop your own “routine” regarding your general approach to patient care; however, you must be able to alter your routine based on the situation and the needs of the patient. Experience also enhances your critical thinking abilities. Critical thinking is a complex combination of skills; it includes the following characteristics:

- **Rationality:** Relying on reason rather than emotion; requiring evidence; not ignoring evidence; following evidence where it leads; and being more concerned about finding the best explanation than about being right; analyzing apparent confusion; and asking questions
- **Self-awareness:** Weighing the influences of your motives and biases and recognizing your own assumptions, prejudices, biases, or point of view
- **Open-mindedness:** Evaluating all reasonable inferences; considering a variety of possible viewpoints or perspectives; remaining open to alternative interpretations; accepting new explanations because they explain the evidence better; accepting new priorities in response to reevaluation of the evidence; and not rejecting unpopular views as out of hand
- **Judgment:** Recognizing the relevance and/ or merit of alternative assumptions and perspectives and recognizing the extent and weight of evidence
- **Discipline:** Being precise, meticulous, comprehensive, and exhaustive; resisting manipulation and irrational appeals; and avoiding snap judgments

3. How do you know if this patient is experiencing a “true emergency?”

An emergency can be defined as any event or situation that requires immediate intervention to minimize or prevent serious injury or death. An emergency to one person may not be an emergency to another. You must recognize that people call EMS when they perceive their situation as an emergency. In the interest of the patient, you should assume an emergency exists unless a thorough and accurate assessment yields otherwise.

Your job is to take care of patients whether a “true emergency” exists or not.

4. The patient has requested you transport her to the hospital, but does not appear to be experiencing any life-threatening conditions. Should you transport her to the hospital?

Delivering excellent and compassionate care and providing transportation to a higher level of care should be the norm. The absence of any obvious life-threatening conditions does not mean this patient does not require further medical evaluation and treatment. She has been experiencing back pain for a month; this could indicate a serious underlying problem that can only be diagnosed in a hospital. You will often encounter patients who are not experiencing any life-threatening conditions but still require EMS treatment—even if it is just supportive—and transport to the hospital.

Consulting with online medical control is recommended when a patient refuses treatment or transportation and you feel these interventions are in the patient's best interest. Similarly, if you feel transportation is not necessary, consulting with online medical control can help ensure this is the correct decision. This consultation should always be documented. If you allow patients with recognized or potentially serious medical problems to refuse care or do not offer these patients transportation to obtain higher level evaluation you expose yourself to greater levels of legal liability.

5. Is the paramedic required to contact medical control prior to administering any medications?

It depends on the EMS system's protocols. Some EMS protocols require prior contact before administering certain medications; others do not. Medical control is either off-line (indirect) or online (direct), as authorized by the EMS medical director. Online medical control consists of direction given over the phone or radio directly from the medical director or designated physician. Off-line medical control consists of standing orders, interventions that do not require prior contact with medical control, as authorized by the medical director. In this case, the paramedic started an IV line and administered medication without contacting medical control first. This indicates he or she had standing orders to do so. The paramedic recognized the need for pain medication, has been appropriately educated and trained on the medication and how to administer it, and has been authorized by the medical director to administer it at his or her discretion. It is important to note that just because your EMS system has standing orders for certain interventions, you should always contact medical control if you have any questions or concerns or need advice. Be familiar with your EMS system's protocols.

6. How should you answer the patient's question regarding her concern that she may have a serious condition?

Honesty is a critical attribute of any EMS provider. Lying to a patient and providing false hope and reassurance are unethical and inhumane. In many cases, the most honest answer to a question is "I don't know." Do not speculate—based solely on your assessment—and tell her she does or does not have a serious condition; you do not have the diagnostic equipment and resources needed to come to any conclusions. If you do not know the answer to a patient's question, do not be afraid to say "I don't know." Follow this up by reassuring her you will give her the best medical care possible and that the physician at the hospital will do the same. Patients deserve to hear the truth; never tell them otherwise.

7. What is the purpose of an EMS call critique?

The purpose of an EMS call critique is to provide feedback regarding how you cared for the patient and met his or her physical and emotional needs. It should not be punitive or demeaning; it is an educational tool that will enable you to enhance your patient care skills. EMTs must be open to constructive criticism; this is how they learn and become more proficient emergency care providers. Informal, one-on-one critiques, such as what the paramedic is conducting with you after the call, are ideal learning opportunities because information about the call is still fresh in your mind. Formal critiques, such as those that are conducted as part of the EMS continuous quality improvement (CQI) process, are designed to ensure that safe and effective patient care is consistently provided by all EMS providers in the system. To provide CQI, periodic run review meetings are held with those involved in patient care to review patient care reports and discuss any areas of care that appear to need change or improvement. Positive feedback should also be provided. If a problem appears to be repeated by a single EMT or crew, the medical director will discuss the details with those involved. If deemed necessary by the medical director, he or she may assign remedial training or develop some other educational activity. Many EMS systems have a designated person, who is assigned by the medical director, to carry out these tasks.

EMS Patient Care Report (PCR)

Date: 3-23-16	**Incident No.:** 010109	**Nature of Call:** Back pain		**Location:** 325 Blossom Ave.	
Dispatched: 0720	**En Route:** 0720	**At Scene:** 0723	**Transport:** 0735	**At Hospital:** 0750	**In Service:** 0801

Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** IV line, pain medication (by paramedic)

Narrative

Dispatched for a 59-year-old woman with back pain. On arrival at the scene, found the patient sitting on the couch in her living room. She was conscious and alert; her airway was patent; and her breathing was adequate. Patient reports lower back pain, which has been present for the past month. She denied injuring her back; she further denied any other symptoms or past medical history. Medications include ibuprofen for pain. Assessment of patient's back revealed no gross evidence of deformity, swelling, or bruising. Pulse, sensory, and motor functions were grossly intact in all extremities. The patient stated she has not been evaluated by a physician for her back pain; however, because it has progressively worsened, she called 9-1-1. Obtained vital signs, placed patient onto stretcher and placed her in position of comfort, loaded her into the ambulance, and began transport to the hospital. En route, paramedic started IV line and administered analgesia. Shortly after analgesia was administered, patient expressed relief of her pain. Reassessment revealed that she remained conscious and alert with stable vital signs. Provided reassurance and reassessment throughout remainder of transport. Delivered patient to emergency department without incident and gave verbal report to staff nurse.**End of report**

Prep Kit

Ready for Review

- The standards for prehospital emergency care and the providers who deliver it are governed by the laws in each state and are typically regulated by a state office of EMS.

- The EMS ambulance is staffed by EMTs who have been trained to the emergency medical technician, advanced EMT (AEMT), or paramedic level according to recommended national standards and have been licensed by the state they serve.
- An EMT has training in basic emergency care skills, including automated external defibrillation, use of airway adjuncts, and assisting patients with certain medications.
- An AEMT has training in specific aspects of advanced life support (ALS), such as intravenous therapy and the administration of certain emergency medications.
- A paramedic has extensive training in ALS, including endotracheal intubation, emergency pharmacology, cardiac monitoring, and other advanced assessment and treatment skills.
- Emergency medical responders, such as law enforcement officers, firefighters, park rangers, ski patrollers, or other organized rescuers often arrive at the scene before the ambulance and EMTs.
- After the EMTs size up the scene and assess the patient, they provide the emergency care and transport that is indicated based on their findings and ordered by their medical director in the service's standing orders and protocols or by the physician who is providing online medical direction.
- The National EMS Scope of Practice Model, developed by NHTSA, provides overarching guidelines as to what skills each level of EMS provider should be able to accomplish.
- The *EMS Agenda for the Future* is a multidisciplinary, national review of all aspects of EMS delivery that encourages the creation of systems that help to protect the well-being of EMS providers. It includes 14 components that make up an EMS system.
- You will often be the first health care professional to assess and treat the patient; as such, you have certain roles and are expected to possess certain attributes.
- EMT attributes include compassion and motivation to reduce suffering, pain, and mortality in those who are injured or acutely ill; a desire to provide each patient with the best possible care; commitment to obtain the knowledge and skills that this position requires; and the drive to continually increase your knowledge, skills, and ability.
- The EMT course that you are now taking will present the information and skills that you will need to pass the required certification examination needed to become a licensed EMT.
- Once you have completed the course, you must assume responsibility for directing your own study through continuing education provided by your service's training officer and medical director or through other opportunities available to you. Your commitment to continued learning is the key to being a good EMT.
- Throughout your career, seek new certifications and roles that will broaden your abilities and experience. Mobile integrated healthcare, including the role of community paramedic, is an example of how EMS roles are evolving.
- As a health care professional and an extension of physician care, you are bound by patient confidentiality.

Vital Vocabulary

advanced EMT (AEMT) An individual who has training in specific aspects of advanced life support, such as intravenous therapy, and the administration of certain emergency medications.

advanced life support (ALS) Advanced lifesaving procedures, some of which are now being provided by the EMT.

Americans With Disabilities Act (ADA) Comprehensive legislation that is designed to protect people with disabilities against discrimination.

automated external defibrillator (AED) A device that detects treatable life-threatening cardiac dysrhythmias (ventricular fibrillation and ventricular tachycardia) and delivers the appropriate electrical shock to the patient.

certification A process in which a person, an institution, or a program is evaluated and recognized as meeting certain predetermined standards to provide safe and ethical care.

community paramedicine A health care model in which experienced paramedics receive advanced training to equip them to provide additional services in the prehospital environment, such as health evaluations, monitoring of chronic illnesses or conditions, and patient advocacy.

continuous quality improvement (CQI) A system of internal and external reviews and audits of all aspects of an EMS system.

emergency medical dispatch (EMD) A system that assists dispatchers in selecting appropriate units to respond to a particular call for assistance and provides callers with vital instructions until the arrival of EMS crews.

emergency medical responder (EMR) The first trained professional, such as a police officer, firefighters, lifeguard, or other rescuer, to arrive at the scene of an emergency to provide initial medical assistance.

emergency medical services (EMS) A multidisciplinary system that represents the combined efforts of several professionals and agencies to provide prehospital emergency care to the sick and injured.

emergency medical technician (EMT) An individual who has training in basic life support, including automated external defibrillation, use of a definitive airway adjunct, and assisting patients with certain medications.

Health Insurance Portability and Accountability Act (HIPAA) Federal legislation passed in 1996. Its main effect in EMS is in limiting availability of patients' health care information and penalizing violations of patient privacy.

intravenous (IV) therapy The delivery of medication directly into a vein.

licensure The process whereby a competent authority, usually the state, allows people to perform a regulated act.

medical control Physician instructions given directly by radio or cell phone (online/direct) or indirectly by protocol/guidelines (off-line/indirect), as authorized by the medical director of the service program.

medical director The physician who authorizes or delegates to the EMT the authority to provide medical care in the field.

mobile integrated healthcare (MIH) A method of delivering health care which involves providing health care within the community rather than at a physician's office or hospital.

National EMS Scope of Practice Model A document created by the National Highway Traffic Safety Administration (NHTSA) that outlines the skills performed by various EMS providers.

paramedic An individual who has extensive training in advanced life support, including endotracheal intubation, emergency pharmacology, cardiac monitoring, and other advanced assessment and treatment skills.

primary prevention Efforts to prevent an injury or illness from ever occurring.

primary service area (PSA) The designated area in which the EMS agency is responsible for the provision of prehospital emergency care and transportation to the hospital.

public health Focused on examining the health needs of entire populations with the goal of preventing health problems.

public safety access point A call center, staffed by trained personnel who are responsible for managing requests for police, fire, and ambulance services.

quality control The responsibility of the medical director to ensure the appropriate medical care standards are met by EMTs on each call.

secondary prevention Efforts to limit the effects of an injury or illness that you cannot completely prevent.

Assessment *in Action*

© Jones & Bartlett Learning. Courtesy of MIEMSS.

You are tasked with teaching a review course for the National Registry written exam. Several students are worried about passing the cardiology and trauma sections. You reassure them that while these are very important topics, the fundamentals form the building blocks for our profession and should not be forgotten. After sharing those words of wisdom, you begin class.

1. Which of the following agencies is the federal source for the EMT education standards?

   A. Department of Health and Human Services
   B. National Highway Traffic Safety Administration
   C. Federal Emergency Management Agency
   D. Department of Transportation

2. What is the primary job of the EMT?

   A. Provide appropriate medical care
   B. Diagnose the patient’s condition
   C. Ensure personal safety
   D. Provide transport to the closest hospital

3. This act of legislation protects people with disabilities from being denied access to programs and services that are provided by state or local governments.

   A. Ryan White Act
   B. Marchman Act
   C. Equal Rights Amendment
   D. Americans with Disabilities Act

4. Which of the following is NOT a component of an EMS system under the EMS Agenda for the Future?

   A. Medical direction
   B. Certification reciprocity

C. Public education
D. EMS research

5. Which of the following is an example of secondary prevention?

A. Providing cervical spine immobilization
B. Administering vaccines
C. Conducting injury surveillance
D. Teaching safety in schools

6. The roles and responsibilities of an EMT include all of the following EXCEPT:

A. performing a patient assessment.
B. upholding medical and legal standards.
C. providing legal advice to patients.
D. ensuring and protecting patient privacy.

7. An example of teamwork and diplomacy is:

A. using your persona to project a sense of trust.
B. being able to communicate while giving respect to the listener.
C. placing others in high regard or importance.
D. delegating multiple tasks ensuring efficiency and safety.

8. The Health Insurance Portability and Accountability Act (HIPAA):

A. enables patients to travel without losing health insurance.
B. requires insurance companies to justify denying health care.
C. prevents an emergency department from refusing to care for a critically ill patient.
D. limits the availability of a patient’s health care information.

9. What is continuous quality improvement (CQI) and how is it used to help ensure the safety of patients?

10. Why is EMS research a vital part in the evolution of patient management?

CHAPTER

2

Workforce Safety and Wellness

National EMS Education Standard Competencies

Medicine

Applies fundamental knowledge to provide basic emergency care transportation based on assessment findings for an acutely ill patient.

Infectious Diseases

Awareness of

› How to decontaminate equipment after treating a patient (pp 48–50)

Assessment and management of

› How to decontaminate the ambulance and equipment after treating a patient (pp 48–50)

Preparatory

Applies fundamental knowledge of the emergency medical services (EMS) system, safety/well-being of the emergency medical technician (EMT), medical/legal, and ethical issues to the provision of emergency care.

Workforce Safety and Wellness

› Standard safety precautions (pp 42–47)
› Personal protective equipment (pp 43–47)
› Stress management (pp 35–36, 67–70)
  • Dealing with death and dying (pp 65–67)
› Prevention of response-related injuries (pp 38, 52–58)
› Prevention of work-related injuries (pp 38, 52–58)
› Lifting and moving patients (p 38)
› Disease transmission (pp 40–42)
› Wellness principles (pp 35–40)

Knowledge Objectives

1. State the steps that contribute to wellness and their importance in managing stress. (pp 35–40)
2. Define infectious disease and communicable disease. (p 40)
3. Describe the routes of disease transmission. (pp 41–42)
4. Describe the routes of transmission and the steps to prevent and/ or deal with an exposure to hepatitis, tuberculosis, and HIV/AIDS. (pp 41–48)
5. Know the standard precautions used in treating patients to prevent infection. (pp 42–47)
6. Describe the steps to take for personal protection from airborne and bloodborne pathogens. (pp 42–47)
7. Explain proper handwashing techniques. (pp 43–44)
8. List the ways immunity to infectious diseases is acquired. (pp 50–51)
9. Explain postexposure management of exposure to patient blood or body fluids, including completing a postexposure report. (p 52)
10. Describe the steps necessary to determine scene safety and to prevent work-related injuries at the scene. (pp 52–58)
11. Describe the different types of protective clothing worn to prevent injury. (pp 58–61)
12. Explain the care of critically ill and injured patients. (pp 61–64)
13. Describe issues concerning care of the dying patient, death, and the grieving process of family members. (pp 65–67)
14. Know the physiologic, physical, and psychological responses to stress. (pp 67–69)
15. Describe posttraumatic stress disorder (PTSD) and steps that can be taken, including critical incident stress management, to decrease the likelihood that PTSD will develop. (pp 69–70)
16. Identify the emotional aspects of emergency care. (pp 69–70)
17. Recognize the stress inherent in many situations, such as mass-casualty scenes. (pp 70–71)
18. Recognize the possibility of violent situations and the steps to take to deal with them. (pp 72–73)
19. Describe how to recognize behavioral emergencies. (pp 73–74)
20. Discuss workplace issues such as cultural diversity, sexual harassment, and substance abuse. (pp 74–76)

Skills Objectives

1. Demonstrate how to properly remove gloves. (p 45, Skill Drill 2-1)
2. Demonstrate the steps necessary to take to manage a potential exposure situation. (p 49, Skill Drill 2-2)

Introduction

There is an ancient proverb, "Physician, heal thyself." As health care providers, physicians need to look after themselves—in all respects—so that they can minister to others. An ill physician is in no position to render care as he or she was trained to do. That dictum applies to all health care providers and goes well beyond just physical issues.

Your personal safety must always be foremost in your mind. If that is threatened, you will not ultimately be able to care for the patient.

As part of your training, you will learn how to recognize possible hazards to your health, safety, and well-being and how to protect yourself from them. These hazards vary greatly, ranging from personal neglect to environmental and human-made threats. You will learn how to cope with the mental and physical stress that result from caring for the sick and injured. Death and dying issues challenge you to deal with the realities of your own mortality and the emotions of the survivors.

Your emotional well-being and the patient's are intertwined, especially in high-stress rescues. This chapter discusses both caring for the well-being of the patient and caring for yourself.

General Health and Wellness

Wellness goes well beyond prevention of disease. Rather, it is a state of complete mental, physical, and social well-being. As a health care provider, you should model a lifestyle of health and wellness. This state of wellness must occur both at work, with protection from communicable disease and scene hazards, and at home by eating a balanced and healthy diet, participating in physical exercise, getting enough sleep, refraining from the use of tobacco, drugs, and excessive alcohol, and taking time to relax and enjoy life.

As an EMT, you will be called upon to work in less than ideal circumstances and situations. This may result in both acute and cumulative stress. Remember, your role as an EMT is to be prepared, anticipate needed resources, control the scene, and care for the patient. Once you arrive, the emergency is in the hands of a competent professional. The calm manner in which you approach the scene will help to calm the patient, family members, and bystanders.

Wellness and Stress Management

Anyone can respond to sudden physical stress for a short time. However, if stress is prolonged, and especially if physical action is not a permitted response, the body can quickly be drained of its reserves. This can leave you depleted of key nutrients, weakened, and more susceptible to illness.

Management of Acute Stress

Stress is defined as any event, thought, or action perceived as a threat. Even people who are completely healthy may be constantly dealing with stress. Though it is an undeniable and unavoidable part of life, understanding how stress affects you physiologically, physically, and psychologically can help you control your reactions and minimize the effects of stress.

Your job is to remain professional at all times. Regardless of how stressful the situation, you must focus on the following, in this order:

1. Personal safety
2. Scene safety, including safety of others
3. Patient care

YOU are the Provider PART 1

You have been working a regular EMS shift—24 hours on and 48 hours off—since you became a certified EMT less than 6 months ago. You receive a call at 0720 hours to 788 East Radcliffe for an unconscious child who is not breathing. You and your paramedic partner respond to the scene; an emergency medical responder (EMR) unit is dispatched at the same time. This is your first call involving a critically ill child.

1. How can you psychologically prepare yourself for this call?

Although stressful situations may test your limits, you must focus on patient care while ensuring a safe and secure scene. Utilize the help of others, including your partner, police, a supervisor, other additional personnel, or even bystanders, to help manage crisis situations. Stay calm while allowing patients to express their feelings. You may be inclined to express your personal opinion but it is your duty to remain professional and focused on patient care.

There are many methods of handling stress. Some are positive and healthy; others are harmful and destructive. Some estimates indicate Americans consume more than 10,000 tons of aspirin per year (more than 27 tons per day), and doctors in the United States prescribe to their patients muscle relaxants, tranquilizers, and sedatives more than 90 million times per year. Although these medications have legitimate uses, they do nothing to combat stress that may cause the medical problems described previously.

The term stress management refers to the tactics that have been shown to alleviate or eliminate stress reactions. These strategies may involve changing a few habits, changing your attitude, and perseverance Table 2-1.

A clue to the management of stress comes from the fact that it is not the event itself but the individual's reaction to it that determines how much it will strain the body's resources.

Words of Wisdom

An overabundance of stress must concern you. If your gut feeling is that things are out of balance, you may be right.

The following sections provide some suggestions for how to prevent the effects of stress from adversely affecting you.

Nutrition

Your body's three sources of fuel—carbohydrates, fat, and protein—are consumed in increased quantities during stress, particularly if physical activity is involved. The quickest source of energy is glucose, taken from stored glycogen in the liver. However, this supply will last less than a day. Protein, drawn primarily from muscle, is a long-term source of fuel. Tissues can use fat for energy. The body also conserves water during periods of stress. To do so, it retains sodium by exchanging and losing potassium from the kidneys. Other nutrients that are susceptible to depletion are the vitamins and minerals that are not stored by the body in substantial quantities. These include water-soluble B and C vitamins and most minerals.

Table 2–1 Strategies to Manage Stress

- Minimize or eliminate stressors as much as possible.
- Change partners to avoid a negative or hostile personality.
- Change work hours.
- Change the work environment.
- Cut back on overtime.
- Change your attitude about the stressor.
- Talk about your feelings with people you trust.
- Seek professional counseling if needed.
- Do not obsess over frustrating situations that you are unable to change, such as relapsing alcoholics and nursing home transfers; focus on delivering high-quality care.
- Try to adopt a more relaxed, philosophical outlook.
- Expand your social support system beyond your coworkers.
- Develop friends and interests outside emergency services.
- Minimize the physical response to stress by using various techniques, including:
  - Periodic stretching or yoga
  - Slow, deep breathing
  - Regular physical exercise (150 min per week, including cardiovascular effort)
  - Progressive muscle relaxation
  - Meditation
  - Limit intake of caffeine, alcohol, and tobacco use

As an EMT, you have little control of what stressors you will face on any given day. Consequently, stress in one form or another is an unavoidable part of your life. As you would study for a test, dress properly for a day of snow skiing, or train for a sporting event, you should physically prepare your body for stress. Physical conditioning and proper nutrition are the two variables over which you have absolute control. Muscles will grow and retain protein only with sufficient activity. Bones will not passively accumulate calcium. In response to the physical stress of exercise, bones store calcium and become denser and stronger. Regular, well-balanced meals are essential to provide the nutrients that are necessary to keep your body fueled **Figure 2-1**. Vitamin-mineral preparations that provide a balanced mix of all the nutrients may be necessary to supplement a less than perfectly balanced diet.

To perform efficiently, you must eat nutritious food. Food is the fuel that makes the body run. The physical exertion and stress that are a part of your job require a high energy output. If you do not have a ready source of fuel, your performance may be less than satisfactory. This can be dangerous for you, your partner, and your patient. Therefore, it is important for you to learn about and follow the guidelines of good nutrition.

In general, you should limit your consumption of sugar, fats, sodium, and alcohol. Candy and soft drinks contain sugar. These foods are quickly absorbed and converted to fuel by the body. But simple sugars also stimulate the body's production of insulin, which reduces blood glucose levels. For some people, eating a lot of sugar can actually result in lower energy levels.

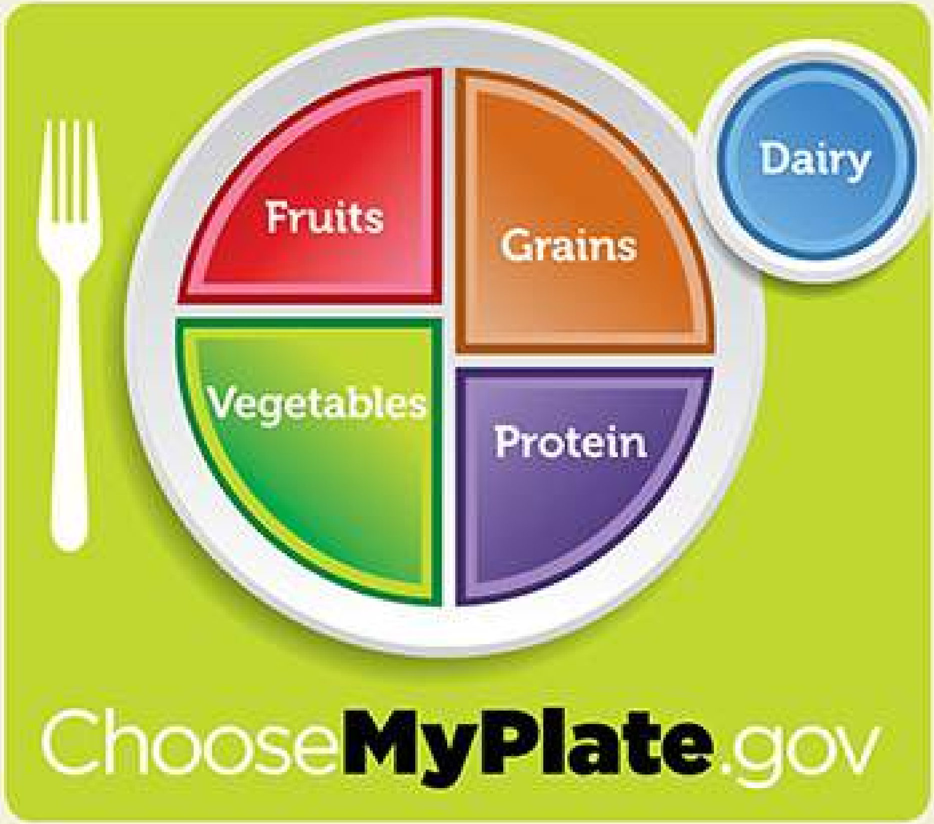

Figure 2-1 The USDA's MyPlate icon emphasizes healthy portions of vegetables, fruits, grains, proteins, and dairy.

Courtesy of the USDA Center for Nutrition Policy and Promotion.

Complex carbohydrates rank next to simple sugars in their ability to produce energy. Complex carbohydrates such as pasta, rice, and vegetables are among the safest, most reliable sources for long-term energy production. However, some carbohydrates take hours to be converted into usable body fuel.

Fats are also easily converted to energy, but eating too much fat can lead to obesity, cardiac disease, and other long-term health problems. The proteins in meat, fish, chicken, beans, and cheese take several hours to convert to energy. Consumption of fats should be limited to 10% of calories and should focus on monounsaturated and polyunsaturated fats while avoiding saturated fats or transfats. It is also important to limit cholesterol intake and salt (sodium) intake.

Carry an individual supply of high-energy food to help you maintain your energy levels **Figure 2-2**. Eat several small meals throughout the day to keep your energy resources at constant high levels. However, remember, overeating may reduce your physical and mental performance. After a large meal, the blood that is needed for the digestive process is not available for other activities.

You must also maintain an adequate fluid intake **Figure 2-3**. Hydration is important for proper functioning. Fluids can be easily replenished by drinking any nonalcoholic, caffeine-free fluid. Water is generally the best fluid available because the body absorbs it faster than any other fluid. Avoid fluids that contain high levels of sugar. These can actually slow the rate of fluid absorption by the body and cause abdominal discomfort. One indication of adequate hydration is frequent urination. Infrequent urination or urine that has a deep yellow color indicates dehydration.

Exercise and Relaxation

Regular exercise will enhance the benefits of maintaining good nutrition and adequate hydration. When you are in good physical condition, you can handle job stress more easily. Regular exercise will increase your strength and endurance. To maintain good health, you should engage in at least 30 minutes of physical activity at least 5 days per week. Exercise should be moderate or vigorous to have good health benefits. In other words, you should break a sweat **Figure 2-4**. You may also wish to practice relaxation techniques, meditation, and visual imagery.

Figure 2-2

Carry a supply of high-energy food with you so you can maintain your energy levels.

Your exercise routine should involve aspects of cardiovascular endurance, muscular strength building, and muscle flexibility. Endurance will ensure your cardiovascular system is able to provide your muscles and brain with needed oxygen. Strength and flexibility building ensures the body is able to handle the requirements that you will place on it by lifting patients, performing cardiopulmonary resuscitation (CPR), and moving heavy equipment.

Figure 2-3 Maintain an adequate fluid intake by drinking plenty of water or other nonalcoholic, caffeine-free fluids.

Figure 2-4 A regular program of exercise will increase strength and endurance.

Remember, if you do not use it, you will lose it. Plan activities ahead of time and use strategies that make your sessions convenient. Is there a gym or exercise facility near your home or en your route to work? Is there a walking path or a football stadium with a running track accessible?

Safe Lifting Practices. We have already discussed the physical requirements of being an EMT. Lifting 125 lb (57 kg) can be difficult if you do not exercise regularly. Lifting is one of the things you will do often, so safe lifting techniques are critical to your health and well-being. Back injuries are a common reason for on-the-job injuries within EMS. Chapter 8, *Lifting and Moving Patients*, discusses lifting and moving in depth. For your health and well-being, remember these tips:

- Preplan the move
- Bend your legs, not your waist
- Keep the weight close to your body
- Lift straight up using your legs, not your back

Sleep

Good productive sleep is as important as eating well and exercise in the maintenance of good health. Sleep should be regular and uninterrupted. The number of hours is not nearly as important as the quality of sleep. Unfortunately, you may not have the luxury of sleeping through the night. In lieu of a full night of sleep, cumulative sleep hours are very important, so taking short naps may help.

The signs that your sleep pattern is ineffective include:

- You fall asleep within seconds of lying down.

- You find yourself routinely fatigued within an hour or so after an EMS call. The excitement is over and now your adrenaline rush crashes.
- You are unable to make it through an entire day without severe fatigue.
- You are unable to concentrate on repetitive tasks such as driving or completing paperwork.

Actions you can take to improve your sleep include limiting your caffeine and alcohol intake and tobacco use. These agents have stimulating effects that can interrupt sleep. Since alcohol is both a stimulant and a depressant, routine or excessive use of alcohol can change sleep patterns, preventing deep sleep from occurring. Try to create as consistent a sleep cycle as possible. This may require naps. Many EMS providers are able to change their sleep pattern into several sleep episodes throughout the day.

If you are unable to get 8 straight hours of sleep, three sleep episodes of 2 to 3 hours each can provide similar effects. Each sleep episode needs to be more than 1 hour in length to allow for deep sleep. Finally, do not forget the effects of exercise and sleep. Routine exercise will promote the needed fatigue to slip into a restful sleep.

Disease Prevention

Besides sleep, diet, exercise, hydration, and all the other things that make up a healthy lifestyle, you need to be aware of your hereditary factors. Consider what you might know about your immediate family's and your ancestors' health. Alzheimer disease, chemical addiction, cancer, cardiac illness, hypertension, migraines, mental illness, and stroke all feature prominent hereditary factors. The most common of all hereditary factors are heart disease and cancer.

Share this information with your personal physician. Your physician is bound by the same oath of confidentiality that you are. Work with him or her to set up a schedule for health assessments, building them into your routine physical check-ups. Your physician should be your ally in screening you for these diseases and in assessing your lifestyle as well as your hereditary factors.

Knowing your hereditary factors will help you adjust your lifestyle to help prevent disease. For example, if you have a history of diabetes in your family, exercise and diet are critical to your well-being. Maintaining a healthy weight and a consistent exercise routine will help minimize your risk of this disease developing.

Smoking and Tobacco. If you don't already smoke, please don't start! If you do, please stop! Not only does this habit fly in the face of everything that EMS stands for, it also produces many of the most horrible cardiovascular and lung disasters that you will confront during your career. In addition, it sets an awful example for the public—especially to people who have breathing disorders such as asthma. And it makes you look and smell like anything but a professional caregiver.

Are you a smoker who is trying to quit? Several strategies can help you. First, try to cultivate a relationship with a mentor who was once truly addicted to tobacco but who has successfully quit smoking. Use that person as a support, and draw on his or her advice and encouragement. There are also programs that attack a smoker's psychologic dependency. These programs may include instructions and audio that provide ongoing support. Other options include therapy, hypnotism, and acupuncture.

Talk to your primary care physician. Your physician should be familiar with more techniques. All of these solutions are cheaper than cigarettes and their associated health risks.

While cigarette use among adults has declined from 42% in 1965 to 18% in 2012, cigarettes remain the most common form of tobacco use in the United States. Use of other tobacco products, including smokeless tobacco (chewing tobacco and snuff), is still common and has actually increased over the past several years. All forms of tobacco are harmful and must be avoided.

In recent years, electronic cigarettes (e-cigarettes) have become a popular alternative to tobacco cigarettes. Also called electronic nicotine delivery systems (ENDS) or personal vaporizers (PVs), these devices simulate smoking tobacco by producing an aerosol made by vaporizing a flavored liquid solution. Though studies indicate that e-cigarettes are less dangerous than their tobacco counterparts, the extent of their danger has not yet been determined. Consequently, these devices should be avoided.

Alcohol Abuse. Acceptable alcohol consumption is considered to be one or two drinks per day (one for women, two for men). Definitions of excessive drinking are shown in Table 2-2. In most cases, people who drink excessively are not alcoholics or alcohol dependent.

According to the Centers for Disease Control and Prevention (CDC), excessive alcohol use causes approximately 88,000 deaths per year in the United States with an economic cost of more than $200 billion per year. Approximately 75% of the total cost of alcohol abuse is attributed to binge drinking.

Table 2-2 Definitions of Excessive Drinking

	Binge Drinking	Heavy Drinking
Men	5 or more drinks during a single occasion	15 or more drinks per week
Women	4 or more drinks during a single occasion	8 or more drinks per week

Data From: Alcohol Use and Your Health. National Center for Chronic Disease Prevention and Health Promotion. Division of Population Health. Centers for Disease Control and Prevention. http://www.cdc.gov/alcohol/pdfs/alcoholyourhealth.pdf. Accessed 10/28/14.

Some studies have touted the health benefits related to alcohol, such as improved heart health from drinking red wine. The CDC notes that no one should start drinking or drink more frequently based on potential reported health benefits. While these benefits may exist, increased alcohol use may adversely impact other body systems, including the cardiovascular, hepatic, immune, and central nervous systems. Excessive alcohol use may also increase the risk of various cancers developing, including those of the mouth, throat, breast, esophagus, and liver.

Drug Use. Both prescription medications and illegal, or illicit, drugs may be abused or misused. Both are potentially dangerous and may lead to numerous additional health problems. According to the CDC, drug abuse costs the United States more than $190 billion annually in lost work productivity, health care, and crime.

Illicit drug use is both illegal and unhealthy, typically resulting in a snowball effect of bad outcomes. Many EMS agencies drug test their employees. Those who test positive for illegal drugs face suspension and/or dismissal. Needless to say, avoid all illegal drugs; take only those drugs prescribed for you personally by a physician, and take them only as directed. If any type of restricted schedule or narcotic drug is prescribed (usually while you are off duty), be sure to notify your employer of the situation.

Balancing Work, Family, and Health

As an EMT, you will often be called to assist the sick and injured any time of the day or night. Unfortunately, there is no rhyme or reason to the timing of illness, injury, or interfacility transfer. Volunteer EMTs may often be called away from family or friends during social activities. Shift workers may be required to be apart from loved ones for long periods of time. You should never let the job interfere excessively with your own needs. Find a balance between work and family; you owe it to yourself and to your family. It is important to make sure you have the time that you need to relax with family and friends.

It is also important to realize that coworkers, family, and friends often may not understand the stress caused by responding to EMS calls. As a result of a "bad call," you might not feel like going out to a movie or attending a planned family event. In these situations, help from a critical incident stress management team or information sessions conducted by your EMS unit's employee assistance program may assist you in resolving these issues.

When possible, rotate your schedule to give yourself time off. If your EMS system allows you to move from station to station, rotate to reduce or vary your call volume. Take vacations to lower stress and improve your physical health so you will be able to better respond the next time you are needed. If at any point you feel the stress of work is more than you can handle, seek help. You may want to discuss your stress informally with your family or coworkers. Help from more experienced team members can be invaluable. You may also wish to get help from peer counselors or other professionals. Seeking help does not make you weak in the eyes of others. Rather, it shows that you are in control of your life.

Infectious and Communicable Diseases

As an EMT, you will be called on to treat and transport patients with a variety of infectious or communicable diseases. An **infectious disease** is a medical condition caused by the growth and spread of small, harmful organisms within the body. A **communicable disease** is a disease that can be spread from one person or species to another. Immunizations, protective techniques, and simple handwashing can dramatically minimize the health care provider's risk of **infection**. When these protective measures are used, the risk of the health care provider contracting a serious disease is negligible.

Familiarize yourself with the following terminology related to infectious diseases. A **pathogen** is a microorganism that is capable of causing disease in a susceptible host. **Contamination** is the presence of infectious organisms or foreign bodies on or into objects such as dressings, water, food, needles, wounds, or a patient's body. **Exposure** is a situation in which a person has had contact with blood, body fluids, tissues, or airborne particles in a manner that may allow disease transmission to occur. **Personal protective equipment (PPE)** is protective equipment that an individual wears to prevent exposure to a pathogen or a hazardous material.

Words of Wisdom

All communicable diseases are infectious, but not all infectious diseases are easily communicable. For example, hepatitis B is an infectious disease that is communicable. However, *Salmonella* is infectious, but not communicable.

Routes of Transmission

Whereas all infections result from an abnormal invasion of body spaces and tissues by germs, different germs use different means of attack, or mechanisms of transmission. **Transmission** is the way an infectious disease is spread. There are several ways infectious diseases can be transmitted: contact (direct or indirect), airborne, foodborne, and vector-borne (transmitted through insects or parasitic worms).

Contact transmission is the movement of an organism from one person to another through physical touch. There are two types of contact transmission: direct and indirect. **Direct contact** occurs when an organism is moved from one person to another through touching without any intermediary.

The scenario of a vehicle crash can help you understand how transmission occurs through direct contact. The driver of the vehicle has **hepatitis** B and is bleeding from an arm injury. The EMT caring for the patient is not wearing gloves and has a small unnoticed cut on his hand. As he touches the patient, the hepatitis B virus moves from the victim's wound into the EMT's body through the cut on his hand, thus infecting him Figure 2-5. This is an example of direct contact where blood is the vehicle. **Bloodborne pathogens** are microorganisms that are present in human blood and can cause disease in humans. Another example of direct contact is sexual transmission. Patients who are infected with the **human immunodeficiency virus (HIV)** can transfer the virus to their partners during sexual intercourse.

Figure 2-5 Finger infection resulting from not wearing gloves during contact with a patient.

Words of Wisdom

Fungi are small, plantlike organisms such as yeast. Fungi cause many common conditions such as athlete's foot and jock itch. Protozoa are single-cell animal-like microorganisms. Protozoa cause malaria. Helminths are worms such as roundworms, pinworms, and hookworms. These worms are parasites that can infect people and cause serious health problems.

Indirect contact involves the spread of infection from the patient with an infection to another person through an inanimate object. The object that transmits the infection is called a fomite. Using the same patient from the example above, the EMT wore gloves. As the EMT was caring for the patient, blood got onto the ambulance stretcher. If the stretcher is not properly cleaned afterward, the virus remains on the stretcher and can be transmitted to someone else days later.

Needlesticks are another example of how infection spreads through indirect contact. In this case, the virus moves from the patient to the needle to the health care provider. This route of transmission was common many years ago before the advent of safety equipment such as needleless IV systems.

Airborne transmission involves spreading an infectious agent through mechanisms such as droplets or dust. The common cold is moved from person to person by coughing and sneezing. Interestingly, when a person sneezes, the moisture from the airway moves forcefully and quickly through a narrow opening. If the moisture droplets are large, they travel short distances and can be involved in direct contact transmission. If the moisture droplets are very small, they are turned into an aerosol and can now float in the air for long distances. Sneezing actually can transmit disease through direct contact and airborne routes **Figure 2-6**.

Because of airborne transmission, it is unsanitary to use your hands to cover a cough or sneeze because the organisms travel onto your hands. If you then touch a telephone, doorknob, or a patient, the organisms will travel. Using a tissue when coughing or sneezing is better for controlling the spread of organisms, but you then have a piece of paper full of organisms. One of the best techniques to avoid contaminating your hands is to cough or sneeze into your arm. Since you do not touch objects with your inner arms, the risk of moving organisms to an object or person is reduced **Figure 2-7**. The organisms are trapped in the fabric and will eventually die.

Foodborne transmission involves the contamination of food or water with an organism that can cause disease. When food is prepared, it is important to ensure raw meats do not come into contact with other foods to prevent the spread of bacteria. It is also important that food is prepared and stored properly at all times to minimize the possibility of illness. Proper cleaning of food preparation surfaces before and after use also helps to decrease the likelihood of transmitting foodborne bacteria.

Vector-borne transmission involves the spread of infection by animals or insects that carry an organism from one person or place to another. The Black Death in Europe and Asia in the Middle Ages killed more than 25 million people. This bacterial disease was caused by infected fleas that live on rats. As the rats moved, so did their fleas, carrying the bubonic plague. Other vector-borne diseases include rabies and Lyme disease.

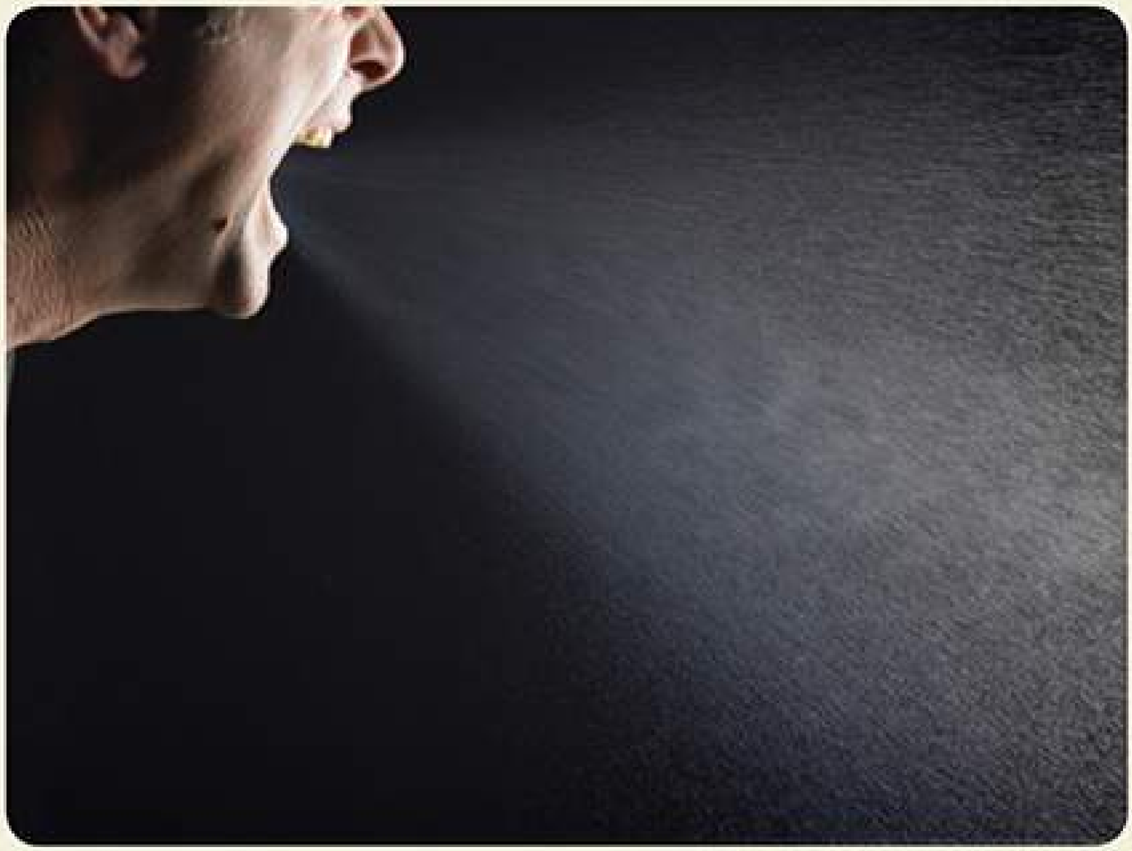

Figure 2-6 Coughing and sneezing create droplets and aerosols.

Risk Reduction and Prevention for Infectious and Communicable Diseases

Standard Precautions

The **Occupational Safety and Health Administration (OSHA)** develops and publishes guidelines concerning reducing hazards in the workplace. It is also responsible for enforcing these guidelines. OSHA requires all EMTs to be trained in handling bloodborne pathogens and in approaching the patient who may have an infectious or communicable disease. Training must be provided for issues including blood and body fluid precautions, airborne precautions, and contamination precautions.

Because health care workers are exposed to so many different kinds of infections, the **Centers for Disease Control and Prevention (CDC)** developed a set of **standard precautions** for health care workers to use in treating patients. Standard precautions are protective measures designed to prevent health care workers from coming into contact with objects, blood, body fluids, and other potential risks that could lead to exposure to germs. The CDC recommendation from 2007 is to assume that every person is potentially infected or can spread an organism that could be transmitted in the health care setting; therefore you must apply **infection control** procedures—procedures to reduce infection in patients and health care personnel. Table 2-3 summarizes the CDC recommendations. You must also notify your **designated officer** if you are exposed.

Figure 2-7 Coughing and sneezing techniques. **A.** Poor coughing and sneezing technique allows for spread of germs. **B.** Acceptable coughing and sneezing technique limits the spread of germs somewhat. **C.** Best coughing and sneezing technique minimizes the extent to which germs can spread.

Table 2-3 Standard Precautions for the Care of All Patients in All Health Care Settings, Centers for Disease Control and Prevention 2007

Component	Recommendations
Hand hygiene	▪ After touching blood, body fluids, secretions, excretions, or contaminated items ▪ Immediately after removing gloves ▪ Between patient contacts
Personal Protective Equipment (PPE)	
Gloves	▪ For touching blood, body fluids, secretions, excretions, or contaminated items ▪ For touching mucous membranes and nonintact skin
Gown	▪ During procedures and patient care activities when contact of the EMT's clothing/exposed skin to blood, body fluids, secretions, excretions, or contaminated items is anticipated
Mask, eye protection, face shield	▪ During procedures and patient care activities likely to generate splashes or sprays of blood, body fluids, secretions, or excretions. Examples include suctioning or endotracheal intubation
Patient Care Environment	
Soiled patient care equipment	▪ Wear gloves ▪ Handle in a manner that prevents transfer of microorganisms to others and to the environment ▪ Hand hygiene
Environmental controls	▪ Have procedures for the routine care, cleaning, and disinfection of environmental surfaces ▪ Special attention to frequently touched surfaces within the ambulance (handrails, seats, cabinets, doors)
Textiles and laundry	▪ Handle in a manner that prevents transfer of microorganisms to others and to the environment
Needles and other sharp objects	▪ Do not recap, bend, break, or hand-manipulate used needles ▪ Use safety features when available (needleless IV systems) ▪ Place sharps in puncture-resistant containers
Special Circumstances	
Patient resuscitation	▪ Use mouthpiece, resuscitation bag, or other ventilation devices to prevent contact with mouth and oral secretions
Respiratory hygiene/cough etiquette	▪ Instruct symptomatic patients to cover mouth/nose when sneezing or coughing ▪ Use tissues and dispose in no-touch receptacle ▪ Perform hand hygiene after touching tissues ▪ Place surgical mask on patient/provider ▪ If mask cannot be used, maintain special separation (> 3 ft) if possible

Proper Hand Hygiene

Proper handwashing is the simplest yet most effective way to control disease transmission Figure 2-8. You should always wash your hands before and after contact with a patient, even if you wear gloves. The longer the germs remain with you, the greater the chance they will get through your barriers. Any breaks in the skin such as tiny cuts and abrasions are potential access points for pathogens. Although soap and water are not protective in all cases, in certain cases they provide excellent protection against further transmission from your skin to others.

Figure 2-8 When washing hands, rub your hands together for at least 20 seconds to work up a lather. Pay particular attention to your fingernails, between fingers, and the back of the hands.

Rinse your hands using warm water. If running water is not available, you may use waterless handwashing substitutes **Figure 2-9**. These solutions can kill many potential bacterial infections. If you use a waterless substitute in the field, make sure you wash your hands using soap and water at the hospital. Finally, dry your hands with a paper towel, and use the paper towel to turn off the faucet.

Gloves

Gloves and eye protection are the minimum standard for all patient care if there is any possibility for exposure to blood or body fluids. Vinyl, nitrile, and latex gloves provide adequate protection. Your department may prefer one type of glove over the other, or you may have the freedom to choose yourself. You should evaluate each situation and choose the glove that works best. (Some patients are allergic to latex. If you suspect you are allergic, consult your supervisor for options.) Vinyl gloves may be best for situations with minimal patient contact or nonsterile procedures, and nitrile or latex gloves may be best for invasive procedures where sterility is required. Change gloves if they have been exposed to motor oil, gasoline, or any petroleum-based product. Do not use petroleum jelly with latex gloves. Wear double gloves if there is substantial bleeding. You may also wear double gloves if you will be exposed to large volumes of other body fluids. Be sure to change gloves as you move from patient to patient. For cleaning and disinfecting the unit, you should use heavy-duty utility gloves **Figure 2-10**. You should never use lightweight latex or vinyl gloves for cleaning.

Figure 2-9 Use a waterless handwashing solution if running water is not available. Be sure to wash your hands with soap and water once you arrive at the hospital.

Figure 2-10 Use heavy-duty utility gloves to clean the unit. You should not use lightweight latex or vinyl gloves for cleaning.

Removing used latex or vinyl gloves requires a methodical technique to avoid contaminating yourself with the materials on the outside of the gloves. Skill Drill 2-1.

1. Begin by partially removing one glove. With your other gloved hand, pinch the first glove at the wrist—being certain to touch only the outside of the first glove—and start to roll it back off your hand, inside out. Leave the exterior of the fingers on that first glove exposed Step 1.
2. Use the gloved fingers to pinch the wrist of the second glove and begin to pull it off, rolling it inside out toward the fingertips as you did with the first glove Step 2.
3. Continue pulling off the second glove until you can pull the second hand free Step 3.
4. With your now-ungloved second hand, grasp the exposed inside of the first glove and pull it free of your first hand and over the now-loose second glove. Be sure that you touch only clean, interior surfaces with your ungloved hand Step 4.

Gloves are the most common type of personal protective equipment (PPE). In many EMS rescue operations, you must also protect your hands and wrists from injury. You may wear puncture-proof leather gloves, with latex gloves underneath. This combination will allow you free use of your hands with added protection from blood and body fluids. Remember that soiled latex or vinyl gloves are considered medical waste and must be properly disposed. Also remember many patients have life-threatening allergies to latex gloves. Leather gloves must be treated as contaminated material until they can be properly decontaminated.

Eye Protection and Face Shields

Eye protection is important in case blood splatters toward your eyes Figure 2-11. Blood splatters are a significant possibility in most trauma situations and many medical situations. Wearing goggles is your best protection. Providers who wear prescription eyeglasses will also need additional protection for their eyes. Prescription eyeglasses offer little side protection. Contact lenses do not offer any added protection from splashing. Face shields will also provide good eye protection Figure 2-12.

Skill Drill 2-1 Proper Glove Removal Technique

Step 1

Partially remove the first glove by pinching at the wrist. Be careful to touch only the outside of the glove.

Step 2

Remove the second glove by pinching the exterior with your partially gloved hand.

Step 3

Pull the second glove inside out toward the fingertips.

Step 4

Grasp both gloves with your free hand, touching only the clean, interior surfaces.

Gowns

Occasionally, you may need to wear a gown. A gown provides protection from extensive blood splatter. Gowns may be worn in situations such as field delivery of a baby or major trauma. However, wearing a gown may not be practical in many situations. In fact, in some instances, a gown may pose a risk for injury. Your department will likely have a policy regarding gowns. Be sure you know your local policy. There are times when a change of uniform is preferred because trying to clean off contaminants is difficult and sometimes impossible without professional cleaning and disinfection or disposing of the uniform entirely.

Figure 2-11 Wear eye protection to prevent blood splatter into your eyes.

Figure 2-12 The surgical mask/face shield combination.

Masks, Respirators, and Barrier Devices

Wearing masks is a complex issue, especially in light of OSHA and CDC requirements regarding protection from tuberculosis. You should wear a standard surgical mask if blood or body fluid spatter is a possibility. If you suspect a patient has an airborne disease, you should place a surgical mask on the patient. However, if you suspect the patient has tuberculosis, place a surgical mask on the patient and a particulate air respirator, such as an N95 mask, on yourself **Figure 2-13**. If the patient needs oxygen, place a nonrebreathing mask instead of a surgical mask on the patient and set the oxygen flow rate at 10 to 15 L/min. Do not place a particulate respirator on the patient; it is unnecessary and uncomfortable. A simple surgical mask will reduce the risk of transmission of germs from the patient into the air. Use of a particulate respirator should comply with OSHA standards, which state facial hair, such as long sideburns or a mustache, will prevent a proper fit. Particulate respirators must be fit-tested to ensure their efficacy.

Although there are no documented cases of disease transmission to rescuers as a result of performing unprotected mouth-to-mouth resuscitation on a patient with an infection, you should use a pocket mask or bag-valve mask **Figure 2-14**. Mouth-to-mouth resuscitation is rarely necessary in a work situation.

Remember, outside surfaces of these devices are considered contaminated after they have been exposed to the patient. You must make sure gloves, masks, gowns, and all other PPE items that have been exposed to infectious processes or blood are properly disposed of according to local guidelines. If you are stuck by a needle, get blood or body fluids in your eye, or have significant body fluid contact with the patient, immediately report the incident to your supervisor.

Figure 2-13

Wear a particulate respirator if you treat a patient you suspect has tuberculosis.

Figure 2-14 Barrier devices such as a pocket mask provide protection when providing mouth-to-mask ventilation.

© Bart_J/ShutterStock.

Proper Disposal of Sharps

Be careful when handling needles, scalpels, and other sharp items. The spread of HIV and hepatitis in the health care setting can usually be traced back to careless handling of sharps.

- Do not recap, break, or bend needles. Even the most careful providers may expose themselves through an accidental needlestick.
- Dispose of all sharp items that have been in contact with human secretions in approved, closed, rigid containers Figure

2-15.

Employer Responsibilities

Your employer cannot guarantee a 100% risk-free environment. The risk of being exposed to a communicable disease is a hazard of your job. You have a right to know about diseases that may pose a risk to you. Remember, though, your risk for infection is not high; however, OSHA regulations, especially for private and federal agencies, require that all employees be offered a workplace environment that reduces the risk for exposure. Note, in some states that have their own OSHA plans, state and municipal employees must also be covered.

Figure 2-15 Properly dispose of sharps in a closed, rigid, marked container.

In addition to OSHA guidelines, other national guidelines and standards, including those from the CDC and National Fire Protection Agency (NFPA) Infection Control Standard 1581, address reducing the risk of exposure to bloodborne pathogens (disease-causing organisms) and airborne diseases. These agencies set a standard of care for all fire and EMS personnel and apply whether you are a full-time paid employee or a volunteer. It is your responsibility to know your department's infection control plan and to use it Table 2-4.

▶ Establishing an Infection Control Routine

Infection control should be an important part of your daily routine. Follow the steps in Skill Drill 2-2 to manage potential exposure situations:

1. En route to the scene, make sure that PPE is out and available Step 1.
2. On arrival, make sure the scene is safe to enter, then perform a rapid scan of the patient, noting whether any blood or body fluids are present.

3. Select the proper PPE according to the tasks you are likely to perform. Typically gloves will be used for all patient contacts **Step 2**.

Table 2-4 Components of an Infection Control Plan

Determination of Exposure Risk

- Determines who is at risk for ongoing contact with blood and other body fluids
- Creates a list of tasks that pose a risk for contact with blood or other body fluids
- Includes personal protective equipment (PPE) required by OSHA

Education and Training

- Explains why a qualified individual is required to answer questions about communicable diseases and infection control, rather than relying on packaged training materials
- Allows for an instructor able to train EMTs regarding bloodborne and airborne pathogens, such as hepatitis B and C, human immunodeficiency virus, syphilis, and tuberculosis
- Ensures the instructor provides appropriate education, which is the best means for dispelling many myths surrounding these issues

Hepatitis B Vaccine Program

- Describes the vaccine offered, its safety and efficacy, record keeping, and tracking
- Addresses the need for postvaccine antibody titers to identify patients who do not respond to the initial three-dose vaccination series

Personal Protective Equipment (PPE)

- Lists the PPE offered and why it was selected
- Lists how much equipment is available and where to obtain additional PPE
- States when each type of PPE is to be used for each risk procedure

Cleaning and Disinfection Practices

- Describes how to care for and maintain vehicles and equipment
- Identifies where and when cleaning should be performed, how it is to be done, what PPE to use, and what cleaning solution to use
- Addresses medical waste collection, storage, and disposal

Tuberculin Skin Testing/Fit Testing

- Addresses how often employees should undergo skin testing
- Addresses how often fit testing should be done to determine the proper size mask to protect the EMT from tuberculosis
- Addresses all issues dealing with particulate respirator masks

Postexposure Management

- Identifies who to notify when an exposure occurs, forms to be filled out, where to go for treatment, and what treatment to give

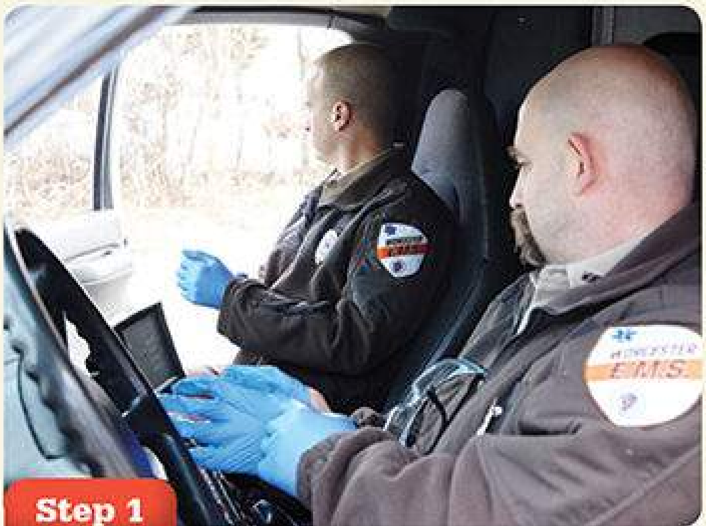
Compliance Monitoring

- Addresses how the service or department evaluates employee compliance with each aspect of the plan
- Ensures employees understand what they are to do and why it is important
- States that noncompliance should be documented
- Indicates what disciplinary action to take in the face of continued noncompliance

Record Keeping

- Lists all records to keep, how confidentiality will be maintained, and how, when, and by whom records can be accessed

Skill Drill 2-2 Managing a Potential Exposure



© Jones & Bartlett Learning.

Step 1

En route to the scene, make sure that PPE is out and available.

© Jones & Bartlett Learning.

Step 2

On arrival, make sure the scene is safe to enter, then perform a rapid scan of the patient, noting whether any blood or body fluids are present. Select the proper PPE according to the tasks you are likely to perform. Typically, gloves will be used for all patient contacts.

4. Change gloves and wash hands between patients; don PPE as quickly as possible to minimize time spent before initiating care. Remove gloves and other gear after contact with the patient, unless you are in the patient compartment. Remember that good hand hygiene is always necessary.
5. Limit the number of people who are involved in patient care if there are multiple injuries and a substantial amount of blood at the scene.
6. If you or your partner is exposed while providing care, try to relieve one another as soon as possible so that you can seek care, including basic first aid care such as cleaning and dressing a wound. Notify the designated officer and report the incident. This will also help to maintain confidentiality for both the patient and for you.

Be sure to routinely clean the ambulance after each run and on a daily basis. Cleaning is an essential part of the prevention and control of communicable diseases, ensuring removal of surface organisms that may remain in the unit. You should clean your unit as quickly as possible so it can be returned to service. Address the high-contact areas, including surfaces that were in direct contact with the patient's blood or body fluids or surfaces that you touched while caring for the patient after having contact with the patient's blood or body fluids. More information about decontaminating the ambulance can be found in Chapter 37, *Transport Operations*.

Whenever possible, cleaning should be done at the hospital. If you clean the unit back at the station, make sure you have a designated area with good ventilation. Any medical waste should be put in a red biohazard bag and disposed of at the hospital whenever possible. Any contaminated equipment that is left with the patient at the hospital should be cleaned by hospital staff or put in a red bag for transport and cleaning at the station.

You can use a bleach and water solution at a 1:10 dilution to clean the unit. The solution you mix should not have a strong odor of bleach if mixed correctly. A hospital-approved disinfectant that is effective against *Mycobacterium tuberculosis* can also be used. Use the cleaning solution in a bucket or use a pistol-handled spray container. Do not use alcohol or aerosol spray products to clean the unit. Pay attention to disinfectant directions.

Bleach solutions and most disinfectant agents will require air drying to be effective. Do not routinely go back over sprayed surfaces and dry them. Allow the sprayed surfaces to air dry unless otherwise indicated in the product directions.

Remove contaminated linen and place it into an appropriate bag for handling. Each hospital may have a different system for handling contaminated linen; you should learn hospital or department protocols Figure 2-16.

Figure 2-16 Contaminated linen and other wastes should be bagged appropriately and disposed of according to your local protocols.

Any reusable medical equipment should be properly cleaned and sterilized per your department's standard operating procedures. Keep in mind that in hospitals entire departments are devoted to sterilizing medical instruments. Proper sterilization requires the right tools and the right skills, so always carefully follow your department's procedures.

Learn the regulations defining medical waste in your area. The disposal of infectious waste, such as needles, sharps, and heavily soiled dressings, may vary from hospital to hospital and from state to state.

Immunity

Even if germs do reach you, you are not necessarily at risk for infection. For example, you may be **immune**, or resistant, to those particular germs. Immunity is a major factor in determining which **hosts** (the organism or the individual that is attacked by the infecting agent) become ill from which germs Table 2-5. One way to gain immunity from many diseases today is to be immunized, or vaccinated, against them. Vaccinations have almost eliminated some childhood diseases, such as measles and polio.

Another way in which the body becomes immune to a disease is to recover from an infection from that germ. Afterward, the body's immune system recognizes and repels that germ when it shows up again. Once exposed, healthy people will develop lifelong immunity to many common pathogens. For example, a person who contracts and becomes infected with the hepatitis A virus may be ill for several weeks, but because immunity will develop, the person will not get the illness again; however, sometimes, the immunity is only partial. Partial immunity protects against new infections. But germs that remain in the body from the first illness may still be able to cause the same disease again when the body is stressed or has some impairment in its immune system. For example, tuberculosis can cause a mild, unnoticeable infection before the body builds up a partial immunity. If the infection is never treated, the infection may be reactivated when immunity is weakened; however, these people are protected against a new infection from another person.

YOU are the Provider — PART 2

You arrive at the scene, enter the residence, and find two EMRs performing cardiopulmonary resuscitation (CPR) on the child, a 4-year-old girl. The child's mother tells you that when she went to wake up her daughter, she was unconscious and not breathing. She called 9-1-1 and started CPR. Your partner quickly assesses the child and asks you to open the jump kit.

Recording Time: 0 Minutes	
Appearance	Cyanotic; motionless
Level of consciousness	Unconscious and unresponsive
Airway	Small amount of vomitus in her mouth
Breathing	Absent
Circulation	Carotid pulse, absent; skin, cool and cyanotic

With CPR continuing, your partner prepares the cardiac monitor and asks you to suction the child's mouth and manage her airway. You quickly and effectively accomplish your assigned task, but notice that you are sweating profusely and can feel your heart racing.

2. What is stress? How does it manifest?
3. What phase of the stress response are you experiencing right now?

Table 2-5 Immunity to Infectious Diseases

Type of Immunity	Characteristics	Examples	Comments
Lifelong	The illness will not recur.	Measles Mumps Polio Rubella Hepatitis A Hepatitis B	Infection or vaccination provides long-term immunity from getting a new infection. A live vaccine is required only for measles.
Partial	The person who has recovered from a first infection is unlikely to get a new infection from another person but may develop illness from germs that lie dormant from the initial infection.	Chickenpox Tuberculosis	Infection provides lifelong immunity to the patient from acquiring a new infection, but the original illness may recur, or it may recur in a different way. In the case of chickenpox, which is caused by the herpes zoster virus, an infection may recur years later in the form of shingles.
None	Exposure confers no protection from reinfection. The infection may wear down the patient's resistance.	Gonorrhea Syphilis Human immuno-deficiency virus (HIV) infection	No vaccine is available. Repeated infections are common. For example, there is effective immediate treatment for gonorrhea, and the germs may be eradicated; however, reinfection is likely if the high-risk practices continue (eg, unprotected sex). For syphilis, the lack of immunity allows the germs to continue to cause damage within the host.

Humans seem unable to mount an effective immune response to some infections, such as HIV, which is an infection with the human immunodeficiency virus that can progress to acquired immunodeficiency syndrome (AIDS).

Although hepatitis A immunization is not required by OSHA, you may wish to be vaccinated as a preventive measure. Hepatitis A vaccination is not necessary if you have had hepatitis A in the past. All these vaccines are effective and rarely cause side effects.

Remember, germs that cause no symptoms in one person may cause serious illness in another.

Immunizations

As an EMT, you are at risk for acquiring an infectious or communicable disease. Using basic protective measures can minimize the risk. You are responsible for protecting yourself, so take an active role in achieving that goal.

Prevention begins by maintaining your personal health. Annual health examinations should be required for all EMS personnel. A history of all your childhood infectious diseases should be recorded and kept on file. Childhood infectious diseases include chickenpox, mumps, measles, rubella, and whooping cough. You must be immunized against these diseases unless you already had the disease or have been previously vaccinated against it.

OSHA has developed requirements for protection from occupational exposure to bloodborne pathogens and needlesticks. Each employer whose employees may reasonably be expected to come in contact with blood or other potentially infectious materials must develop an infection control plan designed to minimize occupational exposure. As part of these requirements, employers are required to offer the hepatitis B vaccine at no cost to employees with risk of occupational exposure. Employees who decline the vaccine must sign a waiver indicating their refusal to take the vaccine and may later decide to take the vaccine at the employer's expense. Further, the CDC recommends the following immunizations for health care workers:

- Hepatitis B (as required by OSHA)
- Influenza (yearly)
- Measles, mumps, and rubella (MMR) (typically a one-time vaccination)
- Varicella (chickenpox) vaccine or having had chickenpox
- Tetanus, diphtheria, pertussis (Tdap) (every 10 years)

Most of these vaccinations are given to infants and children as part of their routine series of immunizations. It is imperative that you keep all these vaccinations up to date to help protect you as well as your family and patients. Health care workers who are routinely exposed to meningitis (often those who work in an institutional setting) should receive one dose of meningococcal vaccine.

Another vaccine being investigated is *Staphylococcus aureus*. This vaccine is not currently on the CDC list of recommended vaccines, but may be included soon. You should also have a skin test for tuberculosis before you begin working as an EMT. The purpose of this test is to identify anyone who has been exposed to tuberculosis in the past. Testing should be repeated yearly.

If you know you will be transporting a patient who has a communicable disease, you have a definite advantage. This is when information in your health record will be valuable. If you have already had the disease or been vaccinated, you are not at risk. However, you will not always know whether a patient has a communicable disease. Therefore, you should always follow standard precautions if there is the possibility of exposure to blood or other body fluids.

General Postexposure Management

The likelihood of you becoming infected during routine patient care is low. In the event that you are exposed to blood or other body substances despite all of your precautions, there are still preventative measures that you can take to protect your health. If you are exposed to a patient's blood or bodily fluids, first turn over patient care to another EMS provider. When it is safe to do so, clean the exposed area with soap and water. If your eyes were exposed, rinse them with water for at least 20 minutes as soon as possible.

Next, activate your department's infection control plan. This usually involves contacting a supervisor or your department's infection control officer to assist you. This person will help you to navigate the postexposure protocols.

You will need to be screened to determine if there was a significant exposure to possible bloodborne pathogens. Just because you were exposed to a patient's blood or body fluids does not mean that there is a risk of infection. Typically, you will need a follow-up evaluation by a physician to determine if a significant exposure occurred. If the exposure was significant, blood may be drawn from both you and the patient to determine if any infectious agents were present.

You will have to complete an exposure report. Questions in the report may include: When did the event happen? What were you doing when you were exposed? What did you do after you were exposed? Completing this paperwork will help relay critical information to the right people, resulting in help for you and possibly new protocols to help prevent another incident in the future.

Time is important! If you are exposed, let your supervisor or infection control officer know immediately. Some diseases will act quickly whereas others may lay dormant for a long time. The best way to reduce your risk of contracting a work-related disease is through early activation of your department's infection control plan.

Words of Wisdom

You should be aware of the procedures you are required to follow if you are involved in an exposure during your clinical or field experience. If you don't know, ask your instructor.

Scene Safety

The personal safety of all those involved in an emergency situation is very important. In fact, it is so important that it is best you internalize the steps necessary to preserve personal safety so your actions become automatic. A scene that appears safe initially can develop into a hazardous situation at any moment. Take care to notice any suspicious person or activity at the scene, as your first priority is your own safety. A second accident at the scene or an injury to you or your partner creates more problems. Delays in emergency medical care for patients increase the burden on other EMTs and may result in unnecessary injury or death.

You should begin protecting yourself as soon as you are dispatched. Before you leave the scene, begin preparing yourself mentally and physically. Make sure you wear seat belts (including both the lap belt and shoulder harness) en route to the scene. Also make sure to wear seat belts and shoulder harnesses at all times during transport unless patient care makes it impossible **Figure 2-17**. Don the appropriate PPE prior to departing the ambulance. Many EMS units have mandatory seat belt policies for the driver at all times, for all EMTs during transit to the scene, and for anyone who is riding with a patient.

Safety Tips

An important safety measure is to always wear seat belts in the ambulance, including when you are en route to the scene and during transport.

Protecting yourself at the scene is also very important. A second accident may damage the ambulance and may result in injury to you, your partner, or additional injury to the patient. The scene must be well marked **Figure 2-18**. If law enforcement has not already done so, you should make sure the proper warning devices are placed at a sufficient distance from the scene. This will alert motorists coming from both directions that a crash has occurred. When you must work in a traffic lane, park a heavy vehicle such as a fire engine (if available) in a position that blocks traffic in the lane where you are working. Park the ambulance at a safe but convenient distance from the scene. Before attempting to access patients who are trapped in a vehicle, check the vehicle's stability. Then take any necessary measures to secure it. Do not rock or push on a vehicle to find out whether it will move. This can overturn the vehicle or send it crashing into a ditch. If you are uncertain about the safety of a crash scene, wait for appropriately trained personnel to arrive before approaching.

Figure 2-17 Wear seat belts and shoulder harnesses whenever you are riding in the ambulance, including when you are responding on a call.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

When working at night, you must have plenty of light. Poor lighting increases the risk of injury to both you and the patient. It also results in poor emergency medical care. Wearing reflective emblems or clothing will help to make you more visible at night and decrease your risk of injury **Figure 2-19**.

Scene Hazards

In the course of your career as an EMT, you will be exposed to many hazards. Some situations will be life threatening. In these cases, you must be properly protected, or you must take steps to avoid the hazard completely.

Hazardous Materials

Your safety is the most important consideration at a hazardous materials incident. On your arrival, you should look at the scene and try to read any labels, placards, and identification numbers from a distance, perhaps using binoculars. Placards are used on transportation vehicles and buildings, and labels are used on individual packages containing hazardous materials. The placards or labels are colored and diamond-shaped **Figure 2-20**. You should never approach any object marked with a placard or label. Remember, some hazardous materials may not be properly marked.

Figure 2-18 Make sure the crash scene is well marked to prevent a second crash that may damage the ambulance or result in injury to you, your partner, or the patient.

Figure 2-19 The ANSI (American National Standards Institute) and ISEA (International Safety Equipment Association) require EMS personnel to wear reflective vests or clothing that meet Class 2 or 3 standards on roadways. You can also wear emblems or clothing to help make you more visible at night and improve your safety in the dark.

A specially trained and equipped hazardous materials team will be called to the scene to handle disposal of materials and removal of patients. You should not begin caring for patients until they have been moved away from the scene and are decontaminated or the scene is safe for you to enter.

The US Department of Transportation (DOT) Emergency Response Guidebook isan important resource when dealing with a hazardous materials incident **Figure 2-21**. It lists common hazardous materials and the proper procedures for scene control and the emergency care of patients. Some state and local government agencies may also have information about hazardous materials commonly present in their areas. A copy of the guidebook and other information relevant to your area should be available in your unit or at the dispatch center; you can also download a copy at the US DOT Pipeline and Hazardous Materials Safety Administration website. With these references, you should be able to begin proper emergency management as soon as the hazardous material is identified. Do not go into an area and risk exposure to yourself or your partner.

Safety Tips

There are all kinds of things that can injure you when you are caring for patients. Your best protection against being injured is to carefully size up the scene and constantly check for potential hazards. Don't be foolish and blindly rush in before conducting a proper assessment.

The following are general guidelines you should follow when dealing with scenes involving hazardous materials:

- Do not enter the scene if there is evidence of hazardous materials.
- Remain upwind and uphill of the scene.

- Keep your distance. This may mean retreating if you become aware of the true nature of the situation.
- Quickly contact dispatch.
- Request additional resources.
- Do not enter the scene until instructed to by trained hazardous materials responders.

Electricity

Electrical shock can be produced by human-made sources (power lines) or natural sources (lightning). No matter what the source, you must evaluate the risk to you and your patient before you begin patient care.

Power Lines. Do not touch downed power lines. Dealing with power lines is beyond the scope of EMT training. You should mark off a danger zone around the downed lines. Energized, or live, power lines, especially high-voltage lines, behave in unpredictable ways. You need in-depth training to operate the equipment that is used in an electrical emergency. The equipment has specific storage needs and requires careful cleaning. Dirt or other contaminants can make this equipment useless or dangerous.

At the scene of a motor vehicle crash aboveground and below-grade power lines may become hazards. Disrupted overhead wires are usually a visible hazard. You must be very careful even if you do not see sparks coming from the lines. Visible sparks are not always present in charged wires. The area around downed power lines is always a danger zone. This danger zone extends well beyond the immediate accident scene.

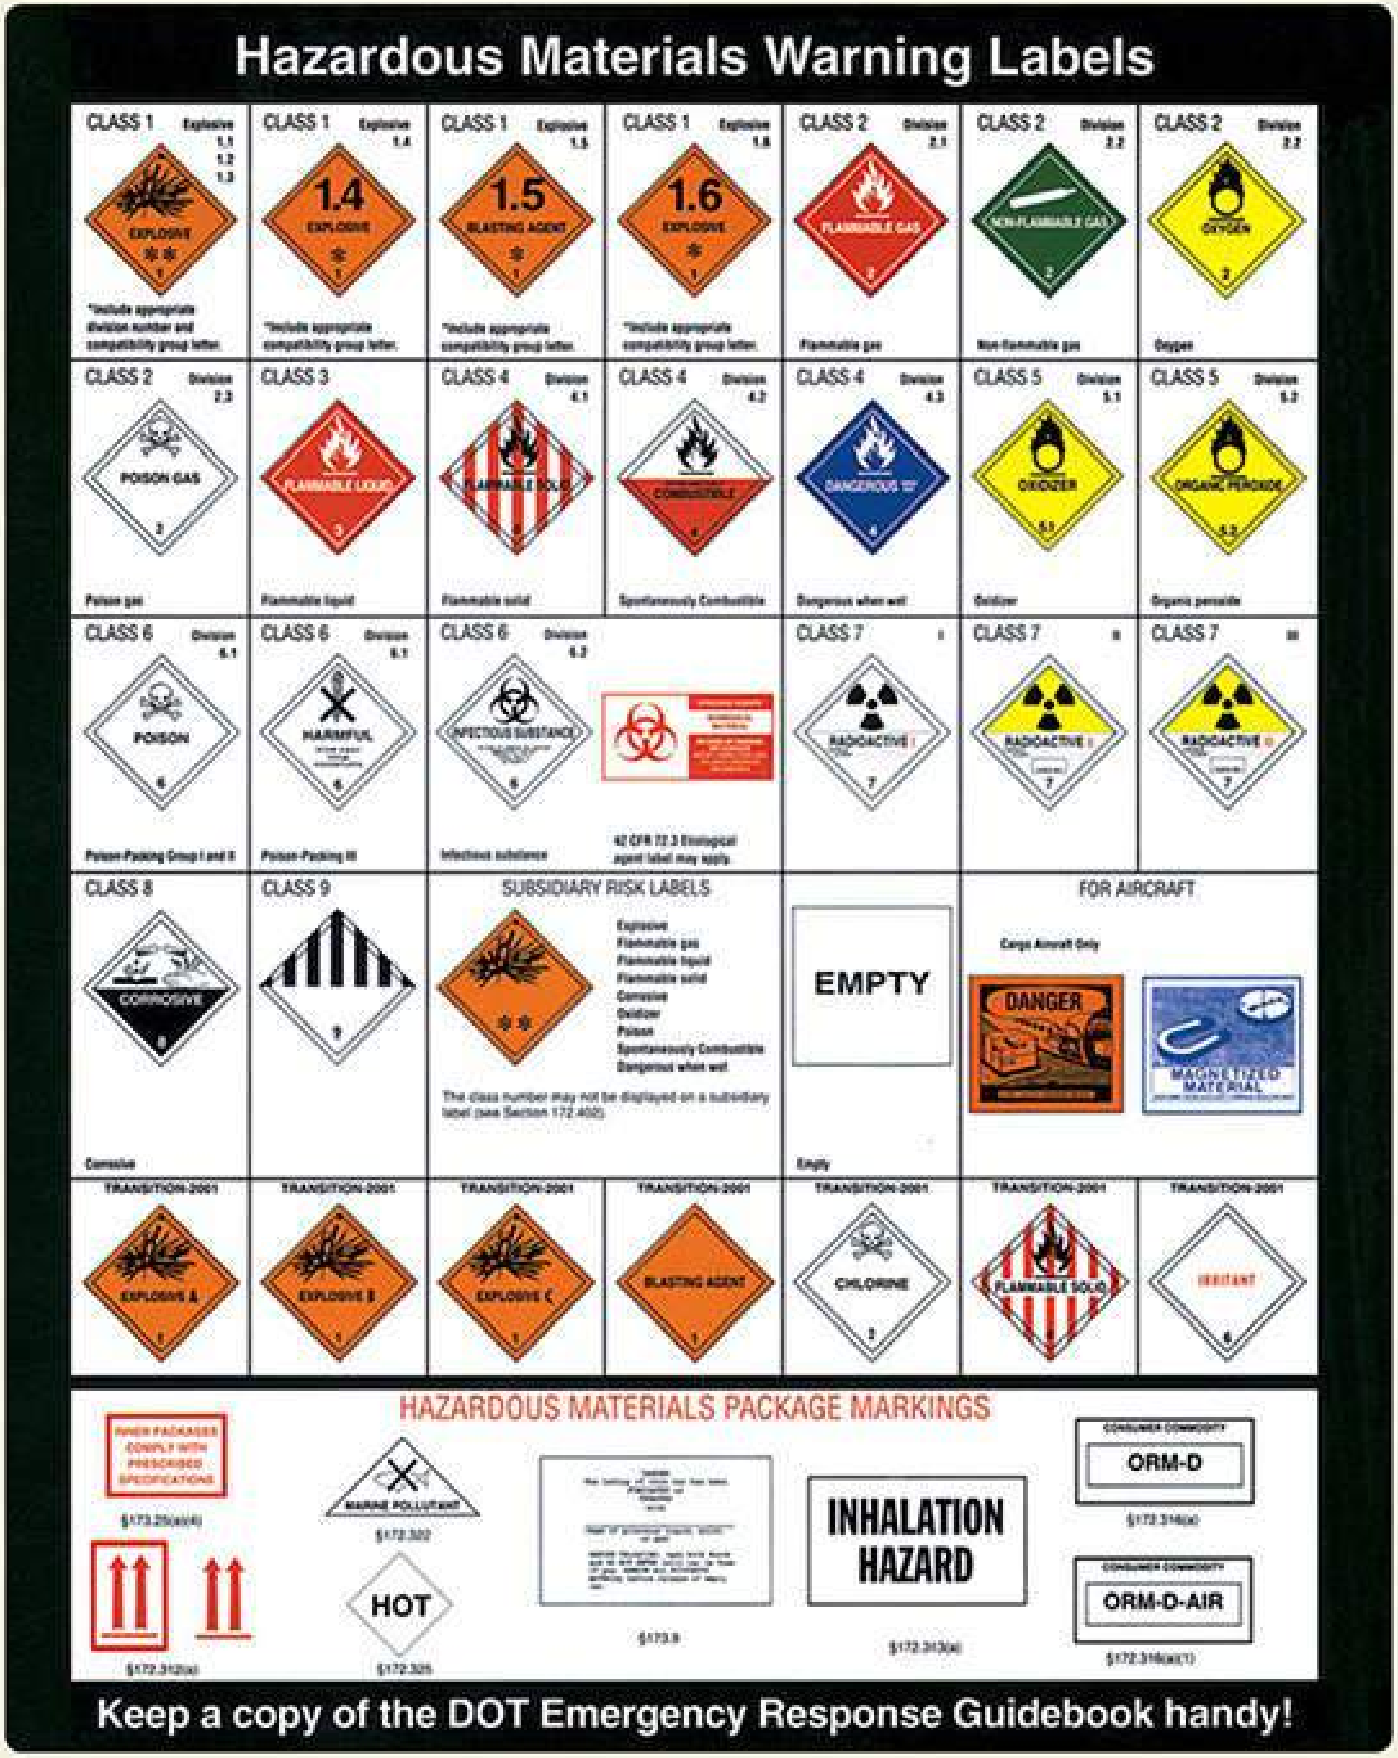


Figure 2-20 Hazardous materials safety placards and labels are colored and diamond-shaped.

Courtesy of the U.S. Department of Transportation.

Use the utility poles as landmarks for establishing the perimeter of the danger zone. The danger zone must be a restricted area. Remember, the safety zone is one span of the power pole's distance. Only emergency personnel, equipment, and vehicles are allowed inside this area. Do not approach downed wires or touch anything that downed wires are in contact with until qualified personnel have concluded that no risk of electrical injury exists. This may mean you are unable to access a severely injured victim of a motor vehicle crash even though you can see and talk to him or her.

If you must enter this type of situation, be sure to wear the proper protective equipment according to the type of incident. A helmet and turnout gear **Figure 2-22** are typically required, but you cannot count on turnout gear for protection from electrical hazards. Other protective equipment may be needed.

Lightning. Lightning is a complex natural phenomenon. It is unwise to think that lightning never strikes in the same place twice. If the right conditions remain, a repeat strike in the same area can occur.

Lightning is a threat in two ways: through a direct hit and through ground current. After the lightning bolt strikes, the current drains along the earth, following the most conductive pathway. Although you should avoid high ground to avoid a direct strike, to avoid being injured by a ground current, stay away from drainage ditches, moist areas, small depressions, and wet ropes. If you are involved in a rescue operation, you may need to delay rescue until the storm passes. Recognize the warning signs just before a lightning strike. As your surroundings become charged, you may feel a slight tingling sensation on your skin, or your hair may even stand on end. In this situation, a strike may be imminent. Move immediately to the lowest possible area.

If you are caught in an open area, make yourself the smallest possible target for a direct hit or for ground current. To avoid being hit by the initial strike, stay away from projections from the ground, such as a single tree. Drop all equipment, particularly metal objects, that project above your body. Avoid fences and other metal objects. These structures can transmit current from the initial strike over a long distance. Position yourself in a low crouch. This position exposes only your feet to the ground current. If you sit, both your feet and your buttocks are exposed. Place an object made of nonconductive material, such as a blanket, under your feet. Get inside a car or your unit, if possible, as vehicles will protect you from lightning.

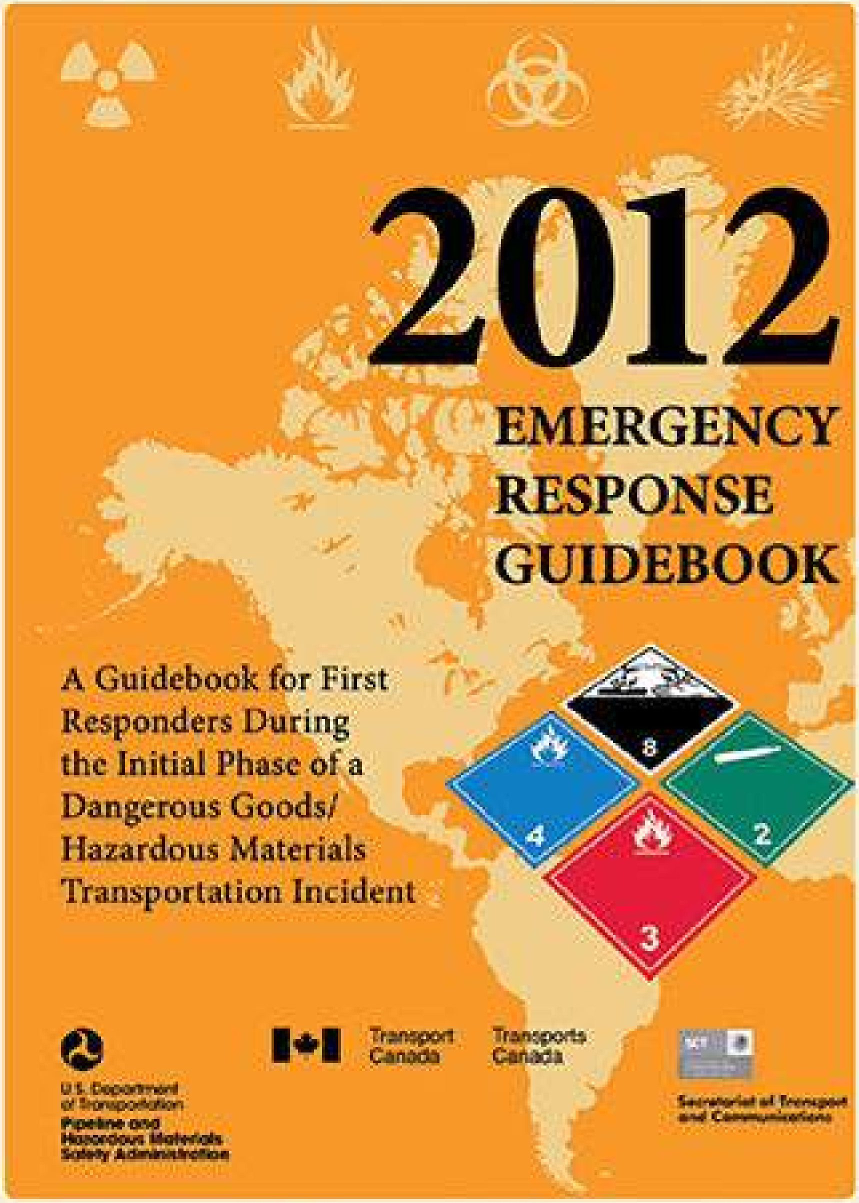

Figure 2-21 The DOT *Emergency Response Guidebook* lists many hazardous materials and the proper procedures for scene control and emergency care of patients.

Courtesy of the U.S. Department of Transportation.

Fire

You will often be called to the scene of a fire. Therefore, you should understand some basic information about fire, if you do not know it already. There are seven common hazards in a fire:

- Smoke
- Oxygen deficiency
- High ambient temperatures
- Toxic gases
- Building collapse
- Equipment
- Explosions

Figure 2-22 Wear a helmet made of a certified electrical nonconductor material, making sure that the chin strap is fastened securely.

Smoke is made up of particles of tar and carbon. These particles irritate the respiratory system on contact. Most smoke particles are trapped in the upper respiratory system, but many smaller particles enter the lungs. Some smoke particles not only irritate the airway, but may also be deadly. You must be trained in the use of appropriate airway protection, such as a disposable short-term device, or, if you are a fire fighter, a self-contained breathing apparatus, and have it available at all fire scenes **Figure 2-23**.

Fire consumes oxygen. Particularly in confined spaces fire may consume most of the available oxygen. This will make breathing difficult for anyone in that space. The high ambient temperatures in a fire can result in thermal burns and damage to the respiratory system. Breathing air that is heated above 120°F (49°C) can damage the respiratory system.

A typical building fire emits a number of toxic gases, including carbon monoxide, cyanide, and carbon dioxide. Carbon monoxide is a colorless, odorless gas that is responsible for more fire deaths each year than any other by-product of combustion. Carbon monoxide combines with the hemoglobin in your red blood cells about 200 times more readily than does oxygen. It blocks the ability of the hemoglobin to transport oxygen to your body tissues. Cyanide is a product of the combustion of many materials that burn. Inhaling cyanide prevents cells from using oxygen. In sufficiently high concentrations, it causes signs and symptoms of shock and severe hypoxia leading to death. Carbon dioxide is also a colorless, odorless gas. Exposure causes increased respirations, dizziness, and sweating. Breathing concentrations of carbon dioxide greater than 10% to 12% will result in death within a few minutes.

Figure 2-23 EMTs who are also fire fighters should be trained in the use of self-contained breathing apparatus and have it available if working near fire scenes.

During and after a fire, there is always a possibility that all or part of the burned structure will collapse. Often, there are no warning signs. As an EMS provider, you should never enter a burning building without proper breathing apparatus and approval. Always follow the instructions of the incident commander and safety officer at the scene, and never undertake any task (ie, enter a burning structure or initiate search and rescue) unless you have been properly trained to do so. Hasty entry into a burning structure may result in serious injury and possibly death. Once inside a burning building, you are subject to an uncontrolled, hostile environment. Fires are not selective about their victims. You must be extremely cautious whenever you are near a burning structure or one in which a fire has just been placed under control.

Fuel and fuel systems of vehicles that have been involved in crashes are also a hazard. Although this rarely happens, any leaking car fuel may ignite under the right conditions. If you see or smell a fuel leak, or people are trapped in the vehicle, you must coordinate appropriate fire protection equipment. Gasoline and other auto fluids are considered hazardous materials.

Make sure you are properly protected if there is or has been a fire in the vehicle. Wear appropriate respiratory protection and thermal protection because the smoke from a vehicle fire contains many toxic by-products. The use of appropriate protective gear at a crash scene can reduce your risk of injury. Avoid using oxygen in or near a vehicle that is smoking, smoldering, or leaking fuel.

Vehicle Crashes

Vehicle crashes are common events for EMS providers. These environments provide some of the most unstable and potentially lethal situations you will face. Traffic hazards are the first risk to consider. As you drive your ambulance to the scene of the crash, it is important to keep several things in mind. What is the flow of traffic near and around the crash? How will you safely leave and move about the scene? Ideally, you should park your ambulance in a manner where you can easily leave the scene. Keep in mind that additional fire, rescue, and police vehicles may also be parked in the same area or they may be blocking your exit. Hydraulic and hose lines are just two examples of common blockages you may encounter.

If you are the first to arrive at the scene, use the ambulance itself as a shield to protect the scene. The ambulance can be relocated for easier exit once additional help arrives. Park at least 100 feet away from all crash sites.

As you approach the scene, be very conscious about the flow of traffic. If needed, request police assistance to shut down the roadway. This will ensure a safe scene as you work with patients. Be aware of any fluids leaking from the vehicles because they can be flammable. A more common problem with leaking fluids is slipping and sliding on the roadway.

How is the vehicle positioned? Is it stable? Cars and trucks can come to rest in a wide array of positions. As the center of gravity of the vehicle is raised, its ability to fall onto you increases. The standard approach for all vehicle crashes should be for firefighters to first stabilize the vehicle to ensure safety for the passengers and any EMS providers.

Are there other hazards such as power lines? Downed lines can generate lethal electrical charges many feet away from vehicle crashes. If there are lines down, you should assume they are power lines, and do not approach. Call for additional resources to manage this hazard. Be aware that most electrical companies will not shut down power to the grid. Though this seems like a logical solution, many injuries can be caused by an unscheduled power outage. If people in their homes are on ventilators or other lifesaving medical devices, this could create another emergency situation when the power is shut off.

Look closer at the scene. Where are the occupants? Does violence appear to be present? Is there a good risk of violence? As you look at the vehicle, are there weapons inside? Do the passengers look suspicious? If you feel there may be violence or if violence is obvious, have the police dispatched to assist you.

With proper equipment and training, you may enter the vehicle itself. Air bags can be another hazard. If the air bag has not deployed, there is a risk that it may accidently activate while you are in the vehicle. Air bags are typically rendered inoperable by the fire department when the power is cut from the car battery.

Your protective clothing will help you to remain safe while working in and around the vehicle crash. The risk of injuries from glass and sharp metal objects cannot be underestimated. Make sure if you are working inside the vehicle you have sufficient protective gear.

Protective Clothing: Preventing Injury

Wearing protective clothing and other appropriate gear is critical to your personal safety. Become familiar with the protective equipment that is available to you. Then you will know what clothing and gear are needed for the job. You will also be able to adapt or change items as the situation and environment change. Remember, protective clothing and gear provide protection only when they are in good condition. It is your responsibility to inspect your clothing and gear. Learn to recognize how wear and tear can make your equipment unsafe. Be sure to inspect equipment before you use it; ideally, this is done before reaching the scene so care is not delayed.

Clothing that is worn for rescue must be appropriate for the activity and the environment where the activity will take place. For example, turnout gear worn for firefighting may be too restrictive for working in a confined space. In every situation involving blood and/or other body fluids, follow standard precautions. You must protect yourself and your patient by wearing gloves and eye protection, as well as any additional protective clothing that may be needed. EMS coats should provide a body fluids barrier if they were purchased after 1998.

Safety Tips

The American National Standards Institute (ANSI) requires all EMS providers to utilize a high-visibility public safety vest while on or near the roadway.

YOU are the Provider — PART 3

The cardiac monitor reveals the child does not have cardiac activity (asystole). With CPR ongoing, your partner intubates the child and an intravenous (IV) line is inserted. The child's mother, who is standing back watching your efforts, is crying and keeps yelling at you, "Why isn't my daughter waking up! Why aren't you saving her!"

Recording Time: 5 Minutes	
Respirations	Absent
Pulse	Absent
Skin	Cool and cyanotic

Blood pressure	Not obtainable
Oxygen saturation (Spo_2)	Not obtainable

4. How should you respond to the mother?
5. What stage of the grieving process is the mother experiencing?

Cold Weather Clothing

When dressing for cold weather, you should wear several layers of clothing. Multiple layers provide much better protection than a single thick cover. You have more flexibility to control your body temperature by adding or removing a layer. Cold weather protection should consist of at least the following three layers:

1. A thin inner layer (sometimes called the transport layer) next to your skin. This layer pulls moisture away from your skin, keeping you dry and warm. Underwear made of polypropylene or polyester material works well. Wool is the best fiber. The goal is to wick moisture away from the skin.
2. A thermal middle layer of bulkier material for insulation. Wool has been the material of choice for warmth, but newer materials, such as polyester pile, are also commonly used.
3. An outer layer that resists chilling winds and wet conditions, such as rain, sleet, or snow. The two top layers should have zippers to allow you to vent some body heat if you become too warm.

When choosing protective clothing, you should pay attention to the type of material from which it is made. Cotton should be avoided in cold, wet environments. Cotton tends to absorb moisture, causing chilling from wetness. For example, if you wear cotton trousers and walk through wet grass, the cotton soaks up the moisture from the grass. This will chill you in cold weather. However, cotton is appropriate in warm, dry weather because it absorbs moisture and pulls heat away from the body.

As an outer layer in cold weather, you might consider plastic-coated nylon, as it provides good waterproof protection. However, it can also hold in body heat and perspiration, which makes you wet both inside and out. Newer, less airtight materials allow perspiration and some heat to escape while the material retains its water resistance. Avoid flammable or meltable synthetic material anytime there is any possibility of fire.

Turnout Gear

Turnout or bunker gear is a fire service term for protective clothing designed for use in structural firefighting environments **Figure 2-24**. Turnout gear provides some protection by using different layers of fabric or other material to provide protection from the heat of fire. It also helps to reduce trauma from impact or cuts and keeps water away from the body. Like most protective clothing, turnout gear adds weight and reduces range of motion to some degree.

Figure 2-24 Turnout or bunker gear is protective clothing designed for use in firefighting.

The exterior fabrics provide increased protection from cuts and abrasions. They also act as a barrier to high external temperatures. In cold weather, an insulated thermal inner layer of material that helps to retain body heat is recommended.

Turnout gear or a bunker jacket provides minimal protection from electrical shock. However, it does protect you from heat, fire, possible flashover, and flying sparks. The front opening of the jacket should be fastened, and the jacket should be worn with the collar up and closed in front to protect your neck and upper chest. Proper fit is important so that you can move freely.

Gloves

Firefighting gloves provide the best protection from heat, cold, and cuts **Figure 2-25**. Yet these gloves reduce manual dexterity. In addition, firefighting gloves will not protect you from electrical hazards. In rescue situations, you must be able to freely use your hands to operate rescue tools, provide patient care, and perform other duties. Wearing puncture-proof leather gloves and latex gloves underneath will permit free use of your hands and offer added protection from both injury and body fluids.

Figure 2-25 Firefighting gloves protect your hands and wrists from heat, cold, and injury.

Helmets

You should wear a helmet any time you are working in a fall zone. A fall zone is an area where you are likely to encounter falling objects. The helmet should provide top and side impact protection. It should also have a secure chin strap **Figure 2-26**. Objects will often fall one after another. If the strap is not secure, the first falling object may knock off your helmet. This leaves your head unprotected as the remaining objects fall.

Construction-type helmets are not well suited for rescue situations. They offer minimal impact protection and have inadequate chin straps. Modern fire helmets offer impact protection. However, the projecting brim at the back of the neck may get in your way in a rescue situation. In cold weather, a great loss of body heat occurs if you are not wearing a hat or helmet. An insulated hat made from wool or a synthetic material can be pulled down over the face and the base of the skull to reduce heat loss in extremely cold weather.

You should always wear a helmet with a chin strap and face shield in situations involving electrical hazards. The shell of the helmet should be made of a certified electrical nonconductor. The chin strap should not stretch. In fact, it should fasten securely so the helmet stays in place if you are knocked down or a power line hits your head. You should also be able to lock the face shield on the helmet. This will protect your face and eyes from power lines and flying sparks. A standard fire turnout helmet should meet all of these needs.

Figure 2-26 A helmet with top and side impact protection.

▶ Boots

Boots should protect your feet. They should be water resistant, fit well, and be flexible so that you can comfortably walk long distances. If you will be working outdoors, you should choose boots that cover and protect your ankles, keeping out stones, debris, and snow. Steel-toed boots are preferred **Figure 2-27**. In cold weather, your boots must also protect you from the cold. Leather is one of the best materials for boots. However, other materials, such as any waterproof, windproof, and breathable fabrics, are also very good. The soles of your boots must provide traction. Lug-type soles may grip well in snow, but they become very slippery when caked with mud.

Figure 2-27 Boots should cover and protect your ankles keeping out stones, debris, and snow. Steel-toed boots are preferred.

Properly fitted boots and shoes are extremely important, because a minor annoyance can develop into a disabling injury. Painful blisters may develop if your feet slip around inside your boots, so, make sure you have enough room to wiggle your toes.

Boots should be puncture-resistant, protect the toes, and provide foot support. It may be difficult to obtain a good fit with firefighting boots; shoe inserts or sock layering may be needed to ensure a comfortable fit. Make sure the tops of your boots are sealed off to keep rain, snow, glass, or other materials from getting into your boots. Moisture increases blistering—wool or wicking socks help prevent feet from becoming wet.

Socks will keep your feet warm and provide some cushioning for you as you walk. In cold weather, two pairs of socks are generally preferable to one thick pair. A thin sock next to the foot helps to wick perspiration away to a thicker, outer sock. This tends to keep your feet warmer, drier, and generally more comfortable. When you purchase new shoes or boots, you may want to try them on while wearing the two pairs of socks to ensure a proper fit.

Eye Protection

The human eye is very fragile, and permanent loss of sight can occur from very minor injuries. You need to protect your eyes from blood and other body fluids, foreign objects, plants, insects, and debris from extrication. You may wear eyeglasses with side shields during routine patient care.

However, when tools are being used during extrication, you should wear a face shield or goggles. In these instances, prescription eyeglasses do not provide adequate protection. In snow or white sand, particularly at higher altitudes, you must protect your eyes from ultraviolet exposure. Specially designed eyeglasses or goggles can provide this. In addition, your eye protection must be adaptable to the weather and the physical demands of the task. It is critical that you have clear vision at all times.

Ear Protection

Exposure to loud noises for long periods of time can cause permanent hearing loss. Certain equipment, such as helicopters, some extrication tools, and sirens, produces high levels of noise. Wearing soft foam industrial-type earplugs usually provides adequate protection.

Skin Protection

Your skin needs protection against sunburn while you are working outdoors. Long-term exposure to the sun increases the possibility of skin cancer. It may be considered simply an annoyance, but sunburn is a type of burn. In reflective areas such as sand, water, and snow, your risk of sunburn increases. Protect your skin by applying a sunscreen with a minimum sun protection factor (SPF) of 15.

Body Armor

The policy for most departments directs EMTs to avoid situations that may involve gun violence. EMS responders in some areas wear body armor (bulletproof vests) for personal protection. Several types of body armor are available. They range from extremely lightweight and flexible to heavy and bulky. The lighter vests do not stop large-caliber bullets. However, they offer more flexibility and are preferred by most law enforcement personnel. Lighter vests are commonly worn under a uniform shirt or jacket. The larger, heavier vests are worn on the outside of your uniform. Vests may not be practical to wear on a daily basis. They are also costly, and do not protect against rifle ammunition or stabbing attacks.

Long/Loose Hair, Rings, Jewelry

You need to be careful wearing long, unsecured hair, loose rings, and jewelry. For example, these items can become caught in machinery during extrication. Due to the multitude of unusual situations in which EMTs may find themselves, many EMS services have restrictive policies regarding hair, rings, and jewelry. You should tie hair up neatly, limit the number of rings worn, and wear only a watch on the wrist.

Caring for Critically Ill and Injured Patients

When you are caring for a critically ill or injured patient, the patient needs to know who you are and what you are doing. Let the patient know you are attending to his or her immediate needs and these are your primary concerns at this moment **Figure 2-28**. As soon as possible, explain to the patient what is going on. Confusion, anxiety, and other feelings of helplessness will be decreased if you keep the patient informed from the start. Never assume a patient cannot hear you. Avoid making unprofessional comments during resuscitation, and treat all patients with dignity and respect.

Figure 2-28 Let the patient know immediately that you are there to help.

Responses of the Critical Patient

Patients who are dying as a result of trauma, an acute medical emergency, or a terminal disease will feel threatened. That threat may be related to their concern about survival. These concerns may involve feelings of helplessness, disability, pain, and separation Table 2-6.

Anxiety

Anxiety is a response to the anticipation of danger. The source of the anxiety is often unknown, but in the case of seriously injured or ill patients, the source is usually recognizable. What may increase the anxiety are the unknowns of the current situation. Patients may ask the following questions:

- What will happen to me?
- What are you doing?
- Will I make it?
- What will my disabilities be?

Patients who are anxious may have the following signs and symptoms:

- Emotional upset
- Sweaty and cool skin (diaphoretic)
- Rapid breathing (hyperventilating)
- Fast pulse (tachycardic)
- Restlessness

Table 2-6 Concerns of the Dying, Critically Ill, or Injured Patient

▪ Anxiety
▪ Pain and fear
▪ Anger and hostility
▪ Depression
▪ Dependency
▪ Guilt
▪ Mental health problems
▪ Receiving unrelated bad news

- Tension
- Fear
- Shakiness (tremulous)

For the anxious patient, time seems to be extended; seconds seem like minutes, and minutes seem like hours. Anxiety is never helpful to a patient and can cause real physiologic harm. It is your job to do everything you can to reduce your patient's anxiety and help your patient cope with what may be the most terrifying experience in his or her lifetime.

Pain and Fear

Pain and fear are closely interrelated. Pain is often associated with illness or trauma. Fear is generally thought of in relation to the oncoming pain and the outcome of the illness or trauma. It is often helpful to encourage patients to express their pains and fears, because expression begins the process of adjustment to the pain and acceptance of the emergency medical care that may be necessary. Some patients find it difficult to openly admit their fear. The fear may be expressed as bad dreams, withdrawal, tension, restlessness, butterflies in the stomach, or nervousness. In some cases, it may be expressed as anger.

Often you may be tempted to make light of a patient's pain and fear. It is easier to say to the stroke patient, "Oh, you'll be OK," than, "I'm sure you are really scared right now because you are not able to talk, but you should know I am doing everything I can to help you." Making a connection with your patient through eye contact and the squeeze of a hand can often do more to allay fear than the most eloquent words.

Anger and Hostility

You may find your patient is expressing anger with very demanding and complaining behavior. Often, this may be related to the fear and anxiety of the emergency medical care that is being given. In other situations, the fear is so acute that the patient may want to express anger toward you or others but is unable to do so because of the dependency factor. If you find you are the target of the patient's anger, make sure you are safe; do not take the anger or insults personally. Be tolerant, and do not become defensive.

Anger may also be expressed physically, and you may be the target of the displaced aggression. If the patient or a relative becomes so emotionally upset that you are physically assaulted or you believe this could happen, back out of the situation. Such hostility must be contained. If emergency medical care is not possible under these circumstances, law enforcement intervention is required.

Depression

Depression is a natural physiologic and psychologic response to illness, especially if the illness is prolonged, debilitating, or terminal. Whether the depression is a temporary sadness or clinical depression that is long-term, there is, of course, little you can do to alleviate the pain of depression during the brief time the patient is being treated and transported. The best you can do in treating and transporting a patient experiencing depression is to be compassionate, supportive, and nonjudgmental.

Dependency

Dependency usually takes longer to develop than during the very brief relationships developed in EMS. When medical care is given to any individual, a sense of dependency may develop. Patients who are placed in this position may feel helpless and become resentful. The resentfulness may arouse feelings of inferiority, shame, or weakness. Make every attempt to remain supportive and compassionate.

Guilt

Many patients who are dying, their families, or the caregivers of those patients may feel guilty over what has happened to them. Occasionally family members or long-term caregivers may feel a degree of relief when an extended illness is finally over. That relief may later turn into guilt. Most of the time, however, no one can explain these feelings.

The magnitude of the guilt may be very great. Sometimes, feelings of guilt can result in a delay in seeking emergency medical care. Again, understanding the complex emotions that often come to the surface during times of emergency and stress may help you cope with some of the intense and often seemingly bizarre behavior you will encounter in your role as an EMT.

Mental Health Problems

As an EMT, you will be called on to treat and transport patients with mental health problems. These problems may be the cause of the patient's distress or may be caused by the stresses of physical illness or injury. Mental health problems such as disorientation, confusion, or delusions may develop in the dying patient. In these instances, the patient may display behavior inconsistent with normal patterns of thinking, feeling, or acting. Common characteristics of such behavior may include the following:

- Loss of contact with reality
- Distortion of perception—patients may have difficulty judging such common factors as time, distance, and relationships
- Regression—patients may regress to an earlier stage in their development, often infancy or childhood
- Diminished control of basic impulses and desires—patients may act out on their urges without being able to exercise the normal judgment expected of adults. For example, patients may become violent or inappropriately affectionate.
- Abnormal mental content, including delusions and hallucinations

The normal course of dying can cause a patient to seem disoriented. In some long-term situations, generalized personality deterioration may occur (see Chapter 22, *Psychiatric Emergencies,* for a discussion on mental health).

Receiving Unrelated Bad News

A patient who is in critical condition or is dying may not want to hear unrelated bad news, such as the death of someone close to him or her. Such news may depress the patient or cause the patient to give up hope.

Techniques for Communicating With the Critical Patient

Avoid Sad and Grim Comments

EMTs, other safety personnel, family members, and bystanders must avoid making grim comments about a patient's condition. Remarks such as "This is a bad one" or "The leg is badly damaged, and I think he will lose it" are inappropriate. These remarks may upset or increase the patient's anxiety and compromise possible recovery outcomes. This is especially true for the patient who may be able to hear but cannot respond.

Orient the Patient

You should expect a patient to be disoriented in an emergency situation. The aura of the emergency situation—lights, sirens, smells, and strangers—is intense. The impact and effect of injuries or acute illness may cause the patient to be confused or unsettled. It is important for you to orient the patient to his or her surroundings **Figure 2-29**. Use brief, concise statements such as "Mr. Smith, you have had an accident, and I am now splinting your arm. I am John Foxworth of the New Britain

EMS; I will be caring for you."

Be Honest

When approaching any patient, you must decide how much information each patient is able to understand and accept. You should be honest without further shocking the patient or giving unnecessary information or information that may not be understood. Simply explain what you are doing, and allow the patient to be part of the care being given; this can relieve feelings of helplessness as well as some of the fear.

Initial Refusal of Care

On occasion you may encounter a patient who refuses emergency medical care and insists you do nothing or leave him or her alone. In these cases, it is important to impress upon the patient the seriousness of his or her condition without causing undue alarm. If you say, "Everything will be okay," when it is obvious that it is not okay, you are not being truthful. Generally, seriously ill or injured patients know they are in trouble; however, many people refuse care because of their inability to pay their medical expenses. Depending on department policy, the patient may be able to make payment arrangements.

Figure 2-29 The aura of an emergency situation can be confusing and frightening to the patient.

Allow for Hope

In trauma and acute medical conditions, patients may ask you whether they are going to die. At these times, you may feel at a loss for words. You may also know, on the basis of past experience or in view of the seriousness of the present situation, that the prognosis is poor. But it is not your decision to tell the patient that he or she is dying. Statements such as "I don't know if you are going to die; let's fight this one out together" or "I am not going to give up on you, so do not give up on yourself" can be helpful to the patient.

These statements transmit a sense of trust and hope, and they let the patient know you are doing everything possible to save his or her life. If there is the slightest chance of hope remaining, you want that message transmitted in your attitude and in the statements you make to the patient.

Locate and Notify Family Members

Many patients will be concerned and ask you to notify their family or others close to them. The patient may not be able to assist you in doing this. You should make sure an appropriate and responsible person makes an effort to locate the desired persons. Assuring the patient that someone is going to make these notifications may be a significant part of the patient's care because it will help to calm the patient.

Injured and Critically Ill Children

Injured and critically ill children who have life-threatening conditions should be cared for the same as any adult patient would, insofar as assessing airway, breathing, and circulation (ABCs) and addressing immediate life threats. Due regard should be given to variations in height, weight, and size when providing emergency medical care to pediatric patients. Because of the increased commotion and the extraordinary nature of the emergency scene for a child, it is important that a relative or responsible adult accompany the child at all times to relieve anxiety and assist in care as appropriate.

Dealing With the Death of a Child

The death of a child is a tragic and dreaded event. It will not be unusual for you to think about the fact that the dead or dying child still has a lot more to do in life and should have many more years to live. In our society, we assume only older people are supposed to die. Today, children die less frequently than they did in the past, so many people are unprepared for what they will feel when a child dies. You may think about your own children, related children, and children of close friends. And you may think, "Why should this child, who is only 5 years old, die?"

Answering the difficult questions of your own mortality will help you deal with the death of a child. Still, the death of a child will never be an easy subject to talk about. This will be especially so for the child's family, and as an EMT involved in a call that involves the death of a child, you will also likely experience stress.

One of your responsibilities may be to help the family through the initial period after the death. As an EMT, until more definitive and professional help can be arranged, you may be in the best position to help the family begin to cope with their loss. How a family initially deals with the death of a child will affect its stability and endurance. You can help a family through their initial period of grief and provide information about follow-up counseling and support services that are available.

Helping the Family

Whether the child has just died in your presence or was dead when you arrived, acknowledging the death is important. This should be done in a private place, even if that is inside an ambulance. Often, the parents cannot believe the death is real, even if they have been preparing for it, as in the case of a terminal illness such as leukemia.

Reactions vary, but shock, disbelief, and denial are common emotions and reactions. Some parents show little emotion at the initial news. If it is possible and appropriate, find a place where the mother and father can hold the child. This is important in the parents' grieving process; it helps to lessen the sense of disbelief and makes the death real. Even if the parents do not ask to see the child, you should tell them that they may do so. Your decision in permitting the parents to see the child may need some discretion on your part. For example, in the case of a traumatic death in which there is significant disfigurement of the body, that decision might have to be delayed. The delay may involve waiting for support services or contacting the family physician or others who can help the parents through this difficult situation. This situation may also involve preparing the parents for what they will see and the changes brought on by rigor mortis or asphyxiation, for example.

Sometimes, you do not need to say much. In fact, silence can sometimes be more comforting than words. You can express your own sorrow. Do not overload grieving parents with a lot of information; at this point, they cannot handle it. Nonverbal communication, such as holding a hand or touching a shoulder, may be more valuable. Let the family's actions be your guide to what is appropriate. If you sense the parents want to talk, it is important for you to encourage them to talk about their feelings.

Words of Wisdom

Patients don't care what you know until you show you care. Most patients are not technical experts. They will judge your treatment based on how you behave toward them.

Death and Dying

Life expectancy has dramatically increased. In fact over two-thirds of all deaths occur among those age 65 years and older. The number one cause of all deaths today is attributed to heart disease. According to the Centers for Disease Control and Prevention, from the age of 1 year to 44 years, trauma and unintentional injuries are the leading cause of death. Unlike in the past, the typical human encounter with death has changed. Death is less likely to occur in the home setting. Today, death occurs in the hospital, a hospice facility or a convalescent home, at the workplace, or on the highway, and death is likely to occur either quite suddenly or after a prolonged terminal illness. For these reasons, we are less familiar with death than our ancestors were. While we all know we are going to die someday, some time, we tend to deny death. Illness can be much more drawn-out and much more removed from daily life. Life support systems and impersonal care remove the whole experience of death from most people's awareness. The mobility of families also makes it less likely there will be extended family support when death does occur.

You may have significant painful personal experience with death. No matter what the frequency of response to emergency calls, death is something that every EMT will face at some time. For some of you, it may be infrequent. Others, in urban settings, may see death many times in responding to motor vehicle crashes, drug overdoses, suicides, or homicides. You may have to deal with the mass-casualty incident of an airplane crash or a hazardous materials incident. In all these situations, coming to grips with your thoughts, understandings, and adjustment to death is not only important personally, but also a function of delivering emergency medical care.

The Grieving Process

Everyone working as an EMT will experience grief at one time or another. This section discusses how to handle patient grief, as well as how to cope with your own grief that may result from a difficult call.

The death of a human being is one of the most difficult events for another human being to accept. If the survivor is a relative or close friend of the deceased, it is even more difficult. Emotional responses to the loss of a loved one or friend are appropriate and should be expected. In fact, it is expected you will feel emotional about the death of a patient. Feelings and emotions are part of the grieving process. All of us experience these feelings after a stressful situation that causes us personal pain.

In 1969, Dr Elisabeth KÃ¼bler-Ross published *On Death and Dying,* which revealed her theory on the stages of grief people go through. They are as follows:

1. **Denial.** Refusing to accept diagnosis or care, unrealistic demands for miracles, or persistent failure to understand why there is no improvement.
2. **Anger, hostility.** Projecting bad news onto the environment and commonly in all directions, at times almost at random. The person lashes out. Someone must be blamed, and those who are responsible must be punished. This is usually an ugly phase, and may even be inappropriately directed toward the EMT.
3. **Bargaining.** Attempting to secure a prize for good behavior or promising to change. "I promise to be a 'perfect patient' if only I can live until 'x' event."
4. **Depression.** Internalizing anger, hopelessness, and the desire to die. It rarely involves suicidal threats, complete withdrawal, or giving up long before the illness seems terminal. The patient is usually silent.
5. **Acceptance.** Accepting the impending death of the patient, or accepting the death of a loved one.

The stages may follow one another, occur simultaneously, or a person may jump back and forth between stages. The stages may last different amounts of time.

Even though the event (death) has not yet happened, the patient knows that it will happen. The patient has no control over this process. The patient will die whether or not he or she is ready to die. As an EMT, you may encounter situations in which the patient is close to death, and you may need to provide reassurance and emotional care.

YOU are the Provider — PART 4

The child is placed onto the stretcher and loaded into the ambulance. Her mother is secured in the front seat of the ambulance. One of the first responders drives the ambulance so that both you and your partner can continue attending to the child. With resuscitative efforts continuing, you depart the scene and proceed to the hospital. The child's condition is reassessed en route.

Recording Time: 11 Minutes

Level of consciousness	Unconscious and unresponsive
Respirations	Absent
Pulse	Absent
Skin	Cool and cyanotic
Blood pressure	Not obtainable
Spo_2	Not obtainable

6. How can poorly managed stress affect your physical well-being?
7. How can you mitigate the stress associated with the job?

What Can the EMT Do?

As patients and bystanders are grieving, you can do helpful things and make simple suggestions. Ask whether there is anything that you can do that will be of help, such as calling a relative or religious advisor. Provide gentle and caring support. Reinforcing the reality of the situation is important. This can be accomplished by merely saying to a grieving person, "I am so sorry for your loss." It is not important that you have a well-rehearsed script, for it is not likely that your exact words or consolations will be remembered. Being honest and sincere are important.

Some statements of consolation tend to be trite, and some suggest a kind of silver lining behind the clouds. Although they may be said with the intention of making the person feel better about a situation, they can also be viewed as an attempt to diminish the person's grief. The grieving person needs to be validated. Statements like these can indicate our inability to comprehend the profound sadness of grief because you have not experienced that kind of loss. If you have not experienced a death, it is okay to say so; do not pretend you have.

Attempts to take grief away too quickly are not good. If you do not know how the person really feels, you should not say so. People may be offended by responses that give advice or explanations about the death **Table 2-7**. Statements such as "Oh, you shouldn't feel that way" are judgmental. If you judge what the grieving person is feeling, it is likely that he or she will stop talking with you. People feel what people feel. It is as simple and clean as that. Remember, anger is a stage of grieving. The anger may be directed at you. The anger seems irrational to everyone but the person grieving; therefore, it is necessary that you maintain a professional attitude and let the person grieve in his or her own way.

Statements and comments that suggest action on your part are generally helpful. These statements imply a sense of understanding; they focus on the grieving person's feelings. It is not necessary to go into an extensive discussion. All you need to do is be sincere and say, "I am so sorry for your loss. I just want you to know that I am thinking about you." What people really appreciate is somebody who will listen to them. Simply ask, "Would you like to talk about how or what you are now feeling?" Then accept the response.

Table 2-7 Responding to Grief

Don't say . . .	Try instead . . .
Give it time. Things will get better.	I'm sorry for your loss.
You should not question God's will.	It is okay to be angry.
You have to get on with your life.	It must be hard to accept.
You have to keep on going.	That must be painful for you.
You can always have another child.	Tell me how you are feeling.
You're not the only one who suffers.	If you want to cry, it's okay.
The living must go on.	People really cared for . . .
I know how you feel.	

Dealing With the Patient and Family Members

There is no right or wrong way to grieve. Each person will experience grief and respond to it in his or her own way. Family members may express rage, anger, and despair. Many people will be rational and cooperative. Their concerns will usually be relieved by your calm, efficient manner. Your actions and words, even a simple touch, can communicate caring. While you must treat all patients with respect and dignity, use special care with dying patients and their families. Be concerned about their privacy and their wishes, and let them know you take their concerns seriously. However, it is best to be honest with patients and their families; do not give them false hope.

Stress Management on the Job

EMS is a high-stress job. Understanding the causes of stress and knowing how to deal with stress is critical to your job performance, health, and interpersonal relationships. To prevent stress from negatively affecting your life, you need to understand what stress is, its physiologic effects, what you can do to minimize these effects, and how to deal with stress on an emotional level.

Stress is the impact of stressors on your physical and mental well-being. Stressors include emotional, physical, and environmental situations or conditions that may cause a variety of physiologic, physical, and psychologic responses. The body's response to stress begins with an alarm response, followed by a stage of reaction and resistance, and then recovery or, if the stress is prolonged, exhaustion. This three-stage response is referred to as the general adaptation syndrome.

The physiologic responses involve the interaction of the endocrine and nervous systems, resulting in chemical and physical responses. This is commonly known as the fight-or-flight response. Positive stress, such as exercise, as well as negative forms of stress, such as shift work, long hours, or the frustration of losing a patient, all have the same physiologic manifestations. These include the following:

- Increased respirations and heart rate
- Increased blood pressure
- Dilated venous vessels near the skin surface (causes cool, clammy skin)
- Dilated pupils
- Tensed muscles
- Increased blood glucose levels
- Perspiration
- Decreased blood flow to the gastrointestinal tract

Situations that are stressful for EMS providers include the following:

- Dangerous situations
- Physical and psychologic demands
- Critically ill or injured patients
- Dead and dying patients
- Overpowering sights, smells, and sounds
- Multiple patient situations
- Angry or upset patients, family, bystanders
- Unpredictability and demands of EMS
- Noncritical/non-9-1-1 patients

As you examine this list, you will see some situations are clearly stressful: a car crash where a child is killed or a terrorist attack. Other situations may seem confusing. You may ask yourself why caring for noncritical patients is considered stressful. You need to manage a large array of patients. One person's definition of an emergency may be quite different from another's. As you begin your career in EMS, you may envision that all of your calls will be exciting life-and-death calls where you are able to save lives. In reality most patients are not critical and the care they need becomes rather routine. This can create stress in people who are unable to make the transition from the TV image of emergency medicine to its reality.

Words of Wisdom

As with most things in life, EMS comes down to balance. You need to understand that not all of the patients you care for will be critically ill or injured. This does not mean that they do not need care, only that they need a different kind of care. A thoughtful word or a hand on a shoulder can be powerful medicine. Care for each person, regardless of his or her complaint, as a person. Be satisfied with the rewards of simple compassion and you will find a home in EMS for many years to come.

A new stressor for those who work in EMS is hospital wait times. Emergency departments (EDs) around the country are dealing with greater numbers of patients. Coupled with shortages of personnel, including nurses, this increased patient load can lead to delays in care. This is where EMS comes into potential conflict. When the ambulance arrives at the hospital with a noncritical patient, the ED may not be able to accept the patient right away. As a result, you may need to sit for hours in the ED hallway, waiting for a bed to open up so your patient can be transferred. This situation can certainly generate stress.

Reactions to stress can be categorized as acute, delayed, or cumulative. **Acute stress reactions** occur during a stressful situation. You feel nervous and excited, and your ability to focus increases. This focus can be very helpful in managing a crisis situation. But if the stress of the situation becomes too great, you are at risk of being caught up in the emotional and physical reactions to stress. Picture stress as a wave in the ocean. If the crest of the wave is too high, you can potentially drown if the stress goes unrecognized and is not relieved.

Delayed stress reactions manifest after the stressful event. During the crisis, you are able to focus and function, but after things have calmed down, you may be left with nervous, excited energy that continues to build and becomes a distraction. With both acute and delayed reactions, the important question to ask yourself is how did you manage these feelings during the stressful event? Were you able to continue, managing the stress well and taking it in stride? Or, were you unable to manage the stress well, resulting in delayed stress reactions?

Cumulative stress reactions are the most important to understand. After the stressful event is over, are you able to shake off the effects? Are you still tired? Cumulative stress occurs when you are exposed to prolonged or excessive stress. You fight to remain in control and you are successful, but you are starting to grow tired. Now the next stressful situation occurs. Each time, you find it harder to recover because the effects of the previous stress are tiring.

Cumulative stress can have physical symptoms such as fatigue, changes in appetite, gastrointestinal problems, or headaches. It may cause insomnia or hypersomnia, irritability, inability to concentrate, and hyperactivity or underactivity. Additionally, it may present with psychologic reactions such as fear, dull or nonresponsive behavior, depression, guilt, oversensitivity, anger, irritability, and frustration. A fast-paced lifestyle compounds these effects by not allowing a person to rest and recover after periods of stress. Prolonged or excessive stress has been proven to be a strong contributor to heart disease, hypertension, cancer, alcoholism, and depression.

Many people are subject to cumulative stress, whereby insignificant stressors accumulate to a larger stress-related problem. In the emergency services environment (EMS, police, fire fighters), stressors may also be sudden and more severe. Some events are unusually stressful or emotional, even by EMS standards. These acute severe stressors result in what is referred to as critical incident stress. Events that can trigger critical incident stress include the following:

- Mass-casualty incidents
- Serious injury or traumatic death of a child
- Crashes with injuries, caused by an emergency services provider while responding to or from a call
- Death or serious injury of a coworker in the line of duty

Posttraumatic stress disorder (PTSD) may develop after a person has experienced a psychologically distressing event. It is characterized by reexperiencing the event and overresponding to stimuli that recalls the event. Stressful events in EMS are sometimes psychologically overwhelming. Some of the symptoms include depression, startle reactions, flashback phenomena, and dissociative episodes (eg, amnesia of the event).

A process called **critical incident stress management (CISM)** was developed to address acute stress situations and potentially decrease the likelihood that PTSD will develop after such an incident **Figure 2-30**. The process theoretically is used to confront the responses to critical incidents and defuse them, directing the emergency services personnel toward physical and emotional equilibrium. CISM can occur formally, as a debriefing for those who were on scene. In such situations, trained CISM teams of peers and mental health professionals may facilitate this. Additionally, CISM can occur at an ongoing scene in the following circumstances:

Figure 2-30 Critical incident stress management is sometimes used to help providers relieve stress.

- When personnel are assessed for signs and symptoms of distress while resting
- Before reentering the scene
- During a scene demobilization in which personnel are educated about the signs of critical incident stress and given a buffer period to collect themselves before leaving

Safety Tips

Coworkers often notice a change in behavior or attitude before a supervisor does. This is especially true in EMS, where close relationships develop between people who work together and share rooms, meals, and social interactions. Being a friend means helping a friend. Talk to your partner about changes in his or her behavior you may notice. If you are the EMT having trouble dealing with a crisis, remember, you are not alone. Talk with your partner.

Defusing sessions are the first to occur. These sessions are held during the event or immediately afterward. A group informally discusses events that they experienced together. Defusing sessions are designed to educate the participants as to the expectations over the next few days and give guidance on proper techniques to manage the feelings they may be experiencing. One example is to discourage drinking alcohol during this stressful time.

Debriefing sessions are held within 24 to 72 hours of a major incident. These meetings are held by a CISM team consisting of peers and mental health professionals. At the debriefing session, pent up emotions can be properly expressed. It is more likely you will be ready to express your emotions more freely a few days following the event.

One of the important rules associated with the debriefing session is to not turn it into an operational critique. No one is right. No one is wrong. No one is to blame. Only emotions about the specific event are to be relayed. These debriefing sessions may also have to be repeated at a later time.

CISM programs are located throughout the United States. You can locate a CISM in your area via the Internet, or it can be requested through your employer. The International Critical Incident Stress Foundation, Inc. is dedicated to limiting the effects of stress on EMS providers through education and support services. For more information, go to the Foundation's website at www.icisf.org.

CISM is an excellent service but not effective for everyone. Some providers are not receptive to openly discussing psychologically traumatic memories. When the individual's behavior is noticeably different after the event and CISM is not an option, private counseling by a mental health professional may be valuable.

Supporting patients in emergency situations is difficult. It is stressful for them and for you. You are vulnerable to all the stresses that go with your profession. It is critical that you recognize the signs of cumulative stress so it does not interfere with your work or life away from work, including your family life. The signs and symptoms of cumulative stress may not be obvious at first. Rather, they may be subtle and not present all the time Table 2-8.

Emotional Aspects of Emergency Care

At times, even the most experienced health care provider has difficulty overcoming personal reactions and proceeding without hesitation. You may have patients that need to be removed from life-threatening situations, or you need to provide life support measures to patients who are severely injured. You may also be called on to recover human remains from highway accidents, aircraft disasters, or explosions Figure 2-31. In all of these situations, you must be calm and act responsibly as a member of the emergency medical care team. You must also realize that even though your personal emotions must be kept under control, these are normal feelings. You must deal with these feelings. The struggle to remain calm in the face of horrible circumstances contributes to the emotional stress of the job.

Table 2-8 Warning Signs of Stress

- Irritability toward coworkers, family, and friends
- Inability to concentrate
- Difficulty sleeping, increased sleeping, or nightmares
- Feelings of sadness, anxiety, or guilt
- Indecisiveness
- Loss of appetite (gastrointestinal disturbances)
- Loss of interest in sexual activities
- Isolation
- Loss of interest in work
- Increased use of alcohol
- Recreational drug use
- Physical symptoms such as chronic pain (headache, backache)
- Feelings of hopelessness

Figure 2-31 As an EMT, you may be asked to recover and remove bodies from incident sites.

Stressful Situations

Many situations, such as mass-casualty scenes, serious vehicle crashes, excavation cave-ins, house fires, infant and child trauma, amputations, abuse of an infant, child, spouse, or older person, and the death of a coworker or other public safety personnel, will be stressful for everyone involved. During these situations, you must exercise extreme professional care in both your words and your actions at the scene. Words that do not seem important, or that are said jokingly, may hurt someone. Conversations at the scene must be professional. You should not say, "Everything will be all right," or "There is nothing to worry about." A person who is trapped in a wrecked car, hurting from head to foot and worried about a loved one, knows that all is not well. What will reassure the patient is your calm and caring approach to the emergency situation. Whether you are a brand new EMT or a seasoned veteran, patients expect you to bring some sense of order and stability to the terrifying chaos that has suddenly engulfed them. Briefly explain your plan of action to assist the patient in the crisis. Inform the patient that you need his or her help and the assistance of family members or bystanders to carry out your plan of action.

How a patient reacts to injury or illness may be influenced by certain personality traits. Some patients may become highly emotional over what may seem to be a minor problem. Others may show little or no emotion, even after serious injury or illness. Many other factors influence how a patient reacts to the stress of an EMS incident. Among these factors are the following:

- Socioeconomic background
- Fear of medical personnel
- Alcohol or substance abuse
- History of chronic disease
- Mental disorders
- Reaction to medication
- Age

- Nutritional status
- Feelings of guilt
- Past experience with illness or injury

You are not expected to always know why a patient is having an unusual emotional response. However, you can quickly and calmly assess the actions of the patient, family members, and bystanders. This assessment will help you to gain the confidence and cooperation of everyone at the scene. In addition, you should use a professional tone and show courtesy, along with sincere concern and efficient action. These simple considerations will go far to relieve worry, fear, and insecurity on the part of everyone involved. Your calm reassurance will inspire confidence and cooperation. Compassion is also important, but you must be careful. Your professional judgment takes priority over compassion. For example, suppose a screaming child with no obvious life-threatening injuries is covered with another patient's blood. This frightened child appeals to your sense of compassion and thus gets your attention. In the meantime, an unconscious, nonbreathing adult nearby could die from lack of care.

YOU are the Provider — PART 5

Full resuscitative efforts are continued en route; however, the child has failed to respond to appropriate advanced life support (ALS) and basic life support (BLS) treatment. The child is reassessed and a radio report is called in to the receiving facility.

Recording Time: 18 Minutes	
Level of consciousness	Unconscious and unresponsive
Respirations	Absent
Pulse	Absent
Skin	Cool and cyanotic
Blood pressure	Not obtainable
Spo_2	Not obtainable

The child is delivered to the emergency department (ED) and care is transferred to the attending physician. After an additional 15-minute period of resuscitative efforts in the ED, the child is pronounced dead. Later that evening, you find your paramedic partner in his dorm; he is crying and tells you he does not want to talk right now.

8. Does the death of a child affect the EMT or paramedic differently than the death of an adult? If so, how?
9. How can you help your partner?

Special Populations

When children are seriously ill or injured, family members and other people at the scene may be frantic. You should remain calm and confident in your skills because this may be all that is needed to provide reassurance to those at the scene.

Patients must be given the opportunity to express their fears and concerns. You can easily relieve many of these concerns at the scene. Usually, patients are concerned about the safety or well-being of others who are involved in the accident and about the damage or loss of personal property. Your responses must be discreet and diplomatic, giving reassurance when appropriate. If a loved one has been killed or critically injured, you should wait, if possible, until clergy or the ED staff can give the patient the news. They can provide the necessary psychological support the patient needs after receiving this type of news.

Words of Wisdom

Calm reassurance on your part will inspire confidence and cooperation. Compassion can also be an important component of your care, but you must be careful that your compassion does not misdirect you to provide inappropriate care. Your professional judgment needs to take priority.

Some patients, especially children and older adults, may be terrified or feel rejected when separated from family members by uniformed EMS providers. Other patients may not want family members to share their stress, see their injury, or witness their pain. It is usually best if parents are transported with their children and relatives accompany older patients. Medical attention for a child often requires adult consent. Treatment may be delayed if a caregiver is not transported with the child.

Religious customs or needs of the patient must also be respected. Some people will cling to religious medals or charms, especially if you make any attempt to remove them. Other people will express a strong desire for religious counsel, baptism, or last rites if death is near. You must try to accommodate these requests. Some people have religious convictions that strongly oppose the use of medications, blood, and blood products. If you obtain such information about your patient, it is imperative that you report it to the next level of care.

In the event of a death, you must handle the body with respect and dignity. It must be exposed as little as possible. Learn your local regulations and protocols about moving the body or changing its position, especially if you are at a possible crime scene. Even in these situations, CPR and appropriate treatment must be given unless there are obvious signs of death.

Uncertain Situations

There will be times when you are unsure whether a true medical emergency exists. In these cases, contact medical control about the need to transport. If you cannot reach medical control, it is always best to transport the patient. For both ethical and medicolegal reasons, a physician must examine all patients who are transported and judge the degree of medical need.

Words of Wisdom

It is always best to assure the patient is an active participant in the medical care he or she receives. Give your patient the information he or she needs to make an informed decision. You will find that patients who are participating in their own care are more likely to be satisfied with the care they receive.

You must also realize that even the most minor symptoms may be early signs of severe illness or injury in your patient. Symptoms of many illnesses can be similar to those of substance abuse, hysteria, or other conditions. You must accept the patient's complaints and provide appropriate care until you are able to transfer care of the patient to the next level (eg, paramedic, nurse, or physician). Your local protocols will direct your actions in these uncertain situations. When in doubt, err on the side of caution, acquire the patient's consent, and transport the patient to a medical facility.

Violent Situations

The safety of you and your team is of primary concern. Civil disturbances, large gatherings of hostile or potentially hostile people, domestic disputes, and crime scenes, especially those involving gangs, can create many hazards for EMS personnel. Several agencies will respond to large civil disturbances. In these instances, it is important for you to know who is in command and will be issuing orders **Figure 2-32**. However, you and your partner may be on your own when a group of people seems to grow larger and become increasingly hostile. In these cases, you should call law enforcement immediately if they are not already present. You may need to wait for law enforcement to arrive before you can begin treatment or safely approach a patient.

Remember, you and your partner must be protected from the dangers at the scene before you can provide patient care. Law enforcement must make sure the scene is safe before you and your partner enter. A crime scene often poses potential problems for EMS personnel. If the perpetrator is still somewhere on the scene, this person could reappear and threaten you and your partner or attempt to further injure the patient you are treating. Bystanders who are trying to be helpful may interfere with your emergency medical care. Family members may be very distraught and not understand what you are doing when you attempt to splint an injured extremity and the patient cries out that what you are doing hurts. Be sure you have adequate assistance from the appropriate public safety agency in these situations.

Sometimes EMTs will be at a scene where a dangerous situation is underway, such as a hostage situation or riot. In these instances, it may be necessary for you to be protected from projectiles such as bullets, bottles, and rocks. Law enforcement personnel will ordinarily provide for concealment or cover of personnel who are responding to the incident. **Cover** involves the tactical use of an impenetrable barrier for protection, while **concealment** involves hiding behind objects to limit a person's visibility of you. You should not be placed in a position that will endanger your life or safety during such incidents. Do not depend on someone else for your safety.

Figure 2-32 Several agencies may respond to a scene. It is important for you to know who is in command and will be issuing orders.

Remember, your personal safety is of the utmost importance. You must thoroughly understand the risks of each environment you enter. Whenever you are in doubt about your safety, do not put yourself at risk. Never enter an unstable environment, such as a shooting, a brawl, a hostage situation, or a riot. Therefore, as part of your scene size-up, evaluate the scene for the potential for violence. If further violence is a possibility, call for additional resources. Failure to do so may put you and your partner at serious risk. When appropriate, allow law enforcement personnel to secure the scene before you approach; they have the necessary experience and expertise in handling these situations.

It is important for you to remember that if you believe an event is a crime scene, you must attempt to maintain the chain of evidence. Make sure you do not disturb the scene unless it is absolutely necessary in caring for the patient.

Behavioral Emergencies

The category of behavioral emergencies covers a wide range of situations. This catchall phrase includes emergencies that do not have a clear physical cause and that result in unusual behavior. Often, the cause turns out to be physical; hypoglycemia, head trauma, hypoxia, and toxic ingestion can all cause altered mental status. Patients with psychiatric diseases, such as certain bipolar disorders or schizophrenia, may have altered sensorium or exhibit abnormal behavior.

Although most behavioral emergencies do not pose a threat to you, the potential of a threat to either the patient or yourself still exists and you should use caution.

Consider these questions as you evaluate the patient in terms of a behavioral or psychiatric emergency that may lead to a violent patient reaction:

- How does this patient respond to you? Are your questions answered appropriately? Are the patient's vocabulary and expressions what you would expect under the circumstances?
- Is the patient withdrawn or detached? Is the patient hostile or friendly? Overly friendly?
- Does the patient understand why you are there?

- How is the patient dressed? Is the dress appropriate for the time of the year and occasion? Are the clothes clean? Dirty?
- Does the patient appear relaxed, stiff, or guarded? Are the patient's movements coordinated or jerky and awkward? Is there hyperactivity? Are the patient's movements purposeful, for example, in putting on his or her clothes? Are the actions aimless, such as sitting and rocking back and forth in a chair?
- Has the patient harmed herself or himself? Is there damage to the surroundings?
- What are the patient's facial expressions? Are they bland or flat, or are they expressive? Does the patient show joy, fear, or anger to appropriate stimuli? If so, to what degree?

It might not be possible for you to gather all of the information that these questions suggest. Sometimes, a patient who is experiencing a behavioral emergency will not respond at all. In those cases, the patient's facial expressions, pulse and respirations, tears, sweating, and blushing may be significant indicators of his or her emotional state. Also see Chapter 22, *Psychiatric Emergencies*, which provides greater depth about psychiatric emergencies.

Workplace Issues

As our society continues to grow more culturally diverse, some groups that may have been satisfied in the past to accept and participate in the traditions of mainstream American cultural may seek instead to assert, preserve, and nurture their differences. And, as our society grows more culturally diverse, so do EMS workplaces. There will be challenges as these changes continue to occur. If you have any concerns working with any particular group of people, you need to address this before finishing your EMT training. You are required to provide an equal standard of care to all patients and also need to be able to work efficiently and effectively with other health care professionals from a variety of different backgrounds.

Cultural Diversity on the Job

Each individual is different, and you should communicate with coworkers and patients in a way that is sensitive to everyone's needs **Figure 2-33**. Look at cultural diversity as assets, and make the most of the differences among people in EMS, thus improving our ability to provide optimum patient care. As the public safety workplace becomes more culturally diverse, changes may occur that could be considered disruptive.

Figure 2-33 Communicate with coworkers in a way that is sensitive and respectful to individual differences.

Alternatively, failure to diversify the workforce in the face of a culturally diverse patient population can lead to cultural incompetence. Diversity is an effective way to strengthen a public safety workforce.

For many years, EMS and public safety have been dominated by Caucasian men. This trend is declining, as more women and minorities are working in public safety. The proactive EMT understands the benefits of using cultural diversity to improve patient care and expects to work alongside coworkers with varying backgrounds, attitudes, beliefs, and values and to accept their differences.

Cultural diversity in EMS allows you to enjoy the benefits of accentuating the skills of a broad range of people. When you accept each coworker as an individual, the need to fit them into rigid roles is eliminated. To be more sensitive to cultural diversity issues, you must first be aware of your own cultural background. Ask yourself, “What are my own issues relative to race, color, religion, and ethnicity?” Because culture is not restricted to different nationalities, you should also consider age, disability, gender, sexual orientation, marital status, work experience, and education.

In sports, you play to your team’s strengths. For example, in football, offensive lines have a fast side and a strong side, and they run plays toward either side depending on the situation. As part of an effective EMS team, you can make it part of your team’s culture to play to your strengths. This may be difficult to do, but once you begin the process, the benefits in terms of improved patient care are immeasurable.

It is important to strive for cultural competency with coworkers as well as patients. For example, some cultures avoid eye contact with others. Understanding the language, mannerisms, colloquialisms (eg, ordinary or local conversation), and practices that exist in the community you serve will make you a more effective EMT.

Your Effectiveness as an EMT

To be an effective EMT, you need to discover the diverse cultural needs of your coworkers, as well as your patients and their families. Although it is unrealistic to expect you to become a cross-cultural expert with knowledge about all ethnicities, you should learn how to relate effectively.

Teamwork is essential in public safety and EMS. To work effectively as a team, you need to communicate to resolve cultural diversity issues.

As a health care professional, you should strive to be a role model for new EMTs by showing them the value of diversity. If you are working with a coworker or patient from a particular cultural group, be aware of any opinion you may have formed about that group. Do not assume there is a language barrier, and do not appear patronizing by saying, “Some of my best friends are....” There are legitimate differences in how various cultures respond to stress. For example, you should be prepared to accept that people of different cultures might respond differently to the death of a loved one.

When you are working with patients or calling the hospital on the radio, other EMTs may be sensitive to how you treat patients from their cultural group. Therefore, when referring to patients, you should use the appropriate language. Avoid using terms such as, “cripple,” “deformed,” “deaf,” “dumb,” “crazy,” and “retard” to describe patients. The word “handicapped” even has a negative connotation. Instead, use the term “disabled,” and describe the specific disability.

You might want to consider taking multilingual training classes. This will not only be useful in communicating with your coworkers; it will also help improve communication with your patients and sensitize you to the cultural richness of the people who are using the language.

Even the perception of discrimination can weaken morale and motivation and negatively affect the goal of EMS. Therefore, to achieve the benefits of cultural diversity in the EMS workplace, you must understand how to communicate effectively with coworkers from various backgrounds.

Avoiding Sexual Harassment

The number of sexual harassment lawsuits skyrocketed in the 1990s because of increased media attention to the problem. Furthermore, guilty verdicts encouraged others to bring lawsuits concerning conduct that once would have gone unchallenged.

Sexual harassment is any unwelcome sexual advance, request for sexual favors, or other verbal or physical conduct of a sexual nature when submitting is a condition of employment, submitting or rejecting is a basis for an employment decision, or such conduct substantially interferes with performance and/ or creates a hostile or offensive work environment. Remember, even an overheard conversation can be construed as sexual harassment.

There are two types of sexual harassment: quid pro quo (the harasser requests sexual favors in exchange for something else, such as a promotion) and hostile work environment (jokes, touching, leering, requests for a date, talking about body parts).

Sexual harassment incidents include complaints of a hostile work environment. Remember, it does not matter the intent of the harasser. What matters is the perception of the act and the impact the behavior has on someone else. For many years, it was not uncommon to walk into a fire station and see sexually suggestive posters, calendars, or cartoons and to hear sexual jokes or comments. This situation is changing because it is not acceptable professional practice.

Because EMTs and other public safety professionals depend on each other for their safety, it is especially important for you to develop nonadversarial relationships with coworkers. Most EMS facilities and fire stations have separate bunkrooms for men and women. If this is not the case at your facility, you should discuss this with your supervisor and talk openly with coworkers of the opposite gender to allow for their privacy.

If you are concerned about a particular behavior, it may be helpful to ask yourself these questions: “Would I do or say this in front of my spouse, significant other, or parents?” “Would I want my family members to be exposed to this behavior?” “Would I want my behavior videotaped and shown on the evening news?”

If you have been harassed, you should report it according to local policy and procedure and keep notes of what happened and what was said. If you are asked to go out on a date, say, “I’m not interested.” If remarks or touching offend you, say, “Please don’t say/do that to me; it offends me.”

Substance Abuse

In the past, part of the fire service ritual was to go back to the fire station after the fire, clean and maintain the equipment, and discuss the call. At some locations, having a few beers was not uncommon. EMS today is very different from the ambulance service of 20 years ago.

Drug and alcohol use in the workplace causes an increase in accidents and tension among workers, but most important, it can lead to poor treatment decisions. EMS personnel who use or abuse substances such as alcohol or marijuana are more likely to have problems with their work habits, and their driver’s licenses may be revoked as a result. They may be absent from work more often than other workers. If the use or abuse has occurred within hours before the start of their shift, their ability to render emergency medical care may be lessened because of mental or physical impairment. Because of the seriousness of substance abuse or misuse, many EMS systems now require their personnel to undergo periodic random tests for illegal drug use. Since public safety workers depend so much on coworkers for their own safety, it is even more important that ways be found to manage this problem.

As an EMT, you will witness firsthand the tremendous effects of violence, trauma, and disease. Beyond CISM, members of the public safety community have a way of covering for each other. It is important to understand the problem behavior will usually get worse before it gets better. Unfortunately, the stereotypical image of the alcoholic or addict lying in the gutter in an urban part of town often blinds EMS personnel to the existence of a coworker's drug or alcohol problem. Not all people with a substance abuse problem fit the stereotype.

As a member of the EMS team, you are responsible for responding to the community's emergency medical needs. Hazards in the EMS workplace are many. If you or one of the members of your team has an alcohol or other drug problem, these risks are increased. Furthermore, drug use that occurs off the job does not necessarily decrease the risk if a team member is showing up at work still under the influence of substance abuse. While it varies from state to state, a drug-related or alcohol-related arrest can result in the revocation of some or all driving privileges and even loss of EMT licensure. Because of the tremendous risk potential, it is critical that you seek help or find a way to confront your partner or coworker even though there will be great pressure to allow the behavior to continue. Addicts and alcoholics are skillful at covering up their behavior. You might even decide not to bother your coworker because you feel he or she has caught too many tough calls lately and needs to blow off some steam. Do not let this happen.

Find a way to confront someone who has a substance abuse problem. Because of the tremendous hazards to patients, the public, and other team members, you have a legitimate right to confront coworkers with drug and alcohol problems.

When confronting a coworker, make it clear to the coworker that if the problem is personal, it is the coworker's responsibility to take care of it. But you also have the power to assist this person. In many workplaces, coworkers are often in a position to notice a change in a coworker's behavior or attitude before a supervisor does. This is especially true in EMS because of the close relationship that develops between people who work together for many hours and share rooms and meals. This may allow you to help someone before his or her job performance is negatively affected.

Safety Tips

Trust is your business. You will be given the privilege—and it is a privilege—to care for patients in their time of highest need. You must demonstrate that trust through consistent professionalism. Remember, you have support to help you make the right choice: your partner, your supervisor, your family.

To help reduce the potential for drug and alcohol use in the EMS workplace, become informed about alcohol and other drugs. Beyond following company policy, you and your coworkers can agree among yourselves what constitutes unacceptable behavior. The best time to confront these issues is usually after a call. Management sets the tone on these issues, but senior EMTs can also emphasize to new EMTs that drug and alcohol abuse will not be tolerated.

Employee assistance programs (EAPs) are often available for EMS personnel. These agencies are contracted with the EMS department to provide a wide array of mental health, substance abuse, crisis management, and counseling services. Talk with your supervisor about resources that are available at your EMS department. Early intervention is the best bet to ensure a safe, alcohol- and drug-free workplace.

Suicide Prevention

A combination of cumulative stress and acute, intense stress can weigh heavily on EMS providers. While awareness of EMS provider suicide has grown over the years, you should understand and select strategies to deal with stress in a constructive manner. If you encounter any suicidal ideations or if a colleague expresses such ideations, you should seek help, including professional counseling.

Injury and Illness Prevention

According to the Bureau of Labor Statistics, approximately 4.1 million serious injuries and 4,500 deaths occur in US workplaces with a direct cost of more than $50 billion each year.

Many companies, as well as EMS departments, have established injury and illness prevention programs to determine workplace hazards and implement a plan to mitigate those hazards. Each injury and illness prevention program should include these six interrelated and interdependent elements:

- Management leadership
- Worker participation

- Hazard identification and assessment
- Hazard prevention and control
- Education and training
- Program evaluation and improvement

Data show that injury and illness prevention programs pay dividends for the companies that implement them. Thirty-four states require companies to have such programs. OSHA developed a Voluntary Protection Program (VPP) to help companies actively mitigate risk and protect their employees. Find out if your company has an injury and illness prevention program and learn how you can participate.

YOU are the Provider — SUMMARY

1. How can you psychologically prepare yourself for this call?

Regardless of your years of experience in EMS, you must prepare yourself psychologically and logistically when responding to *every* call.

You will experience anxiety during your response to the scene; this is a normal human reaction to a stressful event. The key is to recognize this and to remain focused on the critical tasks that lie ahead. Instead of reacting negatively, channel your anxiety into a positive psychologic drive that will make you even more determined to provide the best emergency medical care possible.

You and your partner should have a plan; clearly delineate each of your roles when you arrive at the scene. Discuss the skills and interventions that may need to be performed, the equipment that will be required, and whether additional resources will be needed. Doing so will help minimize confusion at the scene and the psychologic stress it causes.

2. What is stress? How does it manifest?

Stress is the body's physiologic response to any kind of demand—good or bad—and is triggered by one or more stressors. A stressor is any emotional, physical, or environmental situation that causes a variety of physiologic, physical, and psychologic responses.

The body's response to stress begins with an alarm response. When stress is placed on the body—in this case, attempting to resuscitate a child in cardiac arrest—the nervous system releases adrenaline into the bloodstream, causing the fight-or-flight response. The alarm response is followed by a phase of reaction and resistance, and then recovery or, if the stress is prolonged and ineffectively managed, exhaustion. This three-stage response to stress is called the general adaptation syndrome.

3. What phase of the stress response are you experiencing right now?

You are in an acutely stressful situation—attempting to resuscitate a child in cardiac arrest—and are experiencing the alarm response. Your nervous system is releasing adrenaline into the bloodstream, which is triggering the fight-or-flight response and causing your symptoms (eg, sweating, heart racing). As a result, your body has responded with a burst of energy that allows you to carry out your assigned task of suctioning the child's mouth and managing her airway (the "fight" response). If you were experiencing the "flight" response, you would either freeze or try to escape the situation altogether. The ability to effectively do your job—despite experiencing the symptoms of stress—indicates you are able to work under pressure.

4. How should you respond to the mother's question?

Anger is often expressed by very demanding behavior and/or yelling. In this case, anger is a predictable response given the seriousness of the situation.

Clearly, the situation looks grim, so in a calm, professional, and caring manner, reassure her that, although the situation is serious, you and your team are doing everything possible to save her child's life. Be honest, do not give her false hope, and do not make promises you cannot deliver—for example, "Everything will be alright," or "There's nothing to worry about." Your actions and words, even a simple touch, can communicate caring.

5. What stage of the grieving process is the mother experiencing?

The child's mother is actually simultaneously experiencing two stages of the grieving process—denial and anger. There are five stages of the grieving process: denial, anger, bargaining, depression, and acceptance. Not all people grieve in this order, and not all people experience all stages of the grieving process.

A person in denial refuses to accept the seriousness of the situation, makes unrealistic demands for miracles, or persistently fails to understand why there is no improvement in his or her loved one's condition.

Anger is usually the ugliest stage of the grieving process. During this phase, the person lashes out—usually at the EMS provider. Someone must be blamed, and those who are responsible must be punished. Anger often manifests as hostility toward the provider. Some people may become physically abusive, in which case law enforcement should be summoned to the scene.

6. How can poorly managed stress affect your physical well-being?

Most people can respond to sudden stress for a short time. However, prolonged or poorly managed stress can quickly drain the body of its reserves. This leaves it depleted of key nutrients, weakened, and more susceptible to disease.

In addition to the emotional damage that poorly managed stress can cause (eg, depression, guilt, persistent anxiety), it has been proven to be a strong contributor to heart disease, hypertension, cancer, alcoholism, and drug abuse, among others.

7. How can you mitigate the stress associated with the job?

Before you can manage stress, you must first recognize its signs and symptoms and identify the stressors involved. Some stressors can be changed or eliminated altogether; others cannot. Caring for critically sick or injured patients is difficult. It is stressful for them, but also for you. It is critical to recognize the manifestations of stress so it does not interfere with your job or personal life.

The signs of chronic stress are not always obvious at first; they may be subtle and not present all the time. Warning signs include irritability toward coworkers, family, and friends; difficulty concentrating; insomnia, hypersomnia, or nightmares; anxiety; indecisiveness; loss of appetite; decreased sex drive; and loss of interest in work, among others.

There are many useful and healthy strategies for managing stress; they may involve changing a few habits or your attitude. Behavioral tactics that have been shown to alleviate or eliminate the body's stress response include changing or eliminating the stressors (this is not always possible, especially in EMS), changing work hours, cutting back on overtime, changing your attitude about the stressor, developing a social network that does not involve your coworkers, and spending more time with your family.

There are also a number of exercises you can use to minimize the physical response to stress, such as periodic stretching; slow, deep breathing; regular physical exercise; and progressive muscle relaxation. If you are experiencing difficulty managing the stress associated with your job, you should consider seeing a professional counselor.

The key to successful stress management is to find a strategy that works for you and to use that strategy frequently and consistently. Remember, the signs of stress are not always present; you may not feel stressed, despite the fact that you are.

8. Does the death of a child affect the EMT or paramedic differently than the death of an adult? If so, how?

The death of any patient is a tragic event. However, in our society, we assume only older people are supposed to die, so most people are unprepared for what they will feel when a child's death does occur—including EMS personnel. It is common for EMS providers to feel they did not do everything possible for the child, despite the fact that they indeed provided their best resuscitative efforts.

It is normal to feel sadness and depression following the death of a child; however, unlike the death of an older person, these feelings are often more profound. Children only account for about 10% of all EMS calls; therefore, the death of a child—expected or not—often catches the EMT off guard, resulting in a greater degree of stress and anxiety compared to what is experienced following the death of an adult.

9. How can you help your partner?

Your partner's behavior is consistent with a critical incident stress reaction. Many people are prone to cumulative stress. In the emergency services field, stressors are often sudden and more severe; therefore, many events are unusually stressful or emotional, even by emergency services standards.

So, how do you help your partner? If he does not wish to talk, do not force the issue. He needs time to collect his thoughts and to grieve—just like the parents. However, you should reassure him that you are willing to listen; some people experience relief just by talking to a coworker, family member, or friend. In other cases, he or she may need to speak to a counselor.

You should alert your supervisor to your partner's crisis. If he is not emotionally fit to provide safe and effective emergency care, he should be replaced for the rest of the shift. In some cases, a grieving EMT or paramedic will become angry if his or her crisis is reported to the supervisor. However, you should reassure him or her that you reported the incident out of concern for his or her physical and emotional well-being. EMS personnel do not just look out for each other during an EMS call; they should also look out for each other after the call—even if it is just as a "sounding board."

EMS Patient Care Report (PCR)

Date: 4-3-16	**Incident No.:** 020109	**Nature of Call:** Child not breathing		**Location:** 788 E. Radcliffe	
Dispatched: 0720	**En Route:** 0720	**At Scene:** 0725	**Transport:** 0752	**At Hospital:** 0808	**In Service:** 0845

Patient Information

Age: 4 **Sex:** F **Weight (in kg [lb]):** 19 kg (42 lb)	**Allergies:** None **Medications:** None **Past Medical History:** None **Chief Complaint:** Cardiopulmonary arrest

Vital Signs

Time: 0726	**BP:** Unobtainable	**Pulse:** Absent	**Respirations:** Absent	**Spo_2:** Unobtainable

Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** Cardiac monitoring, IV, medication therapy, intubation

Narrative

9-1-1 dispatch for an unconscious child not breathing. On arrival at the scene, found two EMRs performing CPR on a 4-year-old girl. The child's mother stated when she went to wake up her child, she was unconscious, unresponsive, and not breathing; she called 9-1-1 and began CPR. The mother denies her child has any significant past medical history or drug allergies. She further denies any recent trauma or potentially toxic ingestion. After 2 minutes of CPR, reassessment revealed the child remained apneic and pulseless. Continued two-rescuer CPR and applied the cardiac monitor, which revealed asystole. Paramedic on scene successfully performed endotracheal intubation. An IV line was established and medications were administered per protocol. Performed resuscitative efforts at the scene for approximately 10 minutes, and then loaded the child into the ambulance and began transport. The child's mother accompanied her to the hospital, and was secured in the passenger's seat of the ambulance. Continued CPR and appropriate medication therapy en route. The child's condition remained unchanged; she remained apneic and pulseless and the electrocardiogram continued to show asystole. Delivered the child, whose condition remained unchanged, to the emergency department staff and gave verbal report to the attending physician.

Provided emotional support to the child's mother and then returned to service.**End of report**

Prep Kit

Ready for Review

- Your health and wellness are the foundation for your career; without these, you cannot provide care. Wellness includes your mental, physical, and social well-being.
- Components of wellness include protection from communicable disease and scene hazards; proper nutrition; sufficient exercise and relaxation; sufficient sleep; refraining from tobacco and drug use and excessive alcohol; and taking time to relax and enjoy life.
- Every patient encounter should be considered to be potentially dangerous. It is essential that you take all available precautions to minimize exposure and risk to scene hazards and infectious and communicable diseases.
- A communicable disease is any disease that can be spread from person to person or animal to person.
- Infectious diseases can be transmitted by contact (direct or indirect), or they are airborne, foodborne, or vector-borne.
- Even if you are exposed to an infectious disease, your risk of becoming ill is small.
- Whether or not an acute infection occurs depends on several factors, including the amount and type of infectious organism and your resistance to that infection.
- You can take several steps to protect yourself against exposure to infectious diseases, including:
  - Keeping up to date with recommended vaccinations
  - Following standard precautions at all times
  - Handling all needles and other sharp objects with great care
- Because it is often impossible to tell which patients have infectious diseases, you should avoid direct contact with the blood and body fluids of all patients.
- You should know what to do if you are exposed to an airborne or bloodborne disease. Your department’s designated officer will be able to help you follow the protocol set up in your area.
- Infection control should be an important part of your daily routine. Be sure to follow the proper steps when dealing with potential exposure situations.
- If you think you may have been exposed to an infectious disease, see your physician (or your employer’s designated physician) immediately.
- Scene hazards include potential exposure to the following:
  - Hazardous materials
  - Electricity
  - Fire
- At a hazardous materials incident, your safety is the most important consideration. Never approach an object labeled with a hazardous materials placard or label. Use binoculars to read the placards or labels from a safe distance.
- Do not begin caring for patients until they have been moved away from the scene and decontaminated by the hazardous materials team or the scene has been made safe for you to enter.
- There are seven common hazards in a fire:
  - Smoke
  - Oxygen deficiency
  - High ambient temperatures
  - Toxic gases
  - Building collapse
  - Equipment
  - Explosions
- Wearing protective clothing and specialized gear is another important component in preventing injury.
- Part of your role is to know how to care for critically ill and injured patients. Becoming familiar with interpersonal communication techniques to use in these situations will allow you to communicate with patients and their families in an optimal way.
- You will encounter death, dying patients, and the families and friends of those who have died. Your appropriate response to grief can have a significant impact on those you work with.
- Recognizing the signs of stress is important for all EMTs. When signs of stress such as fatigue, anxiety, anger, feelings of hopelessness, worthlessness, or guilt, and other such indicators manifest themselves, behavioral problems can develop.

- Violent situations such as civil disturbances, domestic disputes, and crime scenes can create many hazards for EMS personnel. If you see the potential for violence during a scene size-up, call for additional resources.
- Common workplace issues include cultural diversity, sexual harassment, and substance abuse. You should know what to do to avoid or address these situations.

Vital Vocabulary

acute stress reactions Reactions to stress that occur during a stressful situation.

airborne transmission The spread of an organism via droplets or dust.

bloodborne pathogens Pathogenic microorganisms that are present in human blood and can cause disease in humans. These pathogens include, but are not limited to, hepatitis B virus and human immunodeficiency virus (HIV).

Centers for Disease Control and Prevention (CDC) The primary federal agency that conducts and supports public health activities in the United States. The CDC is part of the US Department of Health and Human Services.

communicable disease A disease that can be spread from one person or species to another.

concealment The use of objects to limit a person's visibility of you.

contamination The presence of infectious organisms on or in objects such as dressings, water, food, needles, wounds, or a patient's body.

cover The tactical use of an impenetrable barrier for protection.

critical incident stress management (CISM) A process that confronts the responses to critical incidents and defuses them, directing the emergency services personnel toward physical and emotional equilibrium.

cumulative stress reactions Prolonged or excessive stress.

delayed stress reactions Reactions to stress that occur after a stressful situation.

designated officer The individual in the department who is charged with the responsibility of managing exposures and infection control issues.

direct contact Exposure or transmission of a communicable disease from one person to another by physical contact.

exposure A situation in which a person has had contact with blood, body fluids, tissues, or airborne particles in a manner that suggests disease transmission may occur.

foodborne transmission The contamination of food or water with an organism than can cause disease.

general adaptation syndrome The body's response to stress that begins with an alarm response, followed by a stage of reaction and resistance, and then recovery or, if the stress is prolonged, exhaustion.

hepatitis Inflammation of the liver, usually caused by a viral infection, that causes fever, loss of appetite, jaundice, fatigue, and altered liver function.

host The organism or individual that is attacked by the infecting agent.

human immunodeficiency virus (HIV) Acquired immunodeficiency syndrome (AIDS) is caused by HIV, which damages the cells in the body's immune system so that the body is unable to fight infection or certain cancers.

immune The body's ability to protect itself from acquiring a disease.

indirect contact Exposure or transmission of disease from one person to another by contact with a contaminated object.

infection The abnormal invasion of a host or host tissues by organisms such as bacteria, viruses, or parasites, with or without signs or symptoms of disease.

infection control Procedures to reduce transmission of infection among patients and health care personnel.

infectious disease A medical condition caused by the growth and spread of small, harmful organisms within the body.

Occupational Safety and Health Administration (OSHA) The federal regulatory compliance agency that develops, publishes, and enforces guidelines concerning safety in the workplace.

pathogen A microorganism that is capable of causing disease in a susceptible host.

personal protective equipment (PPE) Protective equipment that blocks exposure to a pathogen or a hazardous material.

posttraumatic stress disorder (PTSD) A delayed stress reaction to a prior incident. Often the result of one or more unresolved issues concerning the incident, and may relate to an incident that involved physical harm or the threat of physical harm.

transmission The way in which an infectious disease is spread: contact, airborne, by vehicles, or by vectors.

standard precautions Protective measures that have traditionally been developed by the CDC for use in dealing with objects, blood, body fluids, and other potential exposure risks of communicable disease.

vector-borne transmission The use of an animal to spread an organism from one person or place to another.

Assessment *in Action*

You and your partner are dispatched to a sick person. On arrival you find a conscious patient who reports a fever, night sweats, and a cough. The patient also reports a history of tuberculosis. Your partner is assessing the patient, and you notice he has not taken standard precautions by donning personal protective equipment. Lately you have noticed your partner is disinterested in his work and is coming in late, taking unnecessary risks, and has taken to sitting alone at the station and not socializing with other members of the team. The job has been stressful lately; call volume has increased and you rarely have any downtime between calls.

1. What standard precautions should your partner have taken with this patient?

   A. Gloves only
   B. Gloves and surgical mask
   C. Gloves and particulate mask
   D. Gloves, mask, and gown

2. If your partner becomes infected with this patient's illness, what type of transmission would this occur through?

A. Vector-borne
B. Foodborne
C. Indirect contact
D. Airborne

3. Because your partner did not use standard precautions, he has potentially been exposed to an infectious disease. What should he do?

A. Ignore it because the risk of contamination is small.
B. Report it to the hospital staff so they can isolate the patient.
C. Report it to the infection control officer.
D. Sanitize any equipment that was in contact with the patient.

4. On the basis of your partner's actions, what is he most likely experiencing?

A. Acute stress reaction
B. Cumulative stress reaction
C. Posttraumatic stress disorder
D. Delayed stress reaction

5. Which of the following signs and symptoms are *not* usually associated with stress?

A. Headaches
B. Risk taking
C. Night sweats
D. Isolation

6. How can you help your partner to manage his stress?

A. Suggest that he relax and have a few drinks after his shifts.
B. Suggest a vacation.
C. Suggest that the supervisor give him time off.
D. Suggest that he participate in physical activity away from the workplace.

7. Which of the following is *not* a recommended way to manage stress?

A. Alcohol
B. Exercise
C. Proper diet
D. Sleep

8. What are the long-term physical effects of stress?

9. What are the long-term psychologic effects of stress?

10. Discuss the implications of your partner's actions in this scenario.

3

Medical, Legal, and Ethical Issues

© Jack Dagley Photography/ShutterStock.

National EMS Education Standard Competencies

Preparatory

Applies fundamental knowledge of the emergency medical services (EMS) system, safety/well-being of the emergency medical technician (EMT), medical/legal, and ethical issues to the provision of emergency care.

Medical/Legal and Ethics

› Consent/refusal of care (pp 85–90)
› Confidentiality (p 90)
› Advanced directives (pp 90–92)
› Tort and criminal actions (pp 98–100)
› Evidence preservation (p 102)
› Statutory responsibilities (pp 94–98)
› Mandatory reporting (pp 101–102)
› Ethical principles/moral obligations (pp 102–103)
› End-of-life issues (pp 92–94)

Knowledge Objectives

1. Define consent and how it relates to decision making. (p 85)
2. Compare expressed consent, implied consent, and involuntary consent. (pp 86–87)
3. Discuss consent by minors for treatment or transport. (p 87)
4. Describe local EMS system protocols for using forcible restraint. (p 88)
5. Discuss the EMT's role and obligations if a patient refuses treatment or transport. (pp 88–90)
6. Describe the relationship between patient communications, confidentiality, and the Health Insurance Portability and Accountability Act (HIPAA). (p 90)
7. Discuss the importance of do not resuscitate (DNR) orders and local protocols as they relate to the EMS environment.

(pp 90–92)
8. Describe the physical, presumptive, and definitive signs of death. (pp 92–93)
9. Explain how to manage patients who are identified as organ donors. (p 94)
10. Recognize the importance of medical identification devices in treating the patient. (p 94)
11. Discuss the scope of practice and standards of care. (pp 94–97)
12. Describe the EMT's legal duty to act. (pp 97–98)
13. Discuss the issues of negligence, abandonment, assault and battery, and kidnapping and their implications for the EMT. (pp 98–99)
14. Explain the reporting requirements for special situations, including abuse, drug- or felony-related injuries, childbirth, and crime scenes. (pp 101–102)
15. Define ethics and morality and their implications for the EMT. (pp 102–103)
16. Describe the roles and responsibilities of the EMT in court. (pp 103–105)

Skills Objectives

There are no skills objectives for this chapter.

Introduction

A basic principle of emergency care is to do no further harm. As an EMT, you will usually have the opportunity to do considerably more for your patients than simply preventing further injury. A thorough understanding of medical, legal, and ethical issues related to EMS is essential. EMTs who act in good faith, follow an appropriate standard of care, and provide compassionate care usually avoid professional legal problems.

EMTs provide **emergency medical care**—immediate care or treatment. EMTs may be the first link in the chain of prehospital care. As the scope and nature of emergency medical care become more complex, litigation involving participants in EMS systems will likely increase. Providing competent emergency medical care that conforms to the standard of care will help you to avoid both civil and criminal actions. Consider the following situations:

- While transporting a patient to the hospital, he states, "I don't want to go to the hospital anymore. You have to let me out."
- You begin treating a child you suspect might be the victim of abuse, and a parent commands you to stop.
- Your partner takes out his smartphone to post something about the last emergency call.

What should you do? Even when emergency medical care is properly rendered, there are times when you may be sued by a patient who seeks monetary compensation. Administrative action, such as suspension of your state EMT certificate, may be brought against you for failure to abide by the regulations of your state EMS agency. For these reasons, you must understand the various legal aspects of emergency medical care.

You must also consider ethical issues. As an EMT, should you stop and treat patients who were involved in an automobile crash while you are en route to another emergency call? Should you begin CPR on a patient who, according to the family, has terminal cancer? Should you begin treatment on a child with obvious signs of death because the parents are begging you to do something?

Consent

Typically, consent is required from every conscious adult before care can be started. A person receiving care must give permission, or **consent**, for treatment. An adult who is conscious, rational, and capable of making informed decisions has a legal right to refuse care, even though ill or injured. A patient may also consent to some aspects of care and deny consent for others. If the patient refuses care, you may not care for the patient. In fact, doing so may be grounds for both criminal and civil action. Consent can be expressed (actual) or implied.

The foundation of consent is decision-making capacity. **Decision making capacity** is the ability of a patient to understand the information you are providing, coupled with the ability to process that information and make an informed choice regarding medical care. It is important to keep in mind that the law allows the patient to make choices that may seem medically unsound and that might endanger the patient's life. The right of a patient to make decisions concerning his or her health is known as **patient autonomy**. The terms *decision making capacity* and *competence* are often used interchangeably but there is a distinction: competence is generally regarded as a legal term and determinations regarding competence are typically made by a court of law, whereas decision making capacity is the term more commonly used in health care to determine whether or not a patient is capable of making health care decisions.

YOU are the Provider — PART 1

At 1720 hours, you are dispatched to a grocery store at 1175 N. Main Street for a man with a severe headache. You respond to the scene, which is located only a few miles away. The weather is clear, the temperature is 90°F (32°C), and the traffic is heavy.

1. Why is it essential that you obtain consent to treat the patient once you arrive?
2. Should you assess the patient's competency or decision making capacity once you arrive?

The following factors should be considered when determining a patient's decision-making capacity:

- Is the patient's intellectual capacity impaired by mental limitation or any type of dementia?
- Is the patient of legal age (18 years of age in most states)?
- Is the patient impaired by alcohol or drug intoxication or serious injury or illness?
- Does the patient appear to be experiencing significant pain?
- Does the patient have a significant injury that could distract him from a more serious injury? (For example, a significant non-life-threatening injury can cause extreme pain and distract the patient from neck pain, which could indicate a more serious problem.)
- Are there any apparent hearing or visual problems?
- Is a language barrier present? Do you and your patient speak the same language?
- Does the patient appear to understand what you are saying? Does he or she ask rational questions that demonstrate an understanding of the information you are trying to share?

You should be familiar with various types of consent. These include expressed consent, implied consent, and involuntary consent.

Expressed Consent

Expressed consent (or actual consent) is the type of consent given when the patient verbally or otherwise acknowledges that he or she wants you to provide care or transport. Expressed consent may be nonverbal. For example, if you ask a patient if you can check his or her blood pressure and the patient extends an arm to you, the patient is expressing consent nonverbally.

To be valid, the consent the patient provides must be **informed consent**, which means that you explained the nature of the treatment being offered, along with the potential risks, benefits, and alternatives to treatment, as well as potential consequences of refusing treatment, and the patient has given consent. Often, the prehospital environment requires that consent be obtained more quickly than in the hospital setting. Paramedics will often provide additional information if advanced life support interventions are necessary. In such cases, there is a greater potential for side effects and other adverse responses associated with drug administration and other forms of advanced care.

Informed consent is valid if given orally, but it may be difficult to prove at a later point in time. Rarely do EMS providers have patients sign a consent form, so it is always advisable to document consent in your run report. Having someone witness the patient's consent may be helpful if the issue of consent is later challenged in court.

Remember, a patient may agree to certain types of emergency medical care but not to others. The patient's right to refuse treatment is discussed later in this chapter.

Implied Consent

When a person is unconscious or otherwise incapable of making a rational, informed decision about care, and unable to give consent, the law assumes that the patient would consent to care and transport to a medical facility if he or she were able to do so Figure 3-1. Patients who are intoxicated by drugs or alcohol, mentally impaired, or suffering from certain conditions such as head injury might be included in this category. The legal principle that allows treatment under such circumstances is called **implied consent**. Implied consent applies only when a serious medical condition exists and should never be used unless there is a threat to life or limb. For this reason, the principle of implied consent is known as the **emergency doctrine**. Sometimes what represents a "serious threat" may be unclear. This may result in legal proceedings and a **medicolegal** judgment, which should be supported by your best efforts to obtain consent and a thoroughly documented run report. In most instances, the law allows a spouse, a close relative, or next of kin to give consent for an injured person who is unable to do so, and you should make every effort to obtain consent from an available relative before treating based on implied consent;

however, treatment should never be delayed when the patient has imminently life-threatening injuries. It is also important to understand that if a patient being treated based on implied consent were to regain consciousness and appear capable of making an informed decision, the doctrine of implied consent would no longer apply. This often occurs with calls involving diabetic emergencies, overdoses, syncope, and seizures.

Figure 3-1 When a serious threat to life exists and the patient is unconscious or otherwise unable to give consent, the law assumes that the patient would give consent to care and transport to the hospital.

▶ Involuntary Consent

Assisting patients who are mentally ill, developmentally delayed, or who are in behavioral (psychologic) crisis is complicated. An adult patient who is mentally incompetent is not able to give informed consent. From a legal perspective, this situation is similar to those involving minors. Consent for emergency care should be obtained from someone who is legally responsible for the patient, such as a guardian or conservator. In many cases, however, such permission will not be readily obtainable. Many states have protective custody statutes allowing such a person to be taken, under law enforcement authority, to a medical facility. Under certain conditions, law enforcement and prison officials are legally permitted to give consent for any individual who is incarcerated or has been placed under arrest. However, a prisoner who is conscious and capable of making decisions does not necessarily surrender the right to make medical decisions and may refuse care. Know the provisions in your area and involve online medical control in the process.

▶ Minors and Consent

Because a minor might not have the wisdom, maturity, or judgment to give consent, the law requires that a parent or legal guardian, when available, give consent for treatment or transport **Figure 3-2**. In every state, when a parent cannot be reached to provide consent, health care providers are allowed to give emergency care to a child. In some states, a minor can consent to receive medical care, depending on the minor's age and maturity. A great deal of confusion surrounds the issue of emancipated minors. **Emancipated minors** are people who, despite being under the legal age in a given state (in most cases the age is 18 years), can be legally treated as adults based on certain circumstances. For example, many states consider minors to be emancipated if they are married, if they are members of the armed services, or if they are parents. A minor who is a parent may also give consent for his or her own child. In addition, a minor is usually considered emancipated if living away from and no longer relying on his or her parents for support. A court may issue an order declaring a minor to be emancipated but this is not commonly seen. You should know your state's laws concerning the issues surrounding emancipation.

Figure 3-2 The law requires that a parent or a legal guardian give consent for treatment or transport of a minor. However, you must never withhold lifesaving care.

If a minor is injured and requires medical treatment in a school or camp setting, teachers and school officials may act **in loco parentis**, which means in the position or place of a parent, and can legally give consent for treatment of the minor if a parent or guardian is not available. You should still make an effort to obtain consent from a parent or legal guardian whenever possible; however, if a true emergency exists and the parent or legal guardian is not available, the consent to treat the minor is implied, just as with an adult. You must never withhold lifesaving care for a minor because a person authorized to provide consent is not available.

It is important to reach the parent or guardian as quickly as possible. Even though lifesaving interventions will not be delayed, it is possible other interventions at the hospital could be delayed until consent is obtained. Follow local protocol or consult medical control to determine if someone acting in loco parentis will need to accompany the child during transport and be present at the receiving hospital until a parent or guardian arrives.

Forcible Restraint

Forcible restraint is sometimes necessary when you are confronted with a patient who is in need of medical treatment and transportation but is combative and presents a significant physical risk of danger to himself, rescuers, or others **Figure 3-3**. Such behavior may result from an underlying psychiatric or behavioral condition, the effects of drugs, or a medical condition such as a head injury or hypoxia. Physically preventing such people from initiating any physical action is legally permissible and may be required before emergency care can be rendered. Typically, you should consult medical control for authorization to restrain or contact law enforcement personnel who have the authority to restrain people. In some states, only a police officer may forcibly restrain an individual. You should be knowledgeable about local laws. Restraint without legal authority exposes you to potential civil and criminal penalties. Restraint may be used only in circumstances of risk to the patient or others. When a patient is combative and poses a risk to the rescuer, it is advisable to wait for law enforcement to arrive on scene before attempting to treat the patient.

Your service should have clearly defined protocols to deal with situations involving restraint. It is important to remember that if the patient is conscious and the situation is not urgent, consent is required. Restraints should only be considered if the patient has a medical condition that appears serious or if he or she suffers from an apparent behavioral disorder that poses a risk to the patient or others. After restraints are applied, they should not be removed en route unless they pose a risk to the patient, even if the patient promises to behave. It is essential you protect the patient's airway and monitor the patient's respiratory status while restrained to avoid asphyxia, aspiration, and other complications.

Figure 3-3 Be sure that you know the local laws about forcible restraint of a patient. In some states, only a police officer has the authority to restrain a patient.

The Right to Refuse Treatment

Adults who are conscious, alert, and appear to have decision making capacity have the right to refuse treatment or withdraw from treatment at any time. This is true even if doing so may result in death or serious injury. Such patients present you with a dilemma. Should you provide care against their will? Should you leave them alone? Calls involving refusal of treatment pose a high risk of litigation in EMS and require you to proceed very cautiously. You must be familiar with local policies regarding refusal of care. In all such cases, you should involve online medical control and document this consultation. A patient's decision to either accept or refuse treatment should be based on information that you provide. This information should include your assessment of what might be wrong with the patient, a description of the treatment that you feel is necessary, any possible risks of treatment, the availability of alternative treatments, and the possible consequences of refusing treatment. Be sure that the patient understands everything that you say and encourage the patient to ask questions. All of this information should be included in your patient care report. Many jurisdictions have pre-printed refusal forms to ensure that all of these items are documented or acknowledged.

When treatment is refused, you must assess the patient's ability to make an informed decision. Ask and repeat questions, assess the patient's answers, and observe the patient's behavior. If the patient appears confused or delusional, you cannot assume that the decision to refuse is an informed refusal. Patients who have attempted suicide, or conveyed suicidal intent, should not be regarded as having normal mental capacity. Remember, a single assessment finding will not usually enable you to determine whether the patient is capable of making an informed decision about health care. As with most medical conditions, it is the constellation of findings that will support your conclusion. When in doubt, providing treatment is a much more defensible position than failing to treat a patient. Do not endanger yourself to provide care, and use the assistance of law enforcement to ensure your own safety.

Before leaving the scene where a patient has refused care, you should again encourage the patient to permit treatment and remind him or her to call 9-1-1 if he or she changes his or her mind or his or her condition worsens. Advise the patient to contact his or her personal physician as soon as possible. It is essential for you to ask the patient to sign a refusal of treatment form and to thoroughly document all refusals. Your documentation should include any assessment findings that you were able to make and all efforts that you made to obtain consent. Your documentation should also include a description of possible consequences of refusing treatment and transport. The patient's signature should be witnessed by a family member or police officer to help protect you from a later claim for negligence or abandonment. Both of these terms are discussed later in this chapter. A signed patient refusal form does not guarantee your protection against legal action, though it can help defend you when legal actions arise. Also, it is wise, and often required by local protocol, that you notify medical control of your actions; medical control can help guide your decisions.

You may also be faced with a situation in which a parent refuses to permit treatment of an ill or injured child. In this situation, you must consider the emotional impact of the emergency on the parent's judgment. As with most cases of refusal, you can usually resolve the situation with patience and calm persuasion. You may also need the help of others, such as ALS personnel, medical control, or law enforcement officials.

When you are not able to persuade the patient, guardian, or parent to proceed with treatment, you must obtain the signature of the individual who is refusing treatment on an official release form that acknowledges refusal. Document any assessment findings, the emergency care that you provided, your efforts to obtain consent, your consultation with medical control, and the responses to your efforts. You should also obtain a signature from a witness to the refusal. Make every effort to have a responsible person, such as a police officer, serve as a witness to these events. Retain the documents with your records—they will be important in the event a legal claim is filed later. If the patient refuses to sign a release form, inform medical control and thoroughly document the situation and the refusal. In some cases, parents who have refused medical care for a child have been charged with child neglect. You might be called as a witness in such cases and you must be sure that all documentation is thorough and accurate. Remember, your safety is your first priority. Act in the best interest of your patient, but do not place yourself in danger attempting to care for a patient who is refusing care.

YOU are the Provider — PART 2

On arriving at the scene, you find the patient, a 32-year-old man, sitting on the sidewalk outside the grocery store. He is grabbing both sides of his head, but looks up and acknowledges your presence. You begin to assess the patient as your partner opens the jump kit and prepares to take his vital signs.

Recording Time: 0 Minutes	
Appearance	Grabbing both sides of his head; in obvious pain
Level of consciousness	Conscious and alert
Airway	Open; clear of secretions or foreign bodies
Breathing	Increased respiratory rate; adequate depth
Circulation	Radial pulses, bilaterally strong and regular; skin is pink, warm, and dry

Without talking to the patient, your partner begins to take his blood pressure and applies the pulse oximeter to his finger.

3. Are you legally authorized to treat this patient? Why or why not?
4. How does informed consent differ from implied consent?

Words of Wisdom

When a patient, parent, or guardian refuses treatment or transport, protect yourself with both a thorough patient care report (PCR) and an official refusal form. Have the patient or other refusing party sign the form, document what you have done to ensure an informed refusal, and note the involvement of medical control in the situation. Be sure to submit the refusal form with your PCR.

Confidentiality

Communication between you and the patient is considered confidential and generally cannot be disclosed without permission from the patient or a court order. Confidential information includes the patient history, assessment findings, and treatment provided. Disclosure of such information without proper authorization may result in liability for **breach of confidentiality**. In most states, records may be released when a legal subpoena is presented or the patient signs a written release. Patient information may also be shared with third-party billing personnel; this is not considered a breach of confidentiality.

HIPAA

HIPAA is the acronym for the Health Insurance Portability and Accountability Act of 1996. Although this act had many aims, the section of the act that most affects EMS relates to patient privacy. The aim of this section of the act is to strengthen laws for the protection of the privacy of health care information and to safeguard patient confidentiality. It provides guidance on what types of information is protected, the responsibility of health care providers regarding that protection, and the penalties for breaching that protection.

HIPAA considers all patient information that you obtain in the course of providing medical treatment to a patient to be **protected health information (PHI)**. This includes not only medical information, but also any information that can be used to identify the patient. As an EMT, you have an obligation to guard all protected health information from unlawful disclosure, either written or verbal.

PHI may be disclosed for purposes of treatment, payment, or operations. This means you are permitted to report your assessment findings and treatment to other health care providers directly involved in the care of the patient. Information may be used for internal quality improvement and training programs, but all identifying information must first be removed. There are also certain situations when you may be legally mandated to report your findings, such as in the case of child abuse or when you receive a subpoena. In most situations, except for treatment purposes, only the minimum amount of information necessary should be released. Failure to abide by the provisions of the HIPAA laws can result in civil and/ or criminal action against your response agency and against you personally. Each EMS system is required to have a policy and procedure manual and a privacy officer who can answer questions. You can expect to receive further training on how this act impacts your specific response agency.

Words of Wisdom

Do *not* use a personal electronic device, such as a cell phone, to capture information from a call. Digital images such as photos of a patient's injuries or vehicle, or recordings made by crew members during a patient call, are considered protected health information (PHI) and a confidential part of the patient report. *Never* post PHI on social media.

Advance Directives

As an EMT, you will respond to calls in which a patient is dying from an illness. When you arrive at the scene, you may find that family members do not want you to try to resuscitate the patient. Without valid written documentation from a physician, such as an advance directive or a **do not resuscitate (DNR) order** (also known as a "do not attempt resuscitation" order), you may be placed in a very difficult position. A **competent** patient is able to make rational decisions about his or her well-being. An **advance directive** is a written document that specifies medical treatment for a competent patient, should he or she become unable to make decisions. Advance directives are most commonly used when a patient becomes comatose. An advance directive is often referred to as a living will but may also be referred to as a **health care directive**. Not all advance directives are directions to withhold care. Such care may include nutrition and medication for pain.

DNR orders give you permission not to attempt resuscitation **Figure 3-4**. Laws differ from state to state; however, to be valid, DNR orders must meet the following requirements:

PREHOSPITAL MEDICAL CARE DIRECTIVE

(side one)

IN THE EVENT OF CARDIAC OR RESPIRATORY ARREST, I REFUSE ANY RESUSCITATION MEASURES INCLUDING CARDIAC COMPRESSION, ENDOTRACHEAL INTUBATION AND OTHER ADVANCED AIRWAY MANAGEMENT, ARTIFICIAL VENTILATION, DEFIBRILLATION, ADMINISTRATION OF ADVANCED CARDIAC LIFE SUPPORT DRUGS AND RELATED EMERGENCY MEDICAL PROCEDURES.

Patient: ______________________________ Date: ____________

Signature ______________________________

Date ______________________________

B

Figure 3-4 **A.** An example of a wallet-sized DNR order. **B.** An example of a pocket-sized DNR order.

- Clear statement of the patient's medical problem(s)
- Signature of the patient or legal guardian
- Signature of one or more physicians or other licensed health care providers
- In some states, DNR orders contain an expiration date. DNR orders with expiration dates must be dated in the preceding 12 months to be valid.

You may also encounter Physician Orders for Life-Sustaining Treatment (POLST) and Medical Orders for Life-Sustaining Treatment (MOLST) forms when caring for patients with terminal illnesses. These explicitly describe acceptable interventions for the patient in the form of medical orders. These forms must be signed by an authorized medical provider in order to be valid; this may be a physician, physician assistant, or nurse practitioner, and varies by state. If you encounter these documents, contact medical control for guidance.

Some patients may have named surrogates to make decisions for them regarding their health care, in the event that they are incapacitated and unable to make such decisions for themselves. Such designations may be referred to as **durable powers of attorney for health care** or **health care proxies**. There are many different types of powers of attorney and not all are authorized to exercise medical decision making. When presented with a power of attorney at the scene of a medical emergency, you must read it carefully to ascertain its meaning and validity. If there is any question, you should contact online medical control for assistance. Do not delay emergency care while efforts to interpret the power of attorney are made. Keep in mind that a patient who remains conscious and competent does not surrender the right to make medical decisions. The person named in the power of attorney or health care proxy is only authorized to make decisions when the patient is no longer capable of doing so.

Remember, DNR does not mean "do not treat." Even in the presence of a DNR order, you are still obligated to provide supportive measures (oxygen, pain relief, and comfort) to a patient who is not in cardiac arrest. Each agency, in consultation with its medical director and legal counsel, must develop a protocol to follow in these circumstances.

There are a growing number of hospice (end of life) home health programs, so you may be faced with these situations often. Specific guidelines vary from state to state, but the following four statements may be considered general guidelines:

1. Patients have the right to refuse treatment, including resuscitative efforts, provided that they are able to communicate their wishes.
2. A written order from a physician is required for DNR orders to be valid in a health care facility.
3. You should periodically review state and local protocols and legislation regarding advance directives.
4. When you are in doubt or the written orders are not present, you have an obligation to resuscitate.

When presented with an advance directive, you should never become annoyed with family members and allow yourself to wonder, "Why did they bother to call 9-1-1 if they don't want us to do anything?" The patients, and their families, should be treated with the utmost respect and empathy. If information and support is what they called you for, be sure to provide it—it is part of your job.

Physical Signs of Death

Determination of the cause of death is the medical responsibility of a physician. There are both definitive and presumptive signs of death. In many states, death is defined as the absence of circulatory and respiratory function. Many states have also adopted "brain death" provisions; these provisions refer to irreversible cessation of all functions of the brain and brain stem. Questions often arise as to whether to begin basic life support. In the absence of physician orders, such as DNR orders, the general rule is: If the body is still intact and there are no definitive signs of death, initiate emergency medical care.

Hypothermia is a general cooling of the body in which the internal body temperature becomes abnormally low. People have survived hypothermic incidents with temperatures as low as 64°F (18°C). In cases of hypothermia, the patient should not be considered dead until he or she is warm and dead. When the patient's condition in unclear, or if you are unsure if you should initiate care, it is best to begin CPR immediately and contact medical control for guidance. Remember, not all incidents of hypothermia occur outdoors; for example, an older patient in a home without heat or who has been lying on a cold floor could be hypothermic.

Presumptive Signs of Death

Most medicolegal authorities will consider the presumptive signs of death that are listed in Table 3-1 adequate, particularly when they follow a severe trauma or occur at the end stages of long-term illness such as cancer or other prolonged diseases.

These signs would not be adequate in cases of sudden death due to hypothermia, acute poisoning, or cardiac arrest. Usually, in these cases, some combination of the signs is needed to declare death, not just one of them alone.

YOU are the Provider — PART 3

Your partner reports that the patient's blood pressure is very high. The patient tells you that he has "blood pressure problems" and experiences a bad headache whenever he does not take his Prinivil—the medication he takes for his blood pressure. He does not want to go to the hospital and tells you that the clerk called 9-1-1, not him.

Recording Time: 4 Minutes	
Respirations	24 breaths/min; regular and unlabored
Pulse	110 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	200/110 mm Hg
Oxygen saturation (Spo_2)	98% (on room air)

5. What should you do when a patient refuses treatment and/or transport?
6. What questions should you ask yourself to help determine whether you can transport this patient against his will?

Words of Wisdom

EMT Oath

"Be it pledged as an Emergency Medical Technician, I will honor the physical and judicial laws of God and man. I will follow that regimen which, according to my ability and judgment, I consider for the benefit of patients and abstain from whatever is deleterious and mischievous, nor shall I suggest any such counsel. Into whatever homes I enter, I will go into them for the benefit of only the sick and injured, never revealing what I see or hear in the lives of men unless required by law.

I shall also share my medical knowledge with those who may benefit from what I have learned. I will serve unselfishly and continuously in order to help make a better world for all mankind.

While I continue to keep this oath unviolated, may it be granted to me to enjoy life, and the practice of the art, respected by all men, in all times. Should I trespass or violate this oath, may the reverse be my lot.

So help me God."

Written by Charles B. Gillespie, MD
Adopted by the National Association of Emergency Medical Technicians, 1978.

Table 3-1 Presumptive Signs of Death

- Unresponsiveness to painful stimuli
- Lack of a carotid pulse or heartbeat
- Absence of chest rise and fall
- No deep tendon or corneal reflexes
- Absence of pupillary reactivity
- No systolic blood pressure
- Profound cyanosis
- Lowered or decreased body temperature

Definitive Signs of Death

Definitive or conclusive signs of death that are obvious and clear to even nonmedical people include the following:

- Obvious mortal damage, such as decapitation
- **Dependent lividity**: blood settling to the lowest point of the body, causing discoloration of the skin **Figure 3-5**
- **Rigor mortis**, the stiffening of body muscles caused by chemical changes within muscle tissue. It develops first in the face and jaw, gradually extending downward until the body is in full rigor. The rate of onset is affected by the body's ability to lose heat to its surroundings. The rate of heat loss in a thin body is faster than in a fat body. A body on a tile floor has faster heat loss than a body wrapped up in a blanket in a bed. Rigor mortis occurs sometime between 2 and 12 hours after death
- **Putrefaction** (decomposition of body tissues). Depending on temperature conditions, this occurs sometime between 40 and 96 hours after death

Figure 3-5 Dependent lividity is an obvious sign of death caused by discoloration of the body from pooling of the blood to the lower parts of the body.

Medical Examiner Cases

Involvement of the medical examiner, or the coroner in some states, depends on the nature and scene of the death. In most states, when trauma is a factor or the death involves suspected criminal or unusual situations such as hanging or poisoning, the medical examiner must be notified **Figure 3-6**. When the medical examiner or coroner assumes responsibility of the scene, that responsibility supersedes all others at the scene, including the family's. The following are a few examples of deaths that may be considered medical examiner cases:

- When the person is dead on arrival (DOA) (sometimes referred to as dead on scene [DOS])
- Death without previous medical care or when the physician is unable to state the cause of death
- Suicide (self-destruction)
- Violent death
- Poisoning, known or suspected

Figure 3-6 When trauma is a factor or the death involves an unusual or a suspected criminal situation, the medical examiner is required to investigate.

- Death resulting from accidents
- Suspicion of a criminal act
- Infant and child deaths

You should make every attempt to limit your disturbance of a scene involving a death. Once you have adequately determined death based on local protocols, remove yourself from the scene. This is especially important if there is anything potentially suspicious about the death.

If emergency medical care has been initiated, be sure to keep thorough notes of what was done or found. These records may be important during a subsequent investigation.

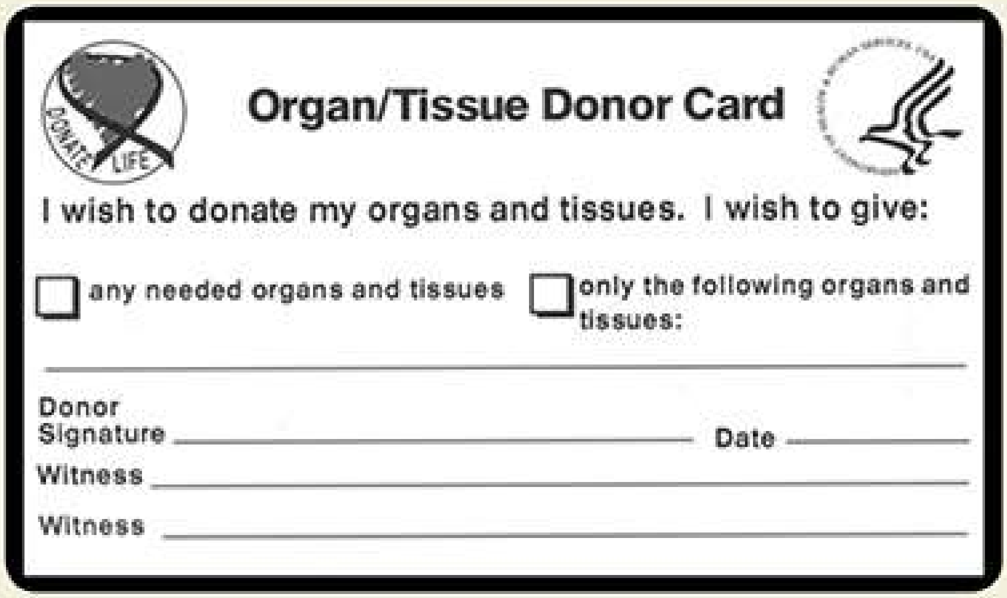
In such instances, there is no urgent reason to move the body. The only immediate action that is required of you is to cover the body and prevent its disturbance. Local protocol will determine your ultimate action in these instances.

Special Situations

Organ Donors

You may be called to a scene involving a potential organ donor. Consent to organ donation is voluntary and knowing. Consent is evidenced by either a donor card or a driver's license indicating that the individual wishes to be a donor Figure 3-7. You may need to consult with medical control when faced with this situation.

In specific circumstances, a patient who is not successfully resuscitated may be a potential organ donor. Certain centers can procure organs, including the kidneys and liver, in certain situations. These situations typically occur after in-hospital cardiac arrest but may be associated with certain specific out-of-hospital cardiac arrest situations that occur in close proximity to specialized centers. Be aware of your local centers and their protocols and capabilities.



Organ/Tissue Donor Card

I wish to donate my organs and tissues. I wish to give:

☐ any needed organs and tissues ☐ only the following organs and tissues:

Donor Signature ______ Date ______

Witness ______

Witness ______

Figure 3-7 The patient may be carrying a donor card or driver's license indicating that he or she wishes to be an organ donor.

Courtesy of the U.S. Department of Health and Human Services.

You should treat a potential organ donor in the same way that you would any other patient needing treatment. Use all means necessary to keep that patient alive. Organs that are often donated, such as a kidney, heart, or liver, need oxygen at all times; you must give oxygen to the possible donor or the organs will be damaged and become useless.

Remember, your priority is to save the patient's life. Be sure to learn what the specific protocols are in your area regarding special situations such as organ donation.

Medical Identification Insignia

Many patients will carry important medical identification and information, often in the form of a bracelet, necklace, key chain, or card that identifies patient history information. This may include a DNR order or information related to medications taken, allergies, diabetes, epilepsy, or some other serious condition Figure 3-8. Some patients wear medical bracelets with a USB flash drive, which contains pertinent patient information, such as drug interactions, allergies, or emergency contact information. This information is often stored as a PDF file that can be read on most computers.

Scope of Practice

The scope of practice, which is most commonly defined by state law, outlines the care you are legally able to provide for the patient. Your medical director further defines the scope of practice by developing protocols and standing orders. The medical director gives you the legal authorization to provide patient care through telephone or radio communication (online) or standing orders and protocols (off-line). It is your responsibility as an EMT to know your scope of practice and follow it. You and other EMS personnel have a responsibility to provide proper, consistent patient care and to report problems, such as possible liability or exposure to infectious disease, to your medical director immediately.

Figure 3-8 The patient may be carrying a medical identification card or wearing a bracelet or necklace that may indicate important medical information and possible DNR orders. In the case of MedicAlert, the EMS provider can obtain stored patient history information from the MedicAlert Foundation.

Courtesy of the MedicAlert Foundation®. © 2006, All Rights Reserved. MedicAlert® is a federally registered trademark and service mark.

If you carry out procedures for which you are not authorized, you are practicing outside your scope of practice, which may be considered negligence or, in some states, even a criminal offense. The scope of practice should not be confused with the standard of care.

Standards of Care

The law requires you to act or behave toward other people in a definite, definable way, regardless of the activity involved. Under given circumstances, you have a duty either to act or not. Generally speaking, you must be concerned about the safety and welfare of others when your behavior or activities have the potential for causing others injury or harm **Figure 3-9**. The manner in which you must act or behave is called a **standard of care**.

Standard of care is established in many ways, among them local customs, statutes, ordinances, protocols, medical literature, textbooks, administrative regulations, and case law. In addition, professional or institutional standards have a bearing on determining the adequacy of your conduct.

Figure 3-9 Act or behave toward others in a way that shows your concern about their safety and welfare.

Standards Imposed by Local Custom

The standard of care is how a reasonably prudent person with similar training and experience would act under similar circumstances, with similar equipment, and in the same or similar place. For example, the conduct of an EMT who is employed by an ambulance service is to be judged in comparison with the expected conduct of other EMTs from comparable ambulance services in the same geographic area. These standards are often based on locally accepted protocols.

As an EMT, you will not be held to the same standard of care as physicians or other more highly trained professionals. In addition, your conduct must be judged in the light of the given emergency situation, taking into consideration the following factors:

- Any issues concerning the safety of the patient or rescuer
- General confusion at the scene of the emergency
- The needs of other patients
- The type of equipment available

In this context, an **emergency** is a serious situation, such as an injury or an illness that arises suddenly, threatens the life or welfare of a person or group of people, and requires immediate intervention.

Prevailing customs within a community are important elements in determining the standard of emergency care within that community. This means the accepted standard of care can change from one community to another. Examples of prevailing customs include how hospital destinations are selected, when EMS helicopters are used, and protocols for cervical spine immobilization **Figure 3-10**.

Figure 3-10 In emergency situations, you will care for those with potentially life-threatening injuries or illnesses by practicing a standard of care—the accepted level of care expected in your profession for your level of training.

▶ Standards Imposed by Law

In addition to local customs, standards of emergency medical care may be imposed by statutes, ordinances, administrative regulation, or case law. In many jurisdictions, violating one of these standards is said to create presumptive negligence. Therefore, you must become familiar with the particular legal standards that may exist in your state. In many states, this may take the form of treatment protocols published by a state agency.

▶ Professional or Institutional Standards

In addition to standards imposed by law, professional or institutional standards may be admitted as evidence in determining the adequacy of an EMT's conduct. Professional standards include recommendations published by organizations and societies that are involved in emergency medical care. Institutional standards include specific rules and procedures of the EMS system, ambulance service, or organization to which you are affiliated.

Two notes of caution: First, you must be familiar with the standards of your organization. Second, if you are involved in formulating standards for a particular agency, they should be reasonable and realistic so that they do not impose an unreasonable burden on EMTs. Regardless, providing the best emergency medical care should be every EMT's goal.

YOU are the Provider **PART 4**

The patient consents to EMS treatment and transport after you tell him he could be experiencing a serious medical emergency. You place the patient onto the stretcher. While loading the patient in the ambulance, the clerk asks, "What's wrong with him? Did I do the right thing?"

Recording Time: 10 Minutes	
Level of consciousness	Conscious and alert
Respirations	22 breaths/min; regular and unlabored
Pulse	104 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	194/108 mm Hg
Spo_2	99%

En route to the hospital, you dim the lights in the ambulance, apply a cool compress to his forehead, and ensure that he is in a comfortable position. You then obtain his patient information and medical history.

7. Does HIPAA affect the medical care you provide to your patients? What information are you allowed to discuss with family members, bystanders, the media, and others?

8. How do you respond to the clerk's question in a professional manner without violating HIPAA regulations?

Many standards of care may be imposed on you. State health department regulations usually govern the scope and level of training. Court decisions have resulted in case law defining standards of care. Professional standards are also imposed. For example, the International Liaison Committee on Resuscitation (ILCOR), along with its member the American Heart Association (AHA), updates the standard for basic life support (BLS) and cardiopulmonary resuscitation (CPR) on a regular basis **Figure 3-11**.

Ordinary care is a minimum standard of care. In general, it is expected that any EMT who offers assistance will exercise reasonable care and act prudently. If you act reasonably, according to the accepted standard, the risk of a civil lawsuit is small. If you apply the standard practices you have been trained to use, you can likely avoid liability. For example, various organizations have defined standards for performing CPR. If you deviate from these standards, you may be liable for civil and possibly criminal prosecution. In addition, state regulatory agencies that oversee EMS operations can sanction EMS personnel for deviating from the standard of care.

Standards Imposed by Textbooks

In the course of a lawsuit, an attorney will often ask an EMT if he or she recognizes various textbooks as being authoritative works in the field of EMS. Since virtually all EMS textbooks follow standards established by the National Highway Transportation Safety Administration (NHTSA), these textbooks are often recognized as contributing to the standard of care that is followed by EMTs. Local protocols or state standards may differ from material presented in textbooks. When such differences occur, you are bound to follow local protocols.

Figure 3-11 Many standards of care are imposed on you as an EMT. If you deviate from these standards, legal action may be taken against you. Learn the standards of care for your level and organization.

▶ Standards Imposed by States

Medical Practices Act

In some states, EMS personnel are exempt from the licensure requirements of the Medical Practices Act because an EMT is regarded as a nonmedical professional. The practice of medicine is defined as the diagnosis and treatment of disease or illness. EMTs and others in the prehospital care chain assess the need for life support and begin care. Some states, however, have adopted legislation that establishes the scope of practice for EMS providers. Therefore, as an EMT you must be aware of the standards established by legislation in your state so you can be sure to provide care that is consistent with those standards.

Certification and Licensure

Some states provide certification, licensure, or credentialing of people who perform emergency medical care. **Certification** is the process by which an individual, institution, or program is evaluated and recognized as meeting certain predetermined standards to ensure safe and ethical patient care. **Licensure** is the process by which a competent authority, usually the state, grants permission to practice a job, trade, or profession. **Credentialing** is an established process to determine the qualifications necessary to be allowed to practice a particular profession, or to function as an organization. The credentialing process for EMTs can vary by state. An EMS provider's credentials typically follow his or her name, eg, *John Smith, NREMT*.

Once certified, you are obliged to conform to the standards that are generally recognized nationally by various registry groups and provide an important link in nationwide EMS. You must ensure that your certification or licensure remains current and that your skill levels are kept up to date.

Duty to Act

Duty to act is an individual's responsibility to provide patient care. Responsibility comes from either statute or function. A bystander is under no obligation to assist a stranger in distress and therefore has no duty to act. There may be a duty to act in certain instances, including the following:

- You are charged with emergency medical response.
- Your service or department's policy states that you must assist in any emergency.

Once your ambulance responds to a call or treatment is begun, you have a legal duty to act. In most cases, if you are off duty and come upon a crash, you are not legally obligated to stop and assist patients. There may be some circumstances where this is not true, and you should be familiar with the laws and policies that apply in your service area. If you choose to intervene while off duty, you must continue to provide competent care until an equal or higher medical authority assumes care of the patient.

Negligence

Negligence is the failure to provide the same care that a person with similar training would provide in the same or a similar situation. It is deviation from the accepted standard of care that may result in further injury to the patient. Determination of negligence is based on the following four factors:

1. **Duty.** The EMT has an obligation to provide care and to do so in a manner that is consistent with the standard of care established by training and local protocols.
2. **Breach of duty.** There is a breach of duty when the EMT does not act within an expected and reasonable standard of care.
3. **Damages.** There are damages when a patient is physically or psychologically harmed in some noticeable way.
4. **Causation.** There must be a reasonable cause-and-effect relationship between the breach of duty and the damages suffered by the patient. An example is dropping the patient during lifting, causing a fracture of the patient's leg. If an EMT has a duty and abuses it, thereby causing harm to another individual, the EMT, the agency, and/or the medical director may be sued for negligence. This is often referred to as **proximate causation**.

All four elements must be present for the legal doctrine of negligence to apply and for a plaintiff to prevail in a lawsuit against an EMS system or provider. It is also possible for an EMT or an EMS system to be held liable even when the plaintiff is unable to clearly demonstrate how an injury occurred, under the theory of **res ipsa loquitor**. An EMT could be held liable under this theory if it can be shown that an injury occurred, that the cause of the injury was in the control of the EMT, and that such injuries generally do not occur unless there is negligence. For example, you and your partner are called to the home of a man with diabetes who has lapsed into unconsciousness. You find the patient lying on a couch with no visible signs of trauma. While loading the patient into the ambulance, your partner slips and the stretcher drops, causing the patient to sustain a facial laceration. The patient later files a lawsuit against you for negligence. Because the patient was unconscious, he is unable to describe exactly how he sustained a facial laceration. Under the theory of res ipsa loquitor, the patient may prevail in his lawsuit by showing that he was under your care, that he suffered an injury, and that his injury would not have occurred unless there was negligence.

In rare cases, the plaintiff may be able to establish liability by using the theory of **negligence per se**. This is a theory that may be used when the conduct of the person being sued is alleged to have occurred in clear violation of a statute. For example, if you were to perform an advanced life support skill, such as the intravenous administration of a cardiac medication, the plaintiff might allege that this was negligence per se. In that case, the plaintiff would not have to establish the circumstances surrounding your conduct. There would be no need to show that the medication was inappropriate for the patient because you clearly exceeded your scope of practice.

All forms of negligence come under the general category known as **torts**. Torts are simply defined as civil wrongs. They are not within the jurisdiction of US criminal courts. Examples of other tort actions are lawsuits for defamation of character and invasion of privacy.

Abandonment

Abandonment is the unilateral termination of care by the EMT without the patient's consent and without making any provisions for continuing care by a medical professional who is competent to provide care for the patient. Once care is started, you have assumed a duty that must not stop until an equally competent EMS provider assumes responsibility. Failure to perform that duty is a serious legal and ethical matter that exposes the patient to harm and can result in civil action against you.

For example, suppose you arrive at the scene of a single-car crash and begin care of two injured patients. A passerby tells you of a two-car crash farther down the road in which five people are injured. You turn over care of the two injured patients from the first crash to the passerby, who is not a trained emergency care provider, and leave to go to the second crash. Abandonment may have occurred because you did not turn care of the patients over to a person who is trained and competent to provide emergency care that meets the needs of the two patients. Consider the following general questions when you are faced with making a decision such as this one:

- What problems may develop from your actions?
- How might the patient's condition worsen if you leave?
- Does the patient need care?
- Are you neglecting your duty to your patient?
- Is the person assuming care capable of providing the level of care needed by the patient?
- Are you abandoning the patient if you leave the scene?
- Are you violating a standard of care?
- Are you acting prudently?

Surprisingly, abandonment may also take place in the emergency department (ED) where you drop off your patient. A part of your obligation as an EMT is to provide hospital personnel with a report of your assessment findings, the care you provided, and any changes in patient status that occurred during transport to the hospital. The failure to do so could result in a delay in treatment or a misdiagnosis. In such a case, a claim for abandonment might be filed against the EMT who failed to provide the report. It is always a good idea for you to obtain a signature on your PCR from the person accepting transfer of care at the hospital. This will help protect you from accusations of abandonment.

Assault and Battery and Kidnapping

Assault is defined as unlawfully placing a person in fear of immediate bodily harm. Threatening to restrain a patient who does not want to be transported could be considered assault. **Battery** is defined as unlawfully touching a person; this includes providing emergency care without consent. Assault and battery can be either civil or criminal in nature. Civil lawsuits for battery are common in health care. To sustain a criminal case of assault or battery, it is generally necessary to prove the intent to cause harm. The element of intent is rarely present in the case of an EMS provider; therefore, criminal cases of assault and/or battery are rare. **Kidnapping** is the seizing, confining, abducting, or carrying away of a person by force. In theory, this might include a situation where a patient is transported against his or her will. In reality, criminal charges of kidnapping are almost unheard of in EMS because the EMT is almost always acting in a good faith effort to provide care to the patient. It is far more likely that an EMT could be the target of a civil lawsuit for **false imprisonment**. This is defined as the unauthorized confinement of a person that lasts for an appreciable period of time. Consider a patient who rescinds consent during transport and demands to be let out of the ambulance. If you refuse, you may be accused of false imprisonment.

Serious legal problems may arise in situations in which a patient has not given consent for treatment. Battery could be considered if you apply a splint to a suspected fracture of the lower leg, or use an EpiPen on a patient without the patient's consent. Under such circumstances, a patient might file a lawsuit for assault, battery, false imprisonment, or all three. Criminal charges are possible but far less likely. To protect yourself from these charges, make sure that you obtain expressed consent or that the situation allows for implied consent. Consult your medical director or service attorney if you have questions or doubt about a specific situation.

Words of Wisdom

The best way to ensure you make good ethical decisions is to make the welfare of your patient your top priority.

Defamation

As an EMT, you should also be aware of the laws involving defamation. **Defamation** is the communication of false information that damages the reputation of a person. Defamation that is in writing is referred to as **libel**, and defamation that is spoken is known as **slander**. A legal claim for defamation could arise out of a false statement on a run report, inappropriate comments made on social media or during "station house" conversations, or sharing "war stories" with friends, relatives, or neighbors. To avoid liability for such a claim and to protect the confidentiality of patients, you must only communicate information about your patients to authorized people and you should be sure that the information contained in your run reports and other documentation is accurate and relevant. There is no reason to post information about your patient on social media. You should never comment on your patient's personal information when it is not relevant to your assessment or treatment of the patient.

Good Samaritan Laws and Immunity

All states have adopted **Good Samaritan laws**, which are based on the common law principle that when you reasonably help another person, you should not be liable for errors and omissions that are made in giving good faith emergency care. However, Good Samaritan laws do not necessarily protect you from a lawsuit. Good Samaritan provisions vary significantly from state to state. Good Samaritan statutes in some jurisdictions provide immunity from a lawsuit while others provide an affirmative defense if you are sued for rendering care. In most cases, they do not prohibit the filing of a lawsuit, nor do they pertain to acts that could be considered wanton, gross, or willful negligence. To be protected by the provisions of a Good Samaritan law, several conditions must generally be met:

1. You acted in good faith in rendering care.
2. You rendered care without expectation of compensation.
3. You acted within the scope of your training.
4. You did not act in a grossly negligent manner.

Gross negligence is defined as conduct that constitutes a willful or reckless disregard for a duty or standard of care.

Another group of laws grants immunity from liability to official EMS providers, such as EMTs, in some circumstances. These laws, which vary from state to state, do not provide immunity when injury or damage is caused by gross negligence or willful misconduct. In most cases, immunity statutes apply to EMS systems that are considered governmental agencies.

Most states have also adopted specific laws granting special privileges to EMS personnel, authorizing them to perform certain medical procedures. Many states also grant partial immunity to EMTs and physicians and nurses who give emergency instructions to EMS personnel via radio or other forms of communication. Consult your medical director or state EMS agency for more information about the laws in your area.

YOU are the Provider — PART 5

While reassessing the patient, he admits to using cocaine. You complete your reassessment and then call in your radio report to the receiving facility. The patient's blood pressure has improved and he tells you that his headache is not as bad as it was before.

Recording Time: 16 Minutes	
Level of consciousness	Conscious and alert
Respirations	18 breaths/min; regular and unlabored
Pulse	90 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	166/94 mm Hg
Spo_2	99%

You deliver the patient to the emergency department and give your oral report to the receiving nurse. After completing your patient care report (PCR), you and your partner return to service.

9. Should you report the patient's use of illegal substances to law enforcement personnel? Why or why not?
10. Why is it a good idea to have the receiving nurse sign your PCR acknowledging the transfer of care?

Records and Reports

Because EMS providers are in a position to observe and gather information about diseases, injuries, and emergency events, an obligation to compile such information and report it to certain agencies may be imposed. Even if there is no such requirement, you should compile a complete and accurate record of all incidents in which you come into contact with sick or injured patients. A complete and accurate record of an emergency medical incident is an important safeguard against legal complications. The absence of a record, or a substantially incomplete record, increases the likelihood that you may have to testify on memory alone. This can prove to be wholly inadequate and embarrassing in the face of aggressive cross-examination.

You should consider the following two rules of thumb regarding reports and records:

- If an action or procedure is not recorded on the written report, it was not performed.
- An incomplete or untidy report is evidence of incomplete or inexpert emergency medical care.

You can avoid both of these potentially dangerous presumptions by compiling and maintaining accurate reports and records of all events and patients. PCRs also help the EMS system evaluate individual and service provider performance. These reports are an integral part of most quality assurance programs. Data extraction from PCRs is also used to conduct prehospital emergency care research, which may improve patient outcomes.

The National EMS Information System (NEMSIS) is a tool for the EMS profession. NEMSIS provides the ability to collect, store, and share standardized EMS data throughout the United States. This incredibly useful database can be used to improve the speed and accuracy of data collection. NEMSIS could, for example, provide early warning of a disease outbreak.

Special Mandatory Reporting Requirements

Abuse of Children, Older People, and Others

All states have enacted laws to protect abused children, and some have added other protected groups such as the older population and "at-risk" adults. Most states have a reporting obligation for certain people, ranging from physicians to any person. You must be aware of the requirements of the law in your state. Such statutes frequently grant immunity from liability for libel, slander, or defamation of character to the individual who is obligated to report, even if the reports are subsequently shown to be unfounded, as long as the reports are made in good faith.

Injury During the Commission of a Felony

Many states have laws requiring the reporting of any injury that is likely to have occurred during the commission of a crime, such as gunshot wounds, knife wounds, or poisonings. Again, you must be familiar with the legal requirements of your state.

Drug-Related Injuries

In some instances, drug-related injuries must be reported. These requirements may affect how you approach documenting the care of a patient. However, it should be stressed that the US Supreme Court has held that drug addiction, in contrast to drug possession or sale, is an illness and not a crime. An injury as a result of a drug overdose, therefore, may not be within the definition of an injury resulting from a crime.

Some states, by statute, specifically establish confidentiality and excuse certain specified people from reporting drug cases, either to a government agency or to a minor's parents, if, in the opinion of those people, withholding reporting is necessary for the proper treatment of the patient. Once again, you must be familiar with the legal requirements of your state.

Childbirth

Many states require that anyone who attends at a live birth in any place other than a licensed medical facility report the birth. As before, you must be familiar with state requirements.

Other Reporting Requirements

Other reporting requirements may include attempted suicides, dog bites, certain communicable diseases, assaults, domestic violence, and sexual assault or rape.

Special Populations

Elder abuse is as prominent as child abuse in our society. Do not forget to be observant and report any suspicious signs or symptoms to the proper authorities.

Most EMS agencies require that all exposures to infectious diseases be reported. You may be asked to transport certain patients in restraints, which may also need to be reported. Each of these situations can present significant legal problems. You should learn your local protocols regarding these situations.

Not only do the events that need to be reported vary significantly from state to state but so do the methods and procedures by which such reporting must take place. For example, although all states require that suspected child abuse be reported, some states require that the report be filed with law enforcement, others with a designated child protection agency, and yet others with the ED. There are often time-sensitive provisions associated with reporting statutes. As has been noted earlier, it is important that you become familiar with reporting requirements of your state. Failure to report may result in disciplinary action, suspension of your privileges to practice as an EMT, a fine, or even criminal prosecution.

Scene of a Crime

If there is evidence at an emergency scene that a crime may have been committed, you must notify the dispatcher immediately so that law enforcement authorities can respond. Such circumstances should not stop you from providing lifesaving emergency medical care to the patient; however, your safety is a priority, so you must ensure that the scene is safe to enter. At times, you may have to transport the patient to the hospital before law enforcement arrives. While emergency medical care is being provided, you must be careful not to disturb the scene of the crime any more than absolutely necessary. Notes and drawings should be made of the position of the patient and of the presence and position of any weapon or other objects that may be valuable to the investigating officers. If possible, do not cut through holes in clothing that were caused by weapons or gunshot wounds. Avoid walking through blood and try to avoid leaving footprints in the dirt or grass at or near a crime scene. When a sexual assault is suspected, try to persuade the victim not to shower or clean himself or herself. You should confer periodically with local authorities and be aware of their wishes regarding actions you should take at the scene of the crime. It is best if these guidelines can be established by protocol.

The Deceased

In most states, EMTs do not have the authority to pronounce a patient dead. If there is any chance that life exists or that the patient can be resuscitated, you must make every effort to save the patient at the scene and during transport. However, at times death is obvious. If a victim is clearly dead and the scene of the emergency may be where a crime was committed, do not move the body or disturb the scene.

Ethical Responsibilities

In addition to legal duties, you have certain ethical responsibilities as a health care provider. These responsibilities are to yourself, your patients, your coworkers, and the public. **Ethics** is the philosophy of right and wrong, of moral duties, and of ideal professional behavior. It is often referred to as the study of morality. **Morality** is a code of conduct that can be defined by society, religion, or a person, affecting character and conscience. An entire field of ethics known as **bioethics** has evolved over the past several decades that addresses issues that arise in the practice of health care. Many such issues have drawn national attention, such as those dealing with the termination of life support, rationing of medical resources, and physician-assisted suicide. Ethical issues are present in nearly every EMS incident. As an EMT, you will be expected to conduct yourself in a manner that is consistent with the standards of your profession and to keep the best interests of your patients at the forefront of your conduct and decision making. The manner in which principles of ethics are incorporated into professional conduct is known as **applied ethics**.

You will encounter ethical dilemmas in the course of your employment that can be challenging to resolve. Examples might include the following:

- Your partner arrives at work smelling of alcohol.
- You are called to the scene of a belligerent driver who has seriously injured several children after causing a crash while drag racing.
- You are dispatched to a 9-1-1 call for chest pain. Your partner recognizes the address and tells you not to use the lights and siren since this is a “frequent flyer” who constantly calls 9-1-1 to get attention.
- You respond to the home of an older woman in cardiac arrest. One relative hands you DNR paperwork and states the patient didn’t want to be resuscitated. Another relative demands that you do everything possible to save the patient.
- One of your coworkers is unable to attend a training session and asks you to sign him in, stating, “You know I would do it for you.”

The manner in which you respond to each of these circumstances requires you to evaluate and apply your own ethical standards as well as those of your profession. Obviously, these choices can be difficult at times, particularly in those cases where your own personal standards of right and wrong do not necessarily agree with the standards of your profession. You know you should report that your partner may be intoxicated while on duty, even if he is a good friend. You might also want to honor the patient's DNR wishes, but medical control may order you to initiate care based on the family's request.

Your behavior both on and off the job will be a reflection of your personal ethical standards. News stories that depict EMS personnel engaging in any immature or illegal activities serve to lessen the public's confidence in the services EMTs provide. Illegal drug use or selling drugs, inappropriate use of emergency vehicles, inappropriate visitors entertained at the station, and use of alcohol on duty can impact negatively on the EMT and EMS in general and should be strictly forbidden.

You also may not stand by silently and watch as other EMS providers engage in misbehavior if you care about your patients, your coworkers, and the EMS system as a whole. Misconduct should be promptly reported to the appropriate chain of command. Similarly, you are obligated to report medical errors you make or witness to the medical director or another appropriate person as soon as possible.

As any group of professionals should, EMS providers should establish their own ethical standards and police the ethical behavior of their members. How can you make sure that you are acting ethically, especially with all the decisions you have to make in the field? First, you should consider all options available to you and the consequence of each option. Have decisions been made in the past regarding a similar situation; can an existing policy or rule be applied? How will the consequences of your decision provide the greatest benefit in view of all the alternatives? Involve online medical control in your decision making **Table 3-2**.

You must meet your legal and ethical responsibilities while caring for your patients' physical and emotional needs. Patient needs will vary depending on the situation, and you must be prepared to offer whatever physical and emotional support is necessary. In most cases that you will encounter as an EMT, there will be a rule, a law, or a policy that will guide your decision making and your actions. As a professional, you are bound to follow all such policies, rules, and laws even in those rare circumstances where your own personal sense of ethics might lead you to a different result. In short, your professional ethics trump personal morals while on duty.

Table 3-2 Ethical Decision Making Checklist

	Yes	No
Is the decision in the best interests of the patient?	❑	❑
Is the decision based on logic and reason rather than emotion?	❑	❑
Does the decision protect the patient's rights?	❑	❑
Would you agree to the same decision if you were the patient?	❑	❑
Would you make the same decision again in similar circumstances?	❑	❑
Can you defend this decision to others?	❑	❑

One unquestionable responsibility you have is honest reporting. Remember, absolute honesty in reporting is essential. You must provide a complete account of the events and the details of all patient care and professional duties.

The EMT in Court

As an EMT, there are a number of different circumstances that might cause you to end up in court, either as a witness or a defendant in a civil lawsuit or as a witness or defendant in a criminal case. Regardless of the circumstances, being in court is often stressful. As a witness in a civil case, you may be called to testify about the condition of the plaintiff when you arrived at the scene of a crash and about the treatment that you provided. In a criminal case, you may be asked to describe a crime scene, the injuries that you found when you examined a crime victim, or to testify concerning any admissions or statements made to you by a criminal defendant.

Whenever you are subpoenaed to testify in any court proceeding, you should immediately notify the director of your service and legal counsel. As a witness you should remain neutral during your testimony. You are simply there to provide the facts as you observed them and not to take sides. In all likelihood, many of the questions that you will be asked will be based on the documentation you wrote at the time of the incident. Be sure to review your run report prior to your court appearance **Figure 3-12**.

As a defendant in either a civil or criminal proceeding, your involvement will obviously be far more significant and the outcome will have far greater personal consequences. In either case, you will definitely require the assistance of an attorney. In a civil lawsuit, where you are being sued in your capacity as an employee or volunteer of an EMS system, your service or its insurance company generally will provide you with legal counsel.

A civil lawsuit begins with the service of a summons and complaint. The complaint will set forth the details of the plaintiff's case and will provide the theory on which the plaintiff is relying to recover a judgment against you and your service. If served with a summons, you must bring this to the attention of the head of your service immediately, because the complaint must be responded to within a set period of time that is usually within 20 to 30 days. The response to the complaint is called an answer and it will generally deny the claims set forth in the complaint and set forth one or more defenses on behalf of you and your service. A defense is essentially a reason why the plaintiff should not recover a judgment against you. Depending on the nature of the case filed against you, the type of EMS system that you work for, and the state where you work, there may be different possible defenses available to you. These may include the defenses of statute of limitations, immunity, or contributory negligence.

The **statute of limitations** is the time within which a case must be commenced. For example, in many states, a claim for negligence must be commenced within 3 years. A case commenced beyond the 3-year period would be barred by the statute of limitations. In such a case, your attorney would include the defense of statute of limitations in the answer that is filed in response to the complaint.

Figure 3-12 Court discussions will be based on your documentation. Make sure your documentation is neat, thorough, and accurate.

Another possible defense is that of governmental immunity. **Governmental immunity** generally applies only to EMS systems that are operated by municipalities or other governmental entities. If your service is covered by immunity, it may mean that you cannot be sued at all or it may limit the amount of the monetary judgment that the plaintiff may recover. State laws vary significantly on both the statute of limitations and immunity, and you should understand the laws that apply in your state.

Contributory negligence is a legal defense that may be raised when the defendant feels that the conduct of the plaintiff somehow contributed to any injuries or damages that were sustained by the plaintiff. For example, you are treating a patient with chest pain and you feel that the administration of aspirin is indicated. You ask the patient if he is allergic to aspirin and he says no. Shortly after you administer the aspirin, the signs and symptoms of a severe allergic reaction develop in the patient. Later in the hospital, the doctor advises you that the patient's medical chart history indicates that the patient has an allergy to aspirin. The patient states that he forgot he was allergic to aspirin. In this case, the defense of contributory negligence might be raised since it was the patient's forgetfulness and his denial of an aspirin allergy that contributed to his allergic reaction.

The next phase of the case is known as **discovery**, and it is an opportunity for both sides to obtain information that will enable the attorneys to have a better understanding of the case and assist in negotiating a possible settlement or in preparing for trial. Discovery may include interrogatories, depositions, requests for production of documents, and physical examinations. **Interrogatories** are written questions that each side sends to the other, and **depositions** are oral questions asked of parties and witnesses under oath. On completion of the discovery phase, the parties may try to negotiate a possible settlement. Most cases are settled and do not go to trial. If a settlement is not able to be negotiated, the case will be set for trial. It is not uncommon for a case to take several years to get to trial.

At trial, each side will have an opportunity to present evidence that includes testimony of witnesses and documents such as medical reports and your run report. Witnesses may include experts such as physicians. Once both sides have concluded presenting evidence, a judge or jury will render a decision or verdict. If a judgment is rendered against you or your service, the plaintiff may be awarded compensatory or punitive damages:

1. **Compensatory damages**. These damages are intended to compensate the plaintiff for the injuries he or she sustained such as medical bills, damages to personal property, lost earnings, and physical or emotional pain and suffering.
2. **Punitive damages**. Punitive damages are not commonly awarded in negligence cases and are reserved for those cases where the defendant has acted intentionally or with a reckless disregard for the safety of the public.

In most cases, if a judgment is rendered against you, your service or its insurance carrier will pay the judgment.

There is also the possibility that you could be arrested and charged with a criminal offense arising out of your employment as an EMS provider. Although these are rare occurrences, there have been EMTs who have been charged with crimes including theft of patient property, assault or sexual assault on a patient, operating a vehicle while under the influence of drugs or alcohol, or various drug-related offenses. Obviously, any arrest is considered very serious because a conviction could lead to imprisonment, the imposition of fines, and possible loss of the ability to practice as an EMT. Any EMT charged with a criminal offense should secure the services of a highly experienced criminal attorney immediately.

YOU are the Provider — SUMMARY

1. Why is it essential that you obtain consent to treat the patient once you arrive?

Consent is required from every conscious adult before care can be started. The adult patient who is conscious, rational, and capable of making informed decisions has a legal right to refuse care. The patient does not forfeit this right simply because you disagree or because it may not be the best medical decision. The law allows the patient to make choices that may seem medically unsound and might even endanger his or her own life. Failing to honor a competent adult patient's right to refuse care or transport may be grounds for both criminal and civil action against you.

2. Should you assess the patient's competency or decision making capacity once you arrive?

Your role is to assess the patient's decision making capacity. Although the terms *competence* and *decision making capacity* are often thought of interchangeably, there is a distinction. Competence is typically determined by a court of law, whereas decision making capacity refers to whether a patient is capable of making a rational decision. Assessing a patient's decision making capacity can often be complicated in the prehospital setting, and you may require the assistance of medical control to make the best decision.

3. Are you legally authorized to treat this patient? Why or why not?

At this point, you have not obtained consent from the patient to begin treating him; in fact, you haven't even introduced yourself. Under most circumstances, you may not begin treatment of a mentally competent adult until he or she has given you permission, or consent, to do so. If the patient has decision making capacity—that is, he or she is conscious, alert, not under the influence of drugs or alcohol, and of legal age (18 years in most states)—you cannot legally provide care, even if the patient is obviously sick or injured. Providing care without the patient's consent may be grounds for both criminal and civil action, such as assault and battery.

4. How does informed consent differ from implied consent?

A patient's consent must be informed, which means you have explained the nature of the treatment being offered, including the potential risks, benefits, and alternatives to treatment, as well as any potential consequences of refusing treatment, and the patient has given consent.

Implied consent is based on the legal assumption that a critically ill or injured patient, who is physically unable to give consent (ie, unconscious, under the influence of drugs or alcohol), would consent to EMS treatment and transport if he or she were physically able to do so. Consent to treat is also implied when caring for a minor whose parents or caregivers are unable to be located; a minor cannot legally consent to or refuse medical care.

5. What should you do when a patient refuses treatment and/or transport?

When a patient refuses treatment and/or transport, it is not unreasonable to ask why he or she does not wish to be treated. Many people refuse treatment because of financial concerns or the fact that they are scared. In this case, you should explain that his high blood pressure and severe headache could indicate bleeding in the brain or some other potentially life-threatening condition and that only a physician can diagnose his problem. Do not be afraid to advise the patient that his refusal could ultimately result in death; this is not a scare tactic, it is the truth and the patient has a right to hear it.

If, despite your best efforts to obtain consent to treat, a mentally competent adult still refuses, there is little else you can legally do. You should, however, inform medical control of the situation. In some cases, the physician may wish to speak directly to the patient.

6. What questions should you ask yourself to help determine whether you can transport this patient against his will?

When a patient refuses treatment, you must assess his or her decision-making capacity. Is the patient's mental condition impaired? Is the patient under the influence of drugs or alcohol? Is the patient of legal age? Is the patient a danger to himself/herself or others? These are but a few of the questions that must be answered.

In this case, there is no evidence that has been uncovered thus far that the patient's decision making capacity is impaired, and although he needs medical attention for his headache and blood pressure, you cannot legally force him to accept it, nor can you transport him against his will.

The best course of action is to ensure that the patient is aware of the potential consequences of his refusal—namely, death—and contact medical control to apprise him or her of the situation.

7. Does HIPAA affect the medical care you provide to your patients? What information are you allowed to discuss with family members, bystanders, the media, and others?

The Health Insurance Portability and Accountability Act of 1996 (HIPAA) has many aims; however, the section of the act that most directly affects EMS relates to patient privacy. *Confidential patient information* includes patient history, assessment findings, treatment, etc. HIPAA provides guidance on why types of information are protected, the responsibility of health care providers regarding that protection, and penalties for breaching that protection. Confidential information can be shared under conditions, such as for continuity of care and for billing purposes. *You should not allow HIPAA to affect the medical care that you provide to a patient*.

You must be very careful about what you discuss with family members, bystanders, the media, etc. You must protect the patient's confidential information. There may be times when this is difficult, especially with concerned family members. When in doubt about what to share, simply provide reassurance that everyone is doing his or her best for the patient.

8. How do you respond to the clerk's question in a professional manner without violating HIPAA regulations?

This is a great opportunity to praise a conscientious bystander who did the right thing. Thank the clerk, but do not provide him with any confidential patient information. For example, "You did the right thing during a stressful situation and we appreciate it. We are required to protect the patient's privacy, but I want to reassure you we will take excellent care of the patient from here."

9. Should you report the patient's use of illegal substances to law enforcement personnel? Why or why not?

The patient's use of cocaine is pertinent medical information that may have an impact on the care he receives at the hospital; therefore, it should be included in your patient care report and your oral report to the receiving facility. However, the US Supreme Court has held that drug use or addiction (in contrast to possession or sale) is an illness and not a crime. Therefore, you are not legally required to report the patient's admitted use of these substances to law enforcement personnel. If you are in doubt, consult with your EMS medical director. More important, you must be familiar with the reporting requirements of the state in which you function as an EMT.

10. Why is it a good idea to have the receiving nurse sign your PCR acknowledging the transfer of care?

Sign-off is important for several reasons. It ensures that an equal or higher medical authority has accepted care of the patient from you. It also provides a record of who accepted care of the patient in the event there are any questions later. Failure to appropriately transfer care at the receiving hospital may be considered abandonment. Your documentation should show that you have met this obligation.

Narrative

9-1-1 dispatch for a man with a severe headache. On arrival at the scene, found the patient, a 32-year-old man, sitting on the sidewalk outside convenience store, grabbing his head in pain. He was conscious and alert; his airway was patent, and his breathing was adequate. Patient states that his headache began a few hours earlier and that he has not taken his prescribed antihypertensive medication. No trauma was involved in this incident. Past medical history significant for hypertension. He denies loss of consciousness, nausea, or any other symptoms. Patient was initially hesitant to consent to EMS treatment and transport. However, after the potential complications of his refusal were explained to him, he agreed to EMS treatment and transport. Obtained vital signs and performed further assessment, which was unremarkable. Placed patient onto stretcher, loaded him into the ambulance, dimmed the lights, and placed him in a position of comfort. Began transport to the hospital and monitored his condition en route. Patient admitted to using cocaine, but he did not feel this was contributing to his condition. Patient remained conscious and alert during transport and stated that his headache was improving. Reassessment of his vital signs revealed that his blood pressure had improved. Delivered patient to emergency department staff and gave oral report to charge nurse.**End of report**

Prep Kit

Ready for Review

- Under most circumstances, consent is required from every conscious adult before care can be started. The foundation of consent is decision making capacity.
- You should never withhold lifesaving care unless a valid do not resuscitate (DNR) order is present.
- Because a minor might not have the wisdom, maturity, or judgment to give consent, the law requires that a parent or legal guardian give consent for treatment or transport.
- Adults who are conscious and alert and who appear to have decision making capacity have the right to refuse treatment or withdraw from treatment at any time, even if doing so may result in serious injury or death.
- You should include all information pertaining to patient refusals in your patient care report (PCR).
- Communication between you and the patient is considered confidential and generally cannot be disclosed without permission from the patient or a court order.
- Advance directives, living wills, or health care directives are most commonly used when a patient becomes comatose. Physician Orders for Life-Sustaining Treatment and Medical Orders for Life-Sustaining Treatment forms explicitly describe acceptable interventions for the patient in the form of medical orders.
- There are both definitive and presumptive signs of death. In many states, death is defined as the absence of circulatory and respiratory function.
- Consent to organ donation is evidenced by either a donor card or a driver's license indicating that the individual wishes to be a donor.
- Standard of care is established in many ways, among them local customs, statutes, ordinances, protocols, textbooks, administrative regulations, and case law. The scope of practice outlines the care you are able to provide for the patient.
- Once your ambulance responds to a call or treatment is begun, you have a legal duty to act. In most cases, if you are off duty and come upon a crash, you are not legally obligated to stop and assist patients.
- Determination of negligence is based on the following four factors: duty, breach of duty, damages, and causation. All four elements must be present for the legal doctrine of negligence to apply and for a plaintiff to prevail in a lawsuit against an EMS system or provider.
- Abandonment is the termination of care without the patient's consent and without making provisions for the transfer of care to a medical professional with skills at the same level or at a higher level than your own skills. Abandonment is legally and ethically a very serious act. Always try to obtain a signature on your PCR from the person accepting transfer of care.
- Assault is defined as unlawfully placing a person in fear of immediate bodily harm. Battery is unlawfully touching a person; this includes providing emergency care without consent. To protect yourself from these charges, be sure to obtain expressed consent whenever possible.
- To avoid liability for defamation, you must only communicate information about your patients to authorized people and you should be sure that the information contained in your run reports and other documentation is accurate and relevant.
- Good Samaritan laws are based on the common law principle that when you reasonably help another person, you should not be liable for errors and omissions that are made in giving good faith emergency care. Whereas some laws provide Good Samaritan protection for anyone who stops to render aid, others only provide protection for those with medical training.
- Records and reports are important; make sure that you compile a complete and accurate record of each incident. The courts consider an action or procedure that was not recorded on the written report as not having been performed, and an incomplete or untidy report is considered evidence of incomplete or inexpert medical care.
- You should know what the special reporting requirements are involving abuse of children, older adults, and others; injuries related to crimes; drug-related injuries; and childbirth.
- You must meet your legal and ethical responsibilities while caring for your patients' physical and emotional needs.
- As an EMT, there are a number of different circumstances that might cause you to end up in court, either as a witness or a defendant in a civil lawsuit or as a witness or defendant in a criminal case.

Vital Vocabulary

abandonment Unilateral termination of care by the EMT without the patient's consent and without making provisions for transferring care to another medical professional with the skills and training necessary to meet the needs of the patient.

advance directive Written documentation that specifies medical treatment for a competent patient should the patient become unable to make decisions; also called a living will or health care directive.

applied ethics The manner in which principles of ethics are incorporated into professional conduct.

assault Unlawfully placing a patient in fear of bodily harm.

battery Unlawfully touching a patient or providing emergency care without consent.

bioethics The study of ethics related to issues that arise in health care.

breach of confidentiality Disclosure of information without proper authorization.

certification A process in which a person, an institution, or a program is evaluated and recognized as meeting certain predetermined standards to provide safe and ethical patient care.

compensatory damages Damages awarded in a civil lawsuit that are intended to restore the plaintiff to the same condition that he or she was in prior to the incident.

competent Able to make rational decisions about personal well-being.

consent Permission to render care.

contributory negligence A legal defense that may be raised when the defendant feels that the conduct of the plaintiff somehow contributed to any injuries or damages that were sustained by the plaintiff.

credentialing An established process to determine the qualifications necessary to be allowed to practice a particular profession, or to function as an organization.

decision-making capacity Ability to understand and process information and make a choice regarding appropriate medical care.

defamation The communication of false information about a person that is damaging to that person's reputation or standing in the community.

dependent lividity Blood settling to the lowest point of the body, causing discoloration of the skin; a definitive sign of death.

depositions Oral questions asked of parties and witnesses under oath.

discovery The phase of a civil lawsuit where the plaintiff and defense obtain information from each other that will enable the attorneys to have a better understanding of the case and which will assist in negotiating a possible settlement or in preparing for trial. Discovery includes depositions, interrogatories, and demands for production of records.

do not resuscitate (DNR) orders Written documentation by a physician giving permission to medical personnel not to attempt resuscitation in the event of cardiac arrest.

durable power of attorney for health care A type of advance directive executed by a competent adult that appoints another individual to make medical treatment decisions on his or her behalf, in the event that the person making the appointment loses decision-making capacity.

duty to act A medicolegal term relating to certain personnel who either by statute or by function have a responsibility to provide care.

emancipated minors A person who is under the legal age in a given state but, because of other circumstances, is legally considered an adult.

emergency A serious situation, such as injury or illness that threatens the life or welfare of a person or group of people and requires immediate intervention.

emergency doctrine The principle of law that permits a health care provider to treat a patient in an emergency situation when the patient is incapable of granting consent because of an altered level of consciousness, disability, the effects of drugs or alcohol, or the patient's age.

emergency medical care Immediate care or treatment.

ethics The philosophy of right and wrong, of moral duties, and of ideal professional behavior.

expressed consent A type of consent in which a patient gives verbal or nonverbal authorization for provision of care or transport.

false imprisonment The confinement of a person without legal authority or the person's consent.

forcible restraint The act of physically preventing an individual from initiating any physical action.

Good Samaritan laws Statutory provisions enacted by many states to protect citizens from liability for errors and omissions in giving good faith emergency medical care, unless there is wanton, gross, or willful negligence.

governmental immunity Legal doctrine that can protect an EMS provider from being sued or which may limit the amount of the monetary judgment that the plaintiff may recover; generally applies only to EMS systems that are operated by municipalities or other governmental entities.

gross negligence Conduct that constitutes a willful or reckless disregard for a duty or standard of care.

health care directive A written document that specifies medical treatment for a competent patient, should he or she become unable to make decisions. Also known as an advance directive or a living will.

health care proxies A type of advance directive executed by a competent adult that appoints another individual to make medical treatment decisions on his or her behalf in the event that the person making the appointment loses decision making capacity. Also known as a durable power of attorney for health care.

implied consent Type of consent in which a patient who is unable to give consent is given treatment under the legal assumption that he or she would want treatment.

informed consent Permission for treatment given by a competent patient after the potential risks, benefits, and alternatives to treatment have been explained.

in loco parentis Refers to the legal responsibility of a person or organization to take on some of the functions and responsibilities of a parent.

interrogatories Written questions that the defense and plaintiff send to one another.

kidnapping The seizing, confining, abducting, or carrying away of a person by force, including transporting a competent adult for medical treatment without his or her consent.

libel False and damaging information about a person that is communicated in writing.

licensure The process whereby a competent authority, usually the state, allows people to perform a regulated act.

medicolegal A term relating to medical jurisprudence (law) or forensic medicine.

morality A code of conduct that can be defined by society, religion, or a person, affecting character, conduct, and conscience.

negligence Failure to provide the same care that a person with similar training would provide.

negligence per se A theory that may be used when the conduct of the person being sued is alleged to have occurred in clear violation of a statute.

patient autonomy The right of a patient to make informed choices regarding his or her health care.

protected health information (PHI) Any information about health status, provision of health care, or payment for health care that can be linked to an individual. This is interpreted rather broadly and includes any part of a patient's medical record or payment history.

proximate causation When a person who has a duty abuses it, and causes harm to another individual, the EMT, the agency, and/or the medical director may be sued for negligence.

punitive damages Damages that are sometimes awarded in a civil lawsuit when the conduct of the defendant was intentional or constituted a reckless disregard for the safety of the public.

putrefaction Decomposition of body tissues; a definitive sign of death.

res ipsa loquitor When the EMT or an EMS system is held liable even when the plaintiff is unable to clearly demonstrate how an injury occurred.

rigor mortis Stiffening of the body muscles; a definitive sign of death.

scope of practice Most commonly defined by state law; outlines the care that the EMT is able to provide for the patient.

slander False and damaging information about a person that is communicated by the spoken word.

standard of care Written, accepted levels of emergency care expected by reason of training and profession; written by legal or professional organizations so that patients are not exposed to unreasonable risk or harm.

statute of limitations The time within which a case must be commenced.

tort A wrongful act that gives rise to a civil lawsuit.

Assessment *in Action*

You are dispatched to a home where you find a 65-year-old man reporting chest pain. The patient is alert and oriented. Assessment of his vital signs shows a pulse rate of 110 beats/min and irregular, a blood pressure of 140/90 mm Hg, and a respiratory rate of 22 breaths/ min. He describes the pain as crushing. He has an extensive cardiac history and is taking numerous medications. The patient states he does not want to go to the hospital and that his friend was overreacting by calling EMS. Your partner hands the patient a refusal form and states "Sign here; it says if you die, it's not our fault." In the ambulance, you tell your partner, "We should have tried to convince him to go to the hospital." Your partner replies, "Don't worry, he signed a refusal. We can't be held liable."

1. Once your ambulance is dispatched to an emergency, you have an obligation to respond. This is known as:

   A. scope of practice.
   B. duty to act.
   C. breach of duty.
   D. mandatory reporting.

2. Upon arrival at the scene, your partner began assessing vital signs without talking to the patient. This demonstrates:

   A. effective interpersonal communication.
   B. patient advocacy.
   C. failure to obtain consent.
   D. breach of duty.

3. Suppose your partner had introduced himself and asked permission to examine the patient. If the patient nodded and extended his arm, this would be considered:

A. mature consent.
B. implied consent.
C. informed consent.
D. expressed consent.

4. What is the best way to care for your patient once he tells you he does not want to go to the hospital?

A. Let him know how important it is that he accept transport to the hospital.
B. Ask him to sign a refusal form, releasing you from liability.
C. Order him to go to the hospital against his wishes.
D. Encourage him to call 9-1-1 again if his condition worsens.

5. While caring for this patient, you hear a neighbor cry for help; a child is drowning just around the corner. You and your partner leave, telling the patient you must respond to this incident and will send another ambulance for him as soon as possible. This decision is an example of:

A. triage.
B. abandonment.
C. patient advocacy.
D. duty to act.

6. On another call that day, your patient consented to treatment and transport after you told her she could be experiencing a serious medical emergency. This is an example of:

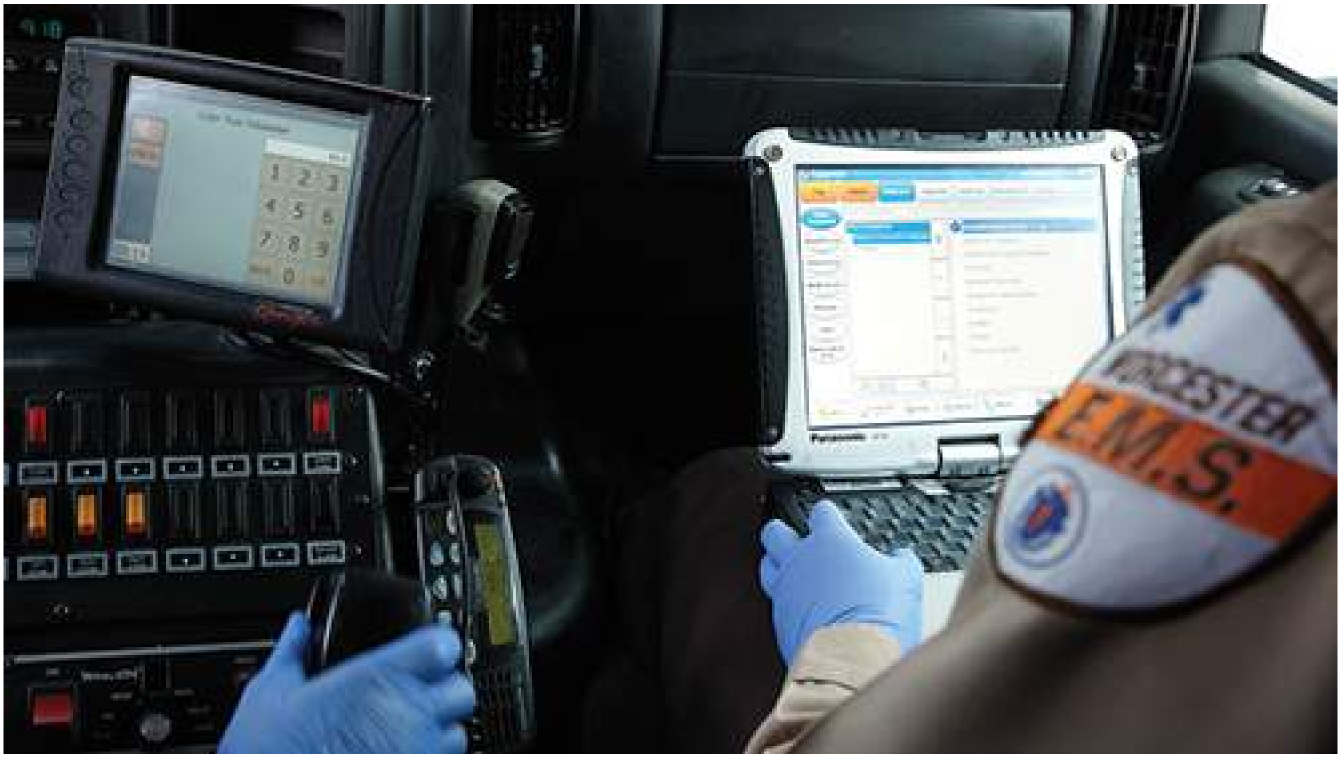
A. scope of practice.
B. implied consent.
C. serving in the patient's best interest.
D. an EMS field impression.

7. What ethical challenges were you presented with during this call?

8. If a patient says he has used heroin recently, who should you tell about this?

CHAPTER 4

Communications and Documentation



National EMS Education Standard Competencies

Preparatory

Applies fundamental knowledge of the emergency medical services (EMS) system, safety/well-being of the emergency medical technician (EMT), medical/legal, and ethical issues to the provision of emergency care.

Therapeutic Communication

Principles of communicating with patients in a manner that achieves a positive relationship

› Interviewing techniques (pp 116–120)
› Adjusting communication strategies for age, stage of development, patients with special needs, and differing cultures (pp 114–115, 120–124)
› Verbal defusing strategies (pp 115–117)
› Family presence issues (pp 119–120)

EMS System Communication

Communication needed to
› Call for resources (pp 140–141)
› Transfer care of the patient (pp 124–127, 142–143)
› Interact within the team structure (pp 140–142)
› EMS communication system (pp 135–139)
› Communication with other health care professionals (pp 124–125, 142–145)
› Team communication and dynamics (pp 124–125, 142–145)

Documentation

› Recording patient findings (pp 126–135)
› Principles of medical documentation and report writing (pp 126–135)

Medical Terminology

Uses foundational anatomical and medical terms and abbreviations in written and oral communication with colleagues and other health care professionals.

Knowledge Objectives

1. Describe the factors and strategies to consider for therapeutic communication with patients. (pp 113–125)
2. Discuss the techniques of effective verbal communication. (pp 116–125)
3. Explain the skills that should be used to communicate with family members, bystanders, people from other agencies, and hospital personnel. (pp 116–125)
4. Discuss special considerations in communicating with older people, children, patients who are hard of hearing, visually impaired patients, and non–English-speaking patients. (pp 120–124)
5. Describe the use of written communications and documentation. (pp 126–134)
6. State the purpose of a patient care report (PCR) and the information required to complete it. (pp 126–132)
7. Explain the legal implications of the PCR. (pp 130–131)
8. Describe how to document refusal of care, including the legal implications. (pp 132–135)
9. Discuss state and/or local special reporting requirements, such as for gunshot wounds, dog bites, and abuse. (p 135)
10. Describe the basic principles of the various types of communications equipment used in EMS. (pp 135–139)
11. Describe the use of radio communications, including the proper methods of initiating and terminating a radio call. (pp 139–145)
12. List the correct radio procedures in the following phases of a typical call: initial receipt of call, en route to call, on scene, arrival at hospital (or point of transfer), and return to service. (pp 139–142)
13. List the proper sequence of information to communicate in radio delivery of a patient report. (pp 142–143)

Skills Objectives

1. Demonstrate the techniques of successful cross-cultural communication. (pp 114–115)
2. Demonstrate completion of a PCR. (pp 126–135)
3. Demonstrate how to make a simulated, concise radio transmission with dispatch. (pp 139–143)

Introduction

Communication is the transmission of information to another person—whether it is verbal or nonverbal (through body language). Effective communication is an essential component of prehospital care and is necessary to achieve a positive relationship with patients and coworkers.

Verbal communication skills are vitally important for EMTs. Your verbal skills will enable you to gather information from the patient and bystanders. These skills will also make it possible for you to effectively coordinate with the variety of responders who are often present at the scene. Excellent verbal communication is also an integral part of transferring the patient's care to the nurses and physicians at the hospital.

Documentation is the written or electronically recorded portion of your patient care interaction that becomes part of the patient's permanent medical record. It serves many purposes, including demonstrating that the care delivered was appropriate and within the scope and practice of the providers involved. Documentation also provides an opportunity to communicate the patient's story to others who may participate in the patient's care in the future. Adequate reporting and accurate records ensure the continuity of patient care. Complete patient records also guarantee proper transfer of responsibility, comply with the requirements of health departments and law enforcement agencies, and fulfill your organization's administrative needs. Reporting and record-keeping duties are an essential aspect of patient care, although they are performed only after the patient's condition has been stabilized. Documentation in the field drives both funding and research for EMS. Seat belts are a prime example. Studies gathered from record keeping in the early 1970s showed that patients have a significantly higher survival rate if seat belts are used during motor vehicle crashes. Armed with this information, laws were passed to enforce seat belt usage, and huge amounts of money were spent on educating the public.

Radio and telephone communications link you and your team with other members of the EMS, fire, and law enforcement communities. This link helps the entire team to work together more effectively and provides an important layer of safety and protection for each member of the team. You must know what your system can and cannot do, and you must be able to use your system efficiently and effectively.

This chapter describes the factors and strategies that you need to be an effective communicator, discusses a variety of effective methods of verbal communication, and provides guidelines for appropriate written documentation of patient care. The chapter concludes by identifying the kinds of communication equipment that are used, along with standard radio operating procedures and protocols. The roles of the Federal Communications Commission in EMS are also described.

Therapeutic Communication

How do we communicate? This simple question can be surprisingly complex as there are a number of things to consider during communication Table 4-1. Therapeutic communication uses various communication techniques and strategies, both verbal and nonverbal, to encourage patients to express how they are feeling and to achieve a positive relationship with the patient. This section will discuss the factors and strategies that are necessary for therapeutic communication.

People communicate in a variety of ways, such as through eye contact, body position, and facial expressions. Factors such as culture and age need to be taken into consideration during communication. Patients with special needs may require you to consider alternative forms of communication. For example, if your patient is deaf and you cannot communicate using sign language, you may need to communicate by having the patient write down his feelings.

YOU are the Provider — PART 1

At 0610 hours, your BLS unit is dispatched to 514 E. Bandera Street for a "sick person." You and your partner proceed to the scene, which is approximately 10 minutes away. En route, the dispatcher contacts you and states that she still has the caller on the phone.

1. What information should you ask the dispatcher to obtain from the caller?
2. Why is effective communication between the responding EMS unit and the dispatcher so important?

Table 4-1 Factors and Strategies to Consider During Communication

Age	Eye contact
Body language	Facial expression
Clothing	Gender
Culture	Posture
Education	Voice tempo
Environment	Volume

Words of Wisdom

The Shannon–Weaver communication model was developed to assist in the mathematical theory of communication for Bell Telephone Labs in the late 1940s **Figure 4-1**. Shannon and Weaver were trying to figure out the math involved in sending information through telephone lines. After its creation, it quickly became apparent that this model had application in areas other than math. Social scientists adopted this model and it remains a valuable tool in understanding the variables involved in human communication. In the communication model, the sender must take a thought, encode it into a message, and send the message to the receiver. The receiver then decodes the message and sends feedback to the sender.

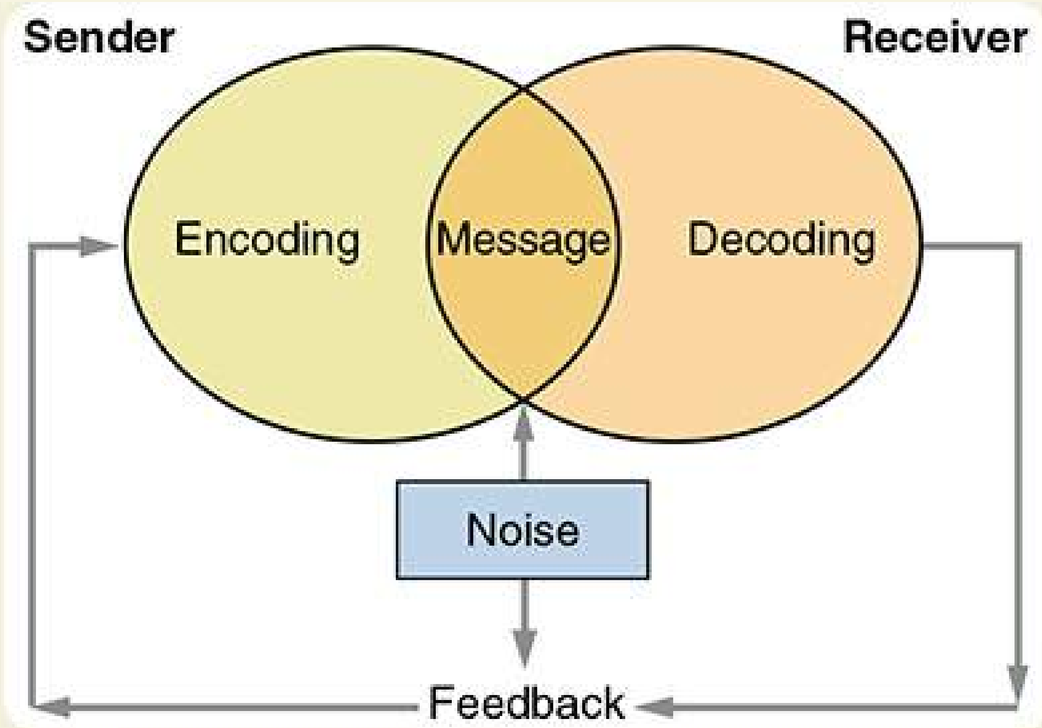


Figure 4-1 Shannon–Weaver communication model.

Age, Culture, and Personal Experience

The thoughts of people are greatly influenced by their personal experiences. For example, an older person who often experiences significant pain may view pain as more of an inconvenience than a problem. A child who has limited experience with pain would likely react much differently. People from various cultures are taught to handle illness, injury, and pain differently. Some cultures encourage people to express their emotions; others see it as a sign of weakness. These social and personal pressures will shape how people communicate.

Patients may talk, make gestures, or write a note to express how they are feeling. “I am so sorry to bother you, but my chest hurts a little.” “Hey! What took you so long? My chest is killing me! Are you going to help me or what?” Both of these messages talk about pain, but they also have much more information within them.

The tone, pace, and volume of the language will tell you about the mood of the person communicating. These clues also provide some insight into the perceived importance of the message. For example, the patient who is yelling at you may be angry, scared, or both. Take note not only of the words being spoken, but how they are said.

You need to recognize that these concepts of body language and eye contact are often greatly affected by culture. In some cultures, direct eye contact is viewed as impolite, while in other cultures, it is impolite to look away while speaking. For example, in the United States and most European countries, direct eye contact conveys honesty and respect. Conversely, in Latin-American, Asian, and African cultures, direct eye contact conveys confrontation.

People tend to translate the messages they receive using their own world view. **Ethnocentrism** occurs when you consider your own cultural values as more important when you are interacting with people of a different culture. If you are North American, for example, you might think that a patient is hiding something, afraid, or untrustworthy if the patient looks away from you while you are talking. These conclusions may be true if the two people communicating are from the same culture. All aspects of communication—eye contact, social distances, body language, and even touching—have a cultural foundation. In Thailand, for example, the touching of the head is reserved for those who are very intimate. This cultural belief can present a problem for you if the patient's head is bleeding.

Cultural imposition takes this idea to an extreme. Some health care providers may consciously or subconsciously force their cultural values onto their patient because they believe their values are better. For example, consider a child who is brought to the emergency department (ED) with red marks on his back from a traditional Asian healing practice called coining—rubbing hot coins on the child's back as a treatment for medical illness. The parents explain to the physician that the coining helped for a short time, but now the child seems to be getting sicker. The physician responds angrily to the parents, accusing them of potential abuse and insisting that their practices are harmful (although they are not). This accusation reflects cultural imposition.

Nonverbal Communication

Facial Expressions, Body Language, and Eye Contact

Eye contact and body language are powerful communication tools. Consider how dogs interact. When two dogs meet for the first time, they look at each other. The position of the head, shoulders, tail, and back all help to communicate to the other dog. Before they get any closer, the dogs need to understand their new relationship. Who is dominant? Will you hurt me? These questions must be answered quickly.

People communicate using a similar technique. The body language we consciously or subconsciously choose provides more information than words alone. Consider the images in Figure 4-2. Without any words, the mood of each of these people should be clear.

Patients can become hostile toward EMS providers. When you are treating a potentially hostile patient, it is important that you understand and be aware of your own body language. People tend to react to anger with anger. If you are dealing with an angry patient, you must stay calm and try to defuse the situation before it escalates. Consider the following steps:

1. **Assess the safety of the scene.** Decide whether you need to call law enforcement. Make sure that you have sufficient backup to ensure the safety of the patient and your crew.
2. **Do not assume an aggressive posture.** Be aware that if you cross your arms, clench your fists, or place your hands on your hips, it sends a message (whether intentional or not) that you are impatient, uninterested, or asserting a position of authority. Instead, stand with your palms facing out; this communicates openness and acceptance and allows for quick movement, if necessary.
3. **Make good eye contact, but do not stare.**
4. **Speak calmly, confidently, and slowly.** With your backup clearly visible, advise the patient what needs to be done, or provide the patient with limited, acceptable choices. "Sir, I need you to sit on the ambulance cot now. Either you will sit on the cot or we will help you to the cot."
5. ***Never* threaten the patient, either verbally or physically.** Personal safety should be your primary concern when caring for any patient, but this is especially true with patients who display hostile behavior.

Figure 4-2 The effectiveness of body language. **A.** Happy. **B.** Angry. **C.** Sad.

Remember, it is important for you to be attentive to facial expressions, body language, and eye contact—your own and your patient's. These physical cues will help you and your patient to truly understand the message being sent. Additional techniques you can use to calm a patient and establish a therapeutic rapport will be discussed later in this chapter.

Words of Wisdom

EMTs must always be dressed professionally. The first impression you make may be influenced by your appearance. Caring for your uniform may improve that impression and enhance your ability to establish trust and rapport with your patients. You are sending the message that you care without speaking a word.

Physical Factors

Various physical factors affect communication, which are referred to as noise. **Noise** is anything that dampens or obscures the true meaning of the message. Literal noise, or sounds in the environment, can make it difficult to understand the patient or for the patient to understand you. Lighting, distance, or physical obstacles are other factors that may affect your communication.

Cultural norms often dictate the amount of space, or proximity, between people when communicating Table 4-2. The degree to which people feel comfortable depends on with whom they are communicating. As a person gets closer, a greater sense of trust must be established. When you finally enter someone's intimate space, there must be a high sense of trust.

Understanding how communication works and the importance of effective communication is important when gathering information from the patient. Your communication skills will be put to the test when you communicate with patients and/or families in emergency situations. Remember that someone who is sick or injured is scared and might not understand what you are doing or saying. Therefore, your gestures, body movements, and attitude toward the patient are critically important in gaining the trust of both patient and family.

Verbal Communication

As an EMT, you must master many communication skills, including those associated with radio operations and written communications. Skilled verbal communication with the patient and family, bystanders, and the rest of the health care team are an essential part of high-quality patient care and transport. You must be able to listen effectively to fully understand the nature of the scene and the patient's problem. You must also be able to organize your thoughts to quickly and accurately verbalize instructions to the patient, bystanders, and other health care professionals.

One of the most fundamental aspects of what EMTs do is to ask patients questions. There are two types of questions: **open-ended questions** are ones in which a patient needs to provide some level of detail to give an answer, whereas **closed-ended questions** can be answered in very short or single-word responses. When first approaching your patient, you should use open-ended questions. "Good day. My name is Chuck and I am an EMT. What seems to be bothering you today?" Open-ended questions allow a free flow of conversation. They let the patient direct you to what is bothering him or her.

Closed-ended questions are important to use when patients are unable to provide long or complete answers to questions. Perhaps the patient is having severe breathing problems, or maybe the patient is a child who is scared and doesn't know what to say. In situations for which thoughtful answers are not possible, closed-ended questions are appropriate and are particularly useful when assessing a patient's condition. "Are you having trouble breathing? Do you take medications for your heart?"

Table 4-2 Guidelines for Personal Space in the United States

Space	Distance	Description
Intimate	Less than 18 in.	Whispering, touching; must be invited
Personal	18 in. to 4 ft	Conversations with close friends or family
Social	4 ft to 10 ft	Conversations with acquaintances
Public	10 ft to 25 ft	Interacting with strangers

With closed-ended questions, however, it is possible for you to miss important issues if pertinent questions are not asked. Imagine how many ways a person can be sick or injured. Now imagine trying to come up with a single yes/no question for each sickness or injury. Closed-ended questions typically provide limited information, and you should consider the answers to these questions as only a starting point toward understanding the patient's condition.

Before beginning your interview with the patient, determine which provider will lead the interview. This will ensure that you and your partner do not ask questions at the same time or ask repetitive questions. When you are asking questions of the patient, be conscious of how many questions you are asking. "How are you doing today? Have you been feeling ill?" This common approach actually asks the patient two kinds of questions, one open-ended and one closed-ended. Often the patient will respond with a simple, "yes." To avoid this situation, it is best to ask a single question, wait for an answer, and then proceed to another question.

There are many powerful communication tools you can use when trying to obtain information from patients. Sometimes patients will hide information, either consciously or unconsciously, due to fear or confusion. The techniques in Table 4-3 provide you with techniques that will assist you in gathering patient information. They can be helpful to use not only with patients who are willing to share, but with those who are resistant to sharing information.

Table 4-3 Therapeutic Communication Techniques

Communication Technique	Definition	Example
Facilitation	Encourage the patient to talk more or provide more information.	EMT: "Can you tell me more about that? I am listening to you."
Silence	Do not speak.	Give the patient space and time to think and respond.
Reflection	Restating a patient's statement made to you to confirm your understanding.	Patient: "I am so depressed that I could die." EMT: "I understand that you are feeling sad."
Empathy	Be sensitive to the patient's feelings and thoughts.	Use eye contact and touching to reinforce communication; adjust tone of voice and pace to allow for open communication
Clarification	Ask the patient to explain what he or she meant by an answer.	Patient: "I just feel sick." EMT: "Can you please tell me what is feeling sick? Can you help me to understand what is going on?"
Confrontation	Make the patient who is in denial or in a mental state of shock focus on urgent and life-critical issues.	Patient: "I am having pain in my chest, my back has been hurting me, I feel nauseated, and I ran out of my blood pressure medication." EMT: "Please tell me about your chest pain. We will talk about your other concerns in a moment."
Interpretation	Restate the patient's complaint to confirm your understanding.	EMT: "If I understand correctly, you have been feeling pain for the past 3 days, and it has gotten worse today." Patient: "That's right."
Explanation	Provide factual information to support a conversation.	Patient: "I do not understand what is happening." EMT: "We have checked your blood sugar and blood pressure and both appear to be normal."
Summary	Provide the patient with an overview of the conversation and the steps you will take.	EMT: "We will be taking you to the emergency department to care for your chest pain. I will be giving you some medication that should make you feel better."

When you interview the patient, consider using touch as a means to communicate caring and compassion. Touch is a powerful tool; therefore, keep in mind that it should be used consciously and sparingly Figure 4-3. Many people will be uncomfortable with a stranger touching them suddenly. If you are going to touch the patient, approach slowly and touch the patient's shoulder or arm respectfully. You can consider holding the patient's hand. This allows you to touch the patient, showing you care about what he or she is telling you, and also allows you to remain at a slight distance.

Avoid touching the patient's torso, chest, or face simply as a means of communication, because these areas are often viewed as intimate. Also, to touch these areas, you will need to get closer to the patient, potentially invading the patient's intimate space. Table 4-4 provides other tips on what to avoid when communicating with patients.

Figure 4-3 Using touch conveys a sense of caring and compassion.

Table 4-4 Interview Techniques to Avoid

Improper Technique	Example	Rationale
Provide false hope or reassurance.	EMT: "It will be okay." "This is nothing to worry about."	You do not know that everything will be okay.
Give unsolicited advice.	EMT: "Well, if I were you, I wouldn't have called the ambulance at all."	This demeans the patient and makes you seem arrogant, rather than helpful.
Ask leading or biased questions.	EMT: "Are you telling me that this cut is the only reason you called the ambulance?"	Your patient deserves respectful communication. It is inappropriate for you to suggest to the patient that an ambulance was not needed, even if that is what you believe.
Talk too much.	The EMT talks to the patient without really listening to the patient, simply going through the motions.	When the patient provides you information, you need to consider the information and guide the conversation toward a goal.
Interrupt the patient.	Patient: "Well, I was having trouble breathing last month and . . ." EMT: "Can we move on to how you are feeling now?"	You may seem bored or annoyed that the patient is taking up your time.
Use "why" questions.	EMT: "Why did you call the ambulance today?"	"Why" questions often appear to accuse the listener. You may seem annoyed that the patient called 9-1-1.
Use authoritative language.	EMT: "Tell me what is wrong with you." "Just give me the details."	This language does not encourage open communication.
Speak in professional jargon.	EMT: "I think we need to take you to the ED stat. We will give you ASA and NTG en route. Any questions?"	This type of communication confuses the patient. Most patients do not understand medical jargon.

Safety Tips

You are constantly communicating, both consciously and unconsciously. As a health care professional, you need to ensure that your body language reflects your words. Remember, people call 9-1-1 when they are in crisis. Part of being a good EMT is being able to project calm and control into a chaotic environment. You may not feel calm, but a good EMT will "never let them see you sweat."

The presence of family, friends, and bystanders during your interview of the patient can be valuable. Sometimes, however, well-meaning family members will speak for the patient, and, at times, you may need to ask the family member to allow the patient to answer. Ultimately, you will need to assess the situation and determine whether the additional people are helping you care for the patient or hindering your efforts. Do not be afraid to ask others to step outside or step aside for a moment while you talk with the patient. It is generally best to keep families together, but in cases where a family member is not helpful, consider giving him or her a task to do, such as gathering medications or clothing. This task can transform the person from a hindrance into a valuable aide. Take into account how the patient will feel without his or her loved ones nearby. Separating them may make the patient more anxious.

These ten Golden Rules will help you to calm and reassure your patient and provide a therapeutic rapport:

1. **Make and keep eye contact with your patient at all times.** Give the patient your undivided attention. This will let the patient know that he or she is your top priority. Look the patient straight in the eye to establish a **rapport**. Establishing a rapport is building a trusting relationship with your patient. This will make caring for the patient much easier.

2. **Provide your name and use the patient's proper name.** Introduce yourself and your partner. If your department provides you with a name tag, wear it. Ask the patient what he or she wishes to be called. Avoid using terms such as "honey" or "dear." Use a patient's first name only if the patient is a child or the patient asks you to use his or her first name. Rather, use a courtesy title, such as "Mr. Peters," "Mrs. Smith," or "Ms. Butler." If you do not know the patient's name, refer to him or her as "sir" or "ma'am."
3. **Tell the patient the truth.** Even if you have to say something very unpleasant, telling the truth is better than lying. Lying will destroy the patient's trust in you and decrease your own confidence. You might not always tell the patient everything, but if the patient or a family member asks a specific question, you should answer truthfully. A direct question deserves a direct answer. If you do not know the answer to a patient's question, say so. For example, a patient may ask, "Am I having a heart attack?" To which you would answer, "I don't know, but we will certainly get more information at the hospital. Right now, I am caring for you just like I would care for someone who is having a heart attack."
4. **Use language that the patient can understand.** Do not talk up or down to the patient in any way. Avoid technical medical terms that the patient might not understand. For example, ask the patient whether he or she has a history of "heart problems." This will usually result in more accurate information than if you ask about "previous episodes of myocardial infarction" or a "history of cardiomyopathy."
5. **Be careful what you say about the patient to others.** You need to understand the relationship between the person you are talking with (such as a bystander) and the patient. Ask the patient if it is okay for you to talk with this person. While speaking to others, ensure that you leave the general area of the patient if you must have a confidential conversation. Be mindful that sharing patient information may be a HIPAA violation. Do not talk about the patient in front of him or her; to do so gives the impression that the patient has no choice in his or her medical care. This is easy to forget when the patient has impaired cognitive (thought) processes or has difficulty communicating.
6. **Be aware of your body language.** Nonverbal communication is extremely important in dealing with patients **Figure 4-4**. In stressful situations, patients may misinterpret your gestures and movements. Be particularly careful not to appear frustrated or threatening. Instead, position yourself at the same level or at a lower level than the patient when practical. Remember that you should always conduct yourself in a calm, professional manner.

Figure 4-4 Watch your body language because patients may misinterpret your gestures, movements, and stance.

7. **Always speak slowly, clearly, and distinctly.** Pay close attention to your tone of voice.
8. **If the patient is hard of hearing, face the person so that he or she can read your lips.** Try lowering or raising the tone of your voice; some people who are hard of hearing can hear certain pitches better than others. Do not shout at a person who is hard of hearing. Shouting will not make it any easier for the patient to hear you and may frighten the patient. Never assume that an older patient is hard of hearing or otherwise unable to understand you. Also, never use "baby talk" with older patients or with anyone other than infants. If you are unable to communicate with the patient, have your partner try. Another technique is to have the patient put the stethoscope in his or her ears while you speak softly into the diaphragm to help amplify the sound.
9. **Allow time for the patient to answer or respond to your questions.** Do not rush a patient unless there is immediate danger. Sick and injured people may not be thinking clearly and may need time to answer even simple questions. This is especially true when treating older patients.
10. **Act and speak in a calm, confident manner while caring for the patient.** Make sure you attend to the patient's pain and needs. Try to make the patient physically comfortable and relaxed. Find out whether the patient is more comfortable sitting or lying down. Is the patient cold or hot? Does the patient want a friend or relative nearby?

Patients literally place their lives in your hands. They deserve to know that you can provide medical care and that you are concerned about their wellbeing. These ten Golden Rules will help provide a good foundation and will make it easier to gather information when the patient wants to talk.

Sometimes, you need to gather information from a reluctant audience. Patients may be defensive about their problems and may not want to talk about them because they are embarrassed. They may direct the conversation away from the true problem. With these patients, start the conversation as usual. Introduce yourself. Be open and compassionate. If you find yourself not getting any real answers, then consider one of the techniques as seen in Table 4-3.

Communicating With Older Patients

According to the US Census Bureau in 2013, nearly 45 million people were older than 65 years. It is projected that by the year 2030, the geriatric population will number more than 70 million, resulting in an ever-increasing number of encounters with people in this category. However, a person's actual age might not be the most important factor in classifying him or her as geriatric. It is more important to determine a person's functional age. The functional age relates to the person's ability to function in daily activities, the person's mental state, health status, and activity pattern.

As an EMS provider, when you enter a scene to care for an older patient, you are being asked to take control. You have been called because a person needs help. What you say and how you say it has an impact on the patient's perception of the call. You should present yourself as competent, confident, and caring. You must take charge of the situation, but do so with compassion. You are there to listen and act on what you learn. Don't limit your assessment to the obvious problem. Oftentimes, older patients who express that they are not well, or who are overly concerned about their health or general condition, are at risk for a serious decline in their physical, emotional, or psychologic state.

Generally speaking, older people think clearly, can give you a clear medical history, and are able to answer your questions appropriately **Figure 4-5**. Do not assume that an older patient is senile or confused. Conversely, communicating with some older patients is extremely difficult, and you may encounter hostility, irritability, and, in fact, some confusion. Do not assume this to be normal behavior for an older patient. These signs may be caused by a simple lack of oxygen (hypoxia), brain injury including a cerebrovascular accident, unintentional drug overdose, infection, abnormal blood glucose, or even insufficient perfusion (circulation of blood and, therefore, nutrients to the cells). Never attribute altered mental status to old age. In addition, your older patients may have difficulty hearing or seeing you. Therefore, you need great patience and compassion when you are called on to care for such a patient. Think of the patient as someone's grandmother or grandfather—or even as yourself when you reach that age.

Words of Wisdom

Remember that not all older patients are cognitively impaired. Be careful to assess each patient's individual abilities.

Approach an older patient slowly and calmly. Allow plenty of time for the patient to respond to your questions. Watch for signs of confusion, anxiety, or impaired hearing or vision. The patient should feel confident that you are in charge and that everything possible is being done for him or her.

Figure 4-5 You need a great deal of compassion and patience when caring for older patients. Never assume that a patient is senile or confused.

Older patients often do not feel much pain. An older person who has fallen or been injured may report no pain. In addition, older patients might not be fully aware of important changes in their body systems. Therefore, be especially vigilant for objective changes—no matter how subtle—in their condition. Objective changes are those that any observer would be able to witness. Respiratory rate, heart rate, sweating, or vomiting are all objective. Subjective findings are those that only the patient can experience, such as pain or nausea. Even minor changes in breathing or mental state may signal major problems.

YOU are the Provider — PART 2

You arrive at the scene and find the patient, an 83-year-old woman, sitting on the couch in her living room. She is conscious and alert and tells you that she started having light-headedness and nausea about an hour ago. As you begin your assessment, you note that she has hearing aids in both ears.

Recording Time: 0 Minutes	
Appearance	Calm; no obvious distress
Level of consciousness	Conscious and alert
Airway	Open; clear of secretions or foreign bodies
Breathing	Normal rate and depth; regular

Circulation	Radial pulses, strong and regular; skin is pink, warm, and dry

3. How can you maximize successful communication with a patient who is hard of hearing?
4. Should your general approach to the assessment process be any different for this patient versus a younger patient? Why or why not?

When possible, give the patient time to pack a few personal items before leaving for the hospital. Be sure to locate hearing aids, eyeglasses, or dentures before departure; it will make the patient's hospital stay far more pleasant. You should document on the patient care report (PCR) that these items accompanied the patient to the hospital and the person to whom they were given in the ED. Older patients are often worried about the safety of their home, valuable items, and pets. Take the time to share these concerns with the person assuming care of the patient at the hospital.

Communicating With Children

Everyone who is thrust into an emergency situation becomes frightened to some degree. However, fear is probably most obvious and severe in children. Children may be frightened by your uniform, the ambulance, and the number of people who have suddenly gathered around. Even a child who says little may be very much aware of all that is going on.

Familiar faces and objects will help to reduce this fright. Let a child keep a favorite toy, doll, or security blanket to give the child some sense of control and comfort. Having a family member or friend nearby is also helpful. When not impractical due to the child's condition, it is often helpful to let the parent or a guardian hold the child during your evaluation and treatment. However, you will have to make sure this person will not upset the child or prevent the child from telling you important information. Sometimes, adult family members are not helpful because they become too upset by what has happened or the child will not share important information in front of them. An overly anxious parent or relative can make things worse. Be careful about selecting the proper adult for this role.

Children can easily see through lies or deceptions, so you must always be honest with them. Make sure that you explain to the child over and over again what and why certain things are happening. If treatment is going to hurt, such as applying a splint, tell the child ahead of time.

Respect a child's modesty. Children are often embarrassed if they have to undress or be undressed in front of strangers. This anxiety often intensifies during adolescence. When a wound or site of injury has to be exposed, try to do so out of the sight of strangers, and when appropriate be sure to have a parent or guardian present. Again, it is extremely important to tell the child what you are doing and why you are doing it.

You should speak to a child in a professional, yet friendly way. When speaking to a child make sure to use an appropriate tone and vocabulary. A child should feel reassured that you are there to help in every way possible. Maintain eye contact with a child, as you would with an adult, to let the child know that you are there to help and that you can be trusted **Figure 4-6**. It is helpful to position yourself at the child's eye level so you do not appear to tower above the child.

Special Populations

A man has fallen and hurt his leg. The injury is not severe, so a vacuum splint is placed on his leg and he is moved to the ambulance. All this time, his 4-year-old daughter is watching. Suddenly she runs to the other side of the room and begins to cry. She watched the EMTs take her daddy away. What should you do?

Talk to the child. Have her come over to the ambulance cot and see that her daddy is okay. Tell her about the splint and how it will make her daddy's leg better. Let her touch her daddy and say goodbye. Let her daddy tell her that he will be home soon. Sometimes the obvious patient is not always the *only* patient.

Figure 4-6 Maintain eye contact with a child to let the child know that you are there to help and that you can be trusted.

Communicating With Patients Who Are Deaf or Hard of Hearing

Patients who are hard of hearing are usually not ashamed or embarrassed by their disability. Often, it is the people around a person who is hard of hearing who have problems coping. Remember that you must be able to communicate with patients who are hard of hearing so you can provide necessary or even lifesaving care.

Most patients who are hard of hearing have normal intelligence and can easily understand what is going on around them, provided you can successfully communicate with them. Most patients who are hard of hearing can read lips to some extent. Therefore, you should place yourself in a position so the patient can see your lips. Many patients who are hard of hearing have hearing aids to help them communicate. Be careful that hearing aids are not lost during an accident or fall. Hearing aids may also be forgotten if the patient is confused or ill. Look around for one in the immediate area, or ask the patient or the family about use of a hearing aid.

Remember the following five steps to efficiently communicate with patients who are hard of hearing:

1. **Have paper and a pen available.** This way, you can write down questions and the patient can write down answers, if necessary. Be sure to print so that your handwriting is not a communication barrier.
2. **If the patient can read lips, you should face the patient and speak slowly and distinctly.** Do not cover your mouth or mumble. If it is dark, consider shining a light on your face.
3. **Never shout.** This will not help the patient hear you and may frighten him or her.
4. **Be sure to listen carefully, ask short questions, and give short answers.** Remember that although many patients who are hard of hearing can speak distinctly, some cannot.

5. **Learn some simple phrases in sign language.** For example, knowing the signs for "sick," "hurt," and "help" may be useful if you cannot communicate in any other way Figure 4-7.

Figure 4-7 Learn simple phrases in sign language. **A.** Sick. **B.** Hurt. **C.** Help.

Communicating With Visually Impaired Patients

Like patients who are hard of hearing, visually impaired and blind patients have usually accepted and learned to deal with their disability. Of course, visually impaired patients are not necessarily completely blind. Many can perceive light and dark or can see shadows or movement. Ask the patient whether he or she can see at all. Also remember, as with other patients who have disabilities, you should expect visually impaired patients to have normal intelligence.

As you begin caring for a visually impaired patient, explain everything you are doing in detail as you are doing it. Be sure to stay in physical contact with the patient as you begin your care. Place your hand lightly on the patient's shoulder or arm, and try to avoid sudden movements. If the patient can walk to the ambulance, guide him or her by placing his or her hand on your arm, taking care not to rush. Transport with the patient any mobility aids, such as a cane, to the hospital. A visually impaired person may have a guide dog. Guide dogs are easily identified by their special harnesses Figure 4-8. They are trained to not leave their masters and to not respond to strangers. A visually impaired patient who is conscious can tell you about the dog and give instructions for its care.

Figure 4-8 A guide dog is easily identified by its special harness.

Courtesy of the Guide Dog Foundation for the Blind. Photographed by Christopher Appoldt.

The following rare situations are difficult to manage. If the patient is very stable, you should consider bringing the guide dog to the hospital in the back of the ambulance with the patient because it will help to alleviate some of the stress for both the patient and the dog. If the patient is unstable, the dog is injured or unruly, or for other safety or patient care reasons it is inappropriate to transport the dog, then you should make arrangements for the care of the dog. Contact your supervisor for assistance. The exact method for managing a patient with a guide dog (or other medical care animal) will be outlined in your department's policies and procedures. Follow your local protocols.

Communicating With Non–English-Speaking Patients

Part of patient care includes obtaining a medical history from the patient. You cannot skip this step simply because the patient does not speak English. Most patients who do not speak English fluently will still know certain important words or phrases.

Your first step is to find out how much English the patient can speak. Use short, simple questions and simple words whenever possible, and avoid difficult medical terms. You can help patients better understand if you point to specific parts of the body as you ask questions. Speaking louder will not increase a patient's ability to understand you.

In many areas, particularly large urban centers, major segments of the population do not speak English. Your job will be much easier if you learn some common words and phrases in their language, especially common medical terms. Pocket cards that show the pronunciation of these terms are available. If the patient does not speak any English, use a smartphone app or website to help you translate, or find an interpreter. In an emergency, it may be necessary to have a family member or friend translate until a professional interpreter is located. Also, remember to request a translator at the hospital while providing the radio report if the patient's language is known. Hospitals must have professional foreign language interpreters in-house or on-call for this purpose.

Communicating With Other Health Care Professionals

Effective communication between the EMT and health care professionals in the receiving facility is an essential cornerstone of efficient, effective, and appropriate patient care.

Your reporting responsibilities do not end when you arrive at the hospital. In fact, they have just begun. The transfer of care officially occurs during your oral report at the hospital. Once you arrive at the hospital, a hospital staff member will take responsibility for the patient from you **Figure 4-9**. However, you may only transfer the care of your patient to someone with at least your level of training. In the hospital, this is a paramedic, nurse, or physician. Once a staff member is ready to take responsibility for the patient, you must provide that person with a formal oral report of the patient's condition.

Giving a report is a longstanding and well-documented end point in transferring the patient's care from one provider to another. Your oral report is usually given at the same time that the staff member is providing care for the patient. For example, a nurse or physician may start assessing the patient or help you to move the patient from the stretcher to an examination table. Therefore, you must report important information in a complete and precise way. The following six components must be included in the oral report:

1. **Opening information** that includes the patient's name (if you know it), chief complaint, nature of the illness, or mechanism of injury. For example: "Good morning. This is Mrs. McCarty. She is 65 years old and reports back pain. She woke up around 0300, tripped, and fell into the bathtub after using the restroom."
2. **Detailed information** that was not provided during the radio report. For example: "She denies a loss of consciousness, states that she has no history of stroke, TIAs, or cardiac compromise, but has been feeling a little light-headed when she stands."

Figure 4-9 Once you arrive at the hospital, a staff member will take responsibility for the patient from you.

3. **Any important history** that was not already provided. For example: "Mrs. McCarty lives by herself. She was unable to get out of the tub and was found by a hospice worker at 1000 this morning. We suspect hypothermia because she had a core temperature of 94 degrees."

4. **The patient's response** to treatment given en route. It is especially important to report any changes in the patient or the treatment provided since your initial radio report. For example: "Although we suspected that the patient's midback pain was a result of her leaning against the faucet of the bathtub for 7 hours, we put her in the Kendrick extrication device for both precautionary and extrication reasons. Hot packs wrapped in hand towels were used to help warm her up."
5. **Vital signs** assessed during transport and after the radio report. For example: "Her vitals include a blood pressure of 112/84 mm Hg, a pulse of 72 beats/min, respirations of 14 breaths/min, and core body temperature of 94 degrees at the time of transport. They are generally unchanged since then, except that her last temperature was 96 degrees."
6. **Other information** you may have gathered that was not important enough to report sooner. Information that was gathered during transport, patient medications you brought with you, known allergies, and any other details about the patient that were provided by family members or friends may be included. For example: "Mrs. Woods, the home hospice worker, has contacted Mrs. McCarty's family and followed us here to answer any questions."

You can use the same process described for giving an oral report if you need to transfer care during an EMS event. For example, if there are multiple patients, you may need to remain on the scene while someone else continues the assessment you began. Begin the oral report with a quick introduction, letting the other EMS provider know who you are and your level of licensure. You should then continue to transfer care just as you would inside the hospital.

You will also need to communicate routinely with many other professionals—police, social service personnel, fire personnel, and other EMS providers. Make sure your language and general demeanor are professional. Remember that federal laws protect a patient's right to privacy and that you should not give any health information about your patient to anyone other than those directly involved in the care of the patient.

As an EMT, you must be able to quickly and accurately find out what the patient needs and be able to tell others. Never forget that you are the vital link between the patient and the health care team.

Words of Wisdom

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 established mandatory patient privacy rules and regulations to safeguard patient confidentiality. The act provides guidance on the types of information that are protected, the responsibility of health care providers regarding that protection, and penalties for breaching that protection.

Most personal health information is protected and should not be released without the patient's permission. These regulations apply to all forms of communication and media—paper, electronic, and verbal. To ensure that you are protecting your patient's right to confidentiality, do not give any information to anyone other than those directly involved in the care of the patient. Make sure you are aware of all policies and procedures governing your particular agency.

Written Communications and Documentation

The **patient care report (PCR)**, also known as a prehospital care report, is the legal document used to record all aspects of the care your patient received, from initial dispatch to arrival at the hospital. Either term can be used and both are acceptable. You may be able to complete the report en route to the hospital if the trip is long enough and the patient needs minimal care. Usually, you will finish the report after you have transferred care of the patient to an ED staff member. There are two types of PCRs: written and electronic (ePCRs), which will be discussed later in this chapter.

The information you collect during a call becomes part of the PCR, and that information is ultimately entered into a data pool. The National Emergency Medical Services Information System (NEMSIS) has been collecting prehospital care information for research purposes since the early 1970s. NEMSIS has identified specific data points (uniform components) needed to enable communication and comparison of EMS runs between agencies, regions, and states. The minimum data set includes both narrative components and check boxes Figures 4-10 and 4-11.

If you go to www.ems.gov, you can see the national data set and discover interesting facts about delivery of EMS within the United States.

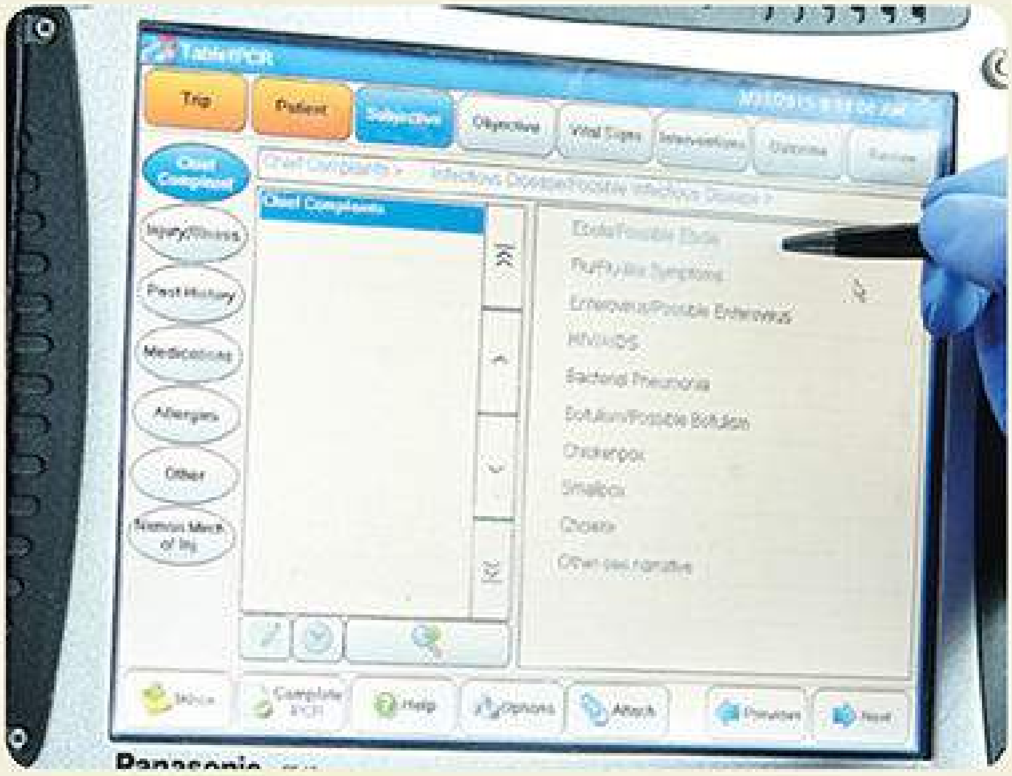

Figure 4-10 The minimum data set includes patient and administrative information, including narrative components and check boxes.

Because EMS systems track their own time, make sure that your watch is synchronized with dispatch time at the beginning of the shift, if that is procedure. Another way you can manage this information is to contact the dispatcher and have him or her provide you with the time. Either way, it is important to be able to keep close track of time. Accurate documentation will depend on it.

You will begin gathering patient information as soon as you reach the patient. Continue collecting information as you provide care until you arrive at the hospital.

Patient Care Report

As discussed, a PCR helps ensure efficient continuity of patient care. This report describes the nature of the patient's injuries or illness at the scene and the initial treatment you provide. Although this report might not be read immediately at the hospital, it may be referred to later for important information. The report serves the following six functions:

1. Continuity of care
2. Legal documentation

Insulin, Paxil | ∅ Drug allergies

38 y.o. ♂ found lying supine on sofa. Per wife, pt took his insulin but did not eat. Pt. responsive to painful stimuli only; combative when aroused. Per wife pt has Hx of IDDM and depression. ∅ other meds. Initial assessment findings revealed patent airway, tachypnea, and tachycardia. ∅ gross bleeding or s/s of trauma. Applied O_2 @ 15 L/min via NRB mask. D-stick: 34 mg/dL. Per protocol, initiated IV NS c̄ 18 ga. cath in Ⓛ hand @ 0827. At 0828, gave 50 mL of 50% Dextrose IVP. Reassessment p̄ D50 revealed that pt. was conscious + alert, asking "what happened." Advised pt of situation + of need to go to hospital; he agreed. Baseline vital signs taken @ 0830 (see flow chart). ECG reveals Sinus Tach @ 104 bpm c̄ ectopy. Loaded pt into unit + began transport to hospital. Medical Control notified @ 0834; ∅ further orders. Continued O_2 and reassessed blood sugar (105 mg/dL). Head to toe exam was unremarkable; pt remained conscious + alert throughout transport. Vital signs repeated (see flow chart). ECG revealed NSR. Pupils E/R + light.

Arrived @ receiving facility @ 0855; pt condition remained unchanged. ~~Verba~~ Verbal report given to ED physician. Cleared receiving facility @ 0903 and returned to service.

38 y/o ♂ appeared drunk upon arrival of EMS. According to wife, he has been rude to her all day, he is also very rude to us. Pt. has heart problems + HTN, he also has insulin-dependent diabetes. It is doubtful that he is compliant c̄ his meds. ? last meal. EMS has responded to this pt. in the past, he is always rude and doesn't want help. Told pt that he needs serious help! Offered oxygen, which pt refused to accept. Pt. not aware of place, time, or day. Advised wife to take pt to hospital as soon as possible. Pt. refused to sign AMA release form. Took 2 sets of vitals (see below), and then returned to service @ 0827.

B

Figure 4-11 Filing a PCR is a critical part of your responsibilities as an EMT. **A.** Proper documentation. **B.** Improper documentation.

3. Education
4. Administrative information
5. Essential research record
6. Evaluation and continuous quality improvement

A good PCR documents any changes in the patient's condition upon arrival at the hospital. It is critical that you document everything in the clearest manner possible because the report serves multiple purposes. The information in the report will help to prove that you have provided a standard of care and, in some instances, shows you have properly handled unusual or uncommon situations. Both objective and subjective information is included in this report.

The following are examples of information collected on a PCR:

- Chief complaint
- Level of consciousness (according to the AVPU scale) or mental status
- Vital signs
- Initial assessment
- Patient demographics (age, gender, ethnic background)

Should you ever be called to provide testimony concerning patient care, you and your PCR will be used to present evidence. As with your personal appearance, your PCR will reflect a professional or a nonprofessional image. A neat, concise, well-written document—including correct spelling and grammar—will reflect good patient care. Consider the adage, "If the report looks sloppy, the patient care was also sloppy."

These reports also provide valuable administrative information, such as that used for patient billing. Information included in PCRs can be used to evaluate response times, equipment usage, and other areas of administrative responsibility. The following are examples of administrative information gathered from a PCR:

- Time the incident was reported
- Time the EMS unit was notified
- Time the EMS unit arrived at the scene
- Time the EMS unit left the scene
- Time the EMS unit arrived at the receiving facility
- Time the patient care was transferred

It is standard procedure to use military time in EMS documentation. This ensures that each time is unique; for example, 12 noon cannot be confused with 12 midnight. Military times are shown in **Table 4-5**.

Data may be obtained from the PCR to analyze causes, severity, and types of illness or injury requiring emergency medical care. These reports may also be used in an ongoing program for evaluation of the quality of patient care. All reports are periodically reviewed by your system to make sure trauma triage and/or other prehospital care criteria have been met.

Table 4-5 Military Times

Regular Time	Military Time	Regular Time	Military Time
Midnight	0000	Noon	1200
1:00 AM	0100	1:00 PM	1300
2:00 AM	0200	2:00 PM	1400
3:00 AM	0300	3:00 PM	1500
4:00 AM	0400	4:00 PM	1600
5:00 AM	0500	5:00 PM	1700
6:00 AM	0600	6:00 PM	1800
7:00 AM	0700	7:00 PM	1900
8:00 AM	0800	8:00 PM	2000
9:00 AM	0900	9:00 PM	2100
10:00 AM	1000	10:00 PM	2200
11:00 AM	1100	11:00 PM	2300

There are many requirements of a PCR Table 4-6. Often, these requirements vary from jurisdiction to jurisdiction, mainly because different agencies obtain information from them. Although no universally accepted form exists, certain uniform data points are common in all areas. The benefits of collecting such information are significant, one being that national trends can be detected. For example, roughly 15% of the nation's EMS calls involve children ages 0 to 9 years. Of those patients, 3% will have a respiratory complaint. Such information is invaluable.

Finally, PCRs are used by individual agencies to determine patterns of EMS responses. Busy times and high call volume areas can be predictive, and a thorough review of PCRs can set the stage for scheduling shifts and for system status management, including where units are placed.

Types of Forms

You will most likely use one of two types of forms. The first type is the traditional written form with check boxes and a narrative section, as shown in Figure 4-10. The second type is a computerized version, or electronic PCR (ePCR), in which you fill in information using a computer or tablet device that uploads data over a secure Internet connection Figure 4-12. EMS agencies across the country are replacing written reports with an electronic reporting system. Electronic PCRs have several advantages over the written forms. For example, ePCRs allow you to transmit patient information directly to hospital computers for review by the physician, pharmacy, and other professionals providing patient care.

If your service uses written forms, be sure to fill in the boxes completely and avoid making stray marks on the sheet. Make sure that you are familiar with the specific procedures for collecting, recording, and reporting the information in your area. Regardless of which format is used to collect information, you must complete a narrative section. For this information to be valuable, it must be correct. Therefore, you should make every effort to ensure the information is accurate.

Table 4-6 Sample Uniform Components of a Patient Care Report

- Patient's name, gender, date of birth, and address
- Dispatched as (When was the ambulance called? What was the nature of the call as reported by the dispatcher?)
- Chief complaint
- Location of the patient when first seen (including specific details, especially if the incident is a car crash or when criminal activity is suspected)
- Rescue and treatment given before your arrival
- Signs and symptoms found during your patient assessment
- Care and treatment given by you at the site and during transport
- Response to treatment
- Vital signs
- SAMPLE history
- Changes in vital signs and condition
- Additional orders received from the hospital
- Name of person receiving the patient report
- Date of the call
- Time of the call
- Location of the call
- Time of dispatch
- Time of arrival at the scene
- Time of leaving the scene
- Time of arrival at the hospital
- Patient's insurance information
- Names and/or certification numbers of the EMTs who responded to the call
- Name of the transport destination
- Type of run to the scene: emergency or routine

The narrative section of the PCR is arguably the most important portion. Here you will describe all of the facts related to the EMS call. The narrative should tell the story and present a clear, detailed picture of what you found, what you did, and how it affected the patient's condition. Be sure to include significant negative findings and important observations about the scene. Make sure that what you write is not an opinion, but fact based on findings. For example, you may write, "The patient admits to drinking today" or "The patient smelled of alcohol." These are clear descriptions that do not make any judgments about the patient's condition. However, stating "the patient was drunk" is a personal judgment that may not be able to be supported. Choose your words carefully and thoughtfully. Your job is to reproduce the important facts of the EMS call in writing.

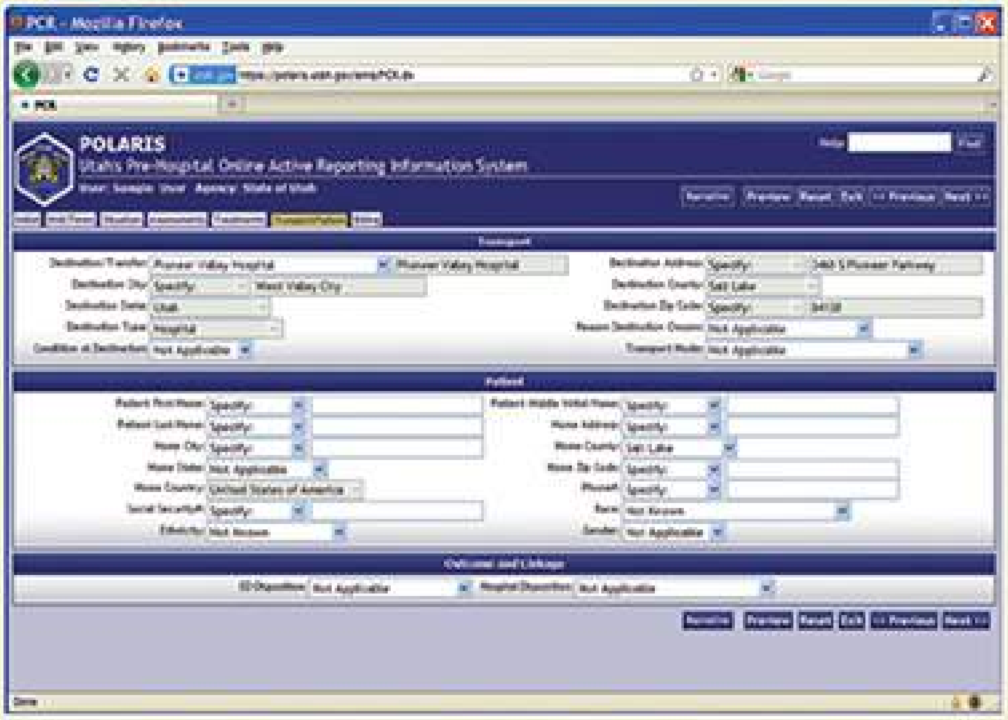

Figure 4-12 An electronic PCR (ePCR).

Courtesy of the Utah Department of Health.

The narrative section of the PCR needs to include the following information:

- Time of events
- Assessment findings
- Emergency medical care provided
- Changes in the patient after treatment
- Observations at the scene
- Final patient disposition
- Refusal of care
- Staff person who continued care

In written documentation, avoid radio codes and use only standard abbreviations, a list of which should be provided by your department. Remember, EMS personnel are not the only people who will be reading this document. Other hospital and billing personnel will need to read and understand what has been written. When information is of a sensitive nature, note the source of the information. Be sure to spell words correctly, especially medical terms. If you do not know the correct spelling of a particular word, find out how to spell it, or use another word. Also be sure to record the time with all assessment findings. Table 4-7 provides guidelines on how to write the narrative portion of your report. Whether you completed a medical or trauma assessment, the assessment-based approach follows each step of the assessment(s) as a guideline to narrative writing.

Table 4-7 How to Write a Narrative Report

Standard precautions	Were standard precautions initiated? If so, state which precautions were used and why.
Scene safety	Did you have to make your scene safe? If so, what did you do and why did you do it? Did this create a delay in patient care?
NOI/MOI	Simply state.
Number of patients	Record only when more than one patient is present; "This is patient 2 of 3."
Additional help	Did you call for help? If so, state why, at what time, and what time the help arrived. Was transport delayed?
Cervical spine	State what cervical spine precautions were initiated. You may want to include why; "Due to the significant MOI . . ."
Initial general impression	Simply record, if not already documented on the PCR.
Level of consciousness	Be sure to report LOC, any changes in LOC, and at what time changes occurred.
Chief complaint	Note and quote pertinent statements made by the patient and/or bystanders. This includes any pertinent denials; "Patient denies chest pain . . ."
Life threats	List all interventions and how the patient responded; "Assisted ventilations with O_2 (15 L/min) at 20 BPM with no change in LOC."
ABCs	Document what you found, and again, any interventions performed.
Oxygen	Record if O_2 was used, how it was applied, and how much was administered.
Primary, secondary, patient history, or reassessment	State the type of assessment used and any pertinent findings; "Secondary assessment revealed unequal pupils, crepitus to right ribs, and an apparent closed fracture of left tibia."
SAMPLE/OPQRST	Note and quote any pertinent answers.
Vital signs	Your service may want you to record vital signs in the narrative portion, as well as other places in the PCR.
Medical direction	Quote any orders given to you by medical control and who gave them.
Management of secondary injuries/treat for shock	Report all patient interventions, at what time they were completed, and how the patient responded.
Receiving facility	Document the name of the facility, the area of the facility where the patient was delivered, and the room number (if known).
Transfer of care	Record the name of the staff person who received your report and took over patient care, as well as the time.

Abbreviations: ABCs, airway, breathing, and circulation; LOC, level of consciousness; MOI, mechanism of injury; NOI, nature of illness; OPQRST, mnemonic used to facilitate the evaluation of a patient's pain: onset, provocation or palliation, quality, region/radiation, severity, and timing of pain; PCR, patient care report; SAMPLE, mnemonic used to determine signs and symptoms, allergies, medications, pertinent past history, last oral intake, and events leading up to the injury or illness.

Remember that the report form itself—and all the information in it—is considered a confidential document. Be sure you are familiar with state and local laws concerning confidentiality. All prehospital forms must be handled with care and stored in an appropriate manner once you have completed them. After you have completed a report, distribute copies to the appropriate locations, according to state and local protocol. In most instances, a copy of the report will remain at the hospital and will become part of the patient's medical record.

Depending on the requirements of the EMS system in which you work, you may not have the time to complete the full PCR while at the hospital; some EMS systems allow for a shorter, modified version of the PCR to be left at the hospital, and the full report can be completed at the station or transmitted electronically. Even in these circumstances, however, a written record should be left with the patient. In these cases, most systems will have a "drop report or transfer report" **Figure 4-13**. These single-page, abbreviated forms are used as a memory aid during an EMS call. If you are unable to remain at the hospital to complete the PCR, copy these documents and leave them with the nurse or doctor.

Reporting Errors

Everyone makes mistakes. If you leave something out of a report or record information incorrectly, do not try to cover it up. Rather, write down what did or did not happen and the steps that were taken to correct the situation. Falsifying information on the PCR may result in suspension and/or revocation of your certification or license, as well as legal implications. More important, falsifying information results in poor patient care, because other health care providers have a false impression of assessment findings or the treatment given. For example, if you did not give the patient oxygen, do not document that the patient was given oxygen.

Figure 4-13 Prehospital notepad/drop report (transfer report).

Document only the vital signs that were actually taken. A classic case of improper documentation occurs with cardiac arrest patients. Consider this scenario. Under "Vital Signs," an EMT documents: pulse 0 beats/min, respirations 0 breaths/min, and blood pressure 0/0 mm Hg. What the EMT meant to document was the application of a blood pressure cuff—inflating it and deflating it while listening for a pulse. Someone reviewing the PCR after the call may ask why the EMT took the time to check the blood pressure on a patient who didn't have a pulse, instead of performing CPR.

What if the wrong drug or the wrong dose is given to a patient? What if the patient is accidentally dropped? Unfortunately these things can and do happen. It is important that you document the event. Do not lie or cover it up. In your narrative, provide a factual account of what happened. For example: "Ordered: one sublingual nitroglycerin. Given: two sublingual nitroglycerin. Patient blood pressure checked following administration. No changes noted" or "While loading the patient into the ambulance, the patient was dropped. Patient was on the ambulance cot when it fell a total of 4 feet. Patient was not thrown off cot. Patient was assessed after being dropped and reported feeling scared and having neck pain. Hospital advised."

If you discover an error as you are writing your report, draw a single horizontal line through the error, initial it, and write the correct information next to it Figure 4-14. Do not try to erase or cover the error with correction fluid. This may be interpreted as an attempt to cover up a mistake.

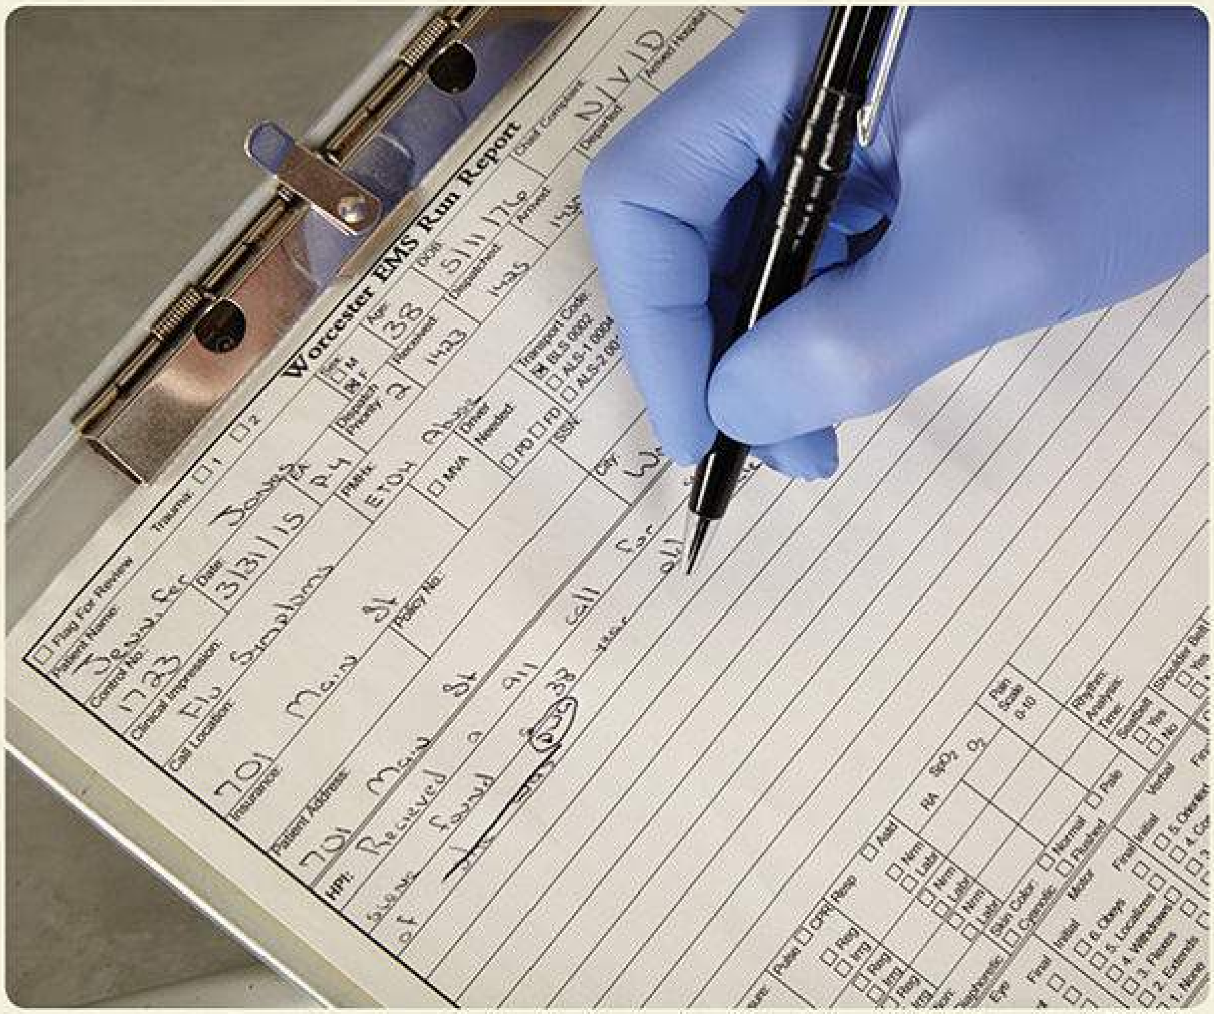

Figure 4-14 If you make a mistake in writing your report, the proper way to correct it is to draw a single horizontal line through the error, initial it, and write the correct information next to it.

If an error is discovered after you submit your report, follow the same process of error correction by drawing a single line through the error—preferably in a different color ink—initialing it, and dating it. Make sure to add a note with the correct information. If you accidentally left out information, begin the new section with the word "addendum," add the new information, and then add the date and your initials. When using a paper system, you may be able to add addendums using specific addendum forms. If you are using an electronic documentation system, refer to the system's direction as to how to make an amendment to the original document. Most electronic systems will allow for amendments but will prevent erasure in a completed document.

Words of Wisdom

In the prehospital setting, several methods of documentation are used, including the following:

CHART or CHARTE method. CHART stands for Chief complaint, History and physical examination, Assessment, Treatment (Rx), and Transport. To use CHARTE, add Exceptions. This method's strength is that it breaks the care and treatment down into smaller sections, which makes it easier to locate specific assessments or care without reading the entire report. Its weakness is that it is difficult to learn.

SOAP method. SOAP stands for Subjective, Objective, Assessment, and Patient care. This is one of the more common forms of documentation. It is simple to learn, and when it is completed, it provides a simple means for the reader to review the assessment and management.

Documenting Refusal of Care

Refusal of care is a common source of litigation in EMS; therefore, thorough documentation is crucial. As discussed in Chapter 3, *Medical, Legal, and Ethical Issues,* competent adult patients have the right to refuse treatment and, in fact, must specifically provide permission for treatment to be initiated. If you are not able to persuade the patient to proceed with treatment, document any patient assessment findings, emergency medical care given, your efforts to obtain consent, and the patient's response to your efforts. Have the patient sign a refusal form **Figure 4-15**. You should also have a family member, police officer, or bystander sign the form as a witness. If the patient refuses to sign the refusal form, have a family member, police officer, or bystander sign the form verifying that the patient refused to sign. Inform online medical control when patients refuse care.

Even if a patient refuses care, you must complete the PCR. You will need to document the advice you gave as to the risks associated with refusal of care. Report clinical information, such as the LOC, showing the competency of the person refusing care. Note pertinent patient comments and any medical advice given to the patient by the physician or medical control through phone or radio. Also include a description of the care that you wished to provide for the patient. There are many local variations of requirements for patient refusals. **Table 4-8** provides a reasonable list of items that should be included within the PCR of a patient refusal.

YOU are the Provider — PART 3

As your partner takes the patient's vital signs, you ask the patient further questions regarding her chief complaint. She denies any other complaints or past medical history and tells you that she only takes vitamins. Her blood glucose level is assessed and found to be 112 mg/dL.

Recording Time: 5 Minutes	
Respirations	20 breaths/min; regular and unlabored
Pulse	68 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	122/62 mm Hg
Oxygen saturation (Spo_2)	98% (on room air)

5. What techniques can facilitate the process of interviewing an older patient?

Patient Initiated Refusal of EMS

Patient Name: Doe, John	Primary Care Giver: John Smith, NREMT-P	
Agency: BALTIMORE COUNTY FIRE DEPARTMENT	Incident#: 1122141	eMEDS#: 00314105399
Unit #: Medic 14	Inc Date Entered: 11/22/2016	Inc Time Entered: 1824 hrs

I (or my guardian) have been informed regarding the state of my present physical condition to the extent I allowed an examination, and I (or my guardian) hereby refuse to accept such medical care and/or transportation as recommended by representatives of the EMS System above.

I (or my guardian) do hereby for myself, my heirs, executors, and administrators and assigns forever release and fully discharge said EMS system, its officers, employees, medical consultants, hospitals, borrowed servants or agents from any and all conceivable liability that might arise from this refusal of care and/or transportation, and I (and my guardian) therefore agree to hold them completely harmless. I (or my guardian) have been informed that a refusal of care and/or transportation for an evaluation may cause me to suffer PAIN, DISABILITY, LOSS of FUNCTION, WORSENING of my CONDITION, or even DEATH as a result of my illness/injury. As a competent adult, I (or my guardian) fully understand all of the above, and am/is capable of determining a rational decision on my own behalf.

Providers: When encountering a patient who is attempting to refuse EMS treatment or transport, access his or her condition, and record whether the patient screening reveals any lack of medical decision-making capability (1-3,4a or b) or high risk criteria (5-8).

1) Medical Capacity: Was the patient disoriented to person? If yes, transport	☐ Yes ☑ No
2) Medical Capacity: Was the patient disoriented to place? If yes, transport	☐ Yes ☑ No
3) Medical Capacity: Was the patient disoriented to time? If yes, transport	☐ Yes ☑ No
4) Medical Capacity: Was the patient disoriented to situation? If yes, transport	☐ Yes ☑ No
5) Medical Capacity: Did the patient show altered level of consciousness? If yes, transport	☐ Yes ☑ No
6) Medical Capacity: Alcohol or drug ingestion by history or exam with slurred speech? If yes, transport	☐ Yes ☑ No
7) Medical Capacity: Alcohol or drug ingestion by history or exam with unsteady gait? If yes, transport	☐ Yes ☑ No
8) Medical Capacity: Patient does not understand the nature of illness and potential for bad outcome? If yes, transport	☐ Yes ☑ No
9) At Risk Criteria (Abnormal vital signs): For adults. Pulse greater than 120 or less than 60? If yes, consult	☐ Yes ☑ No
10) At Risk Criteria (Abnormal vital signs): For adults. Systolic BP less than 90? If yes, consult	☐ Yes ☑ No
11) At Risk Criteria (Abnormal vital signs): For adults. Respirations greater than 30 or less than 10? If yes, consult	☐ Yes ☑ No
12) At Risk Criteria (Abnormal vital signs): For minor/pediatric patients. Age inappropriate HR? If yes, consult	☐ Yes ☑ No
13) At Risk Criteria (Abnormal vital signs): For minor/pediatric patients. Age inappropriate RR? If yes, consult	☐ Yes ☑ No
14) At Risk Criteria (Abnormal vital signs): For minor/pediatric patients. Age inappropriate BP? If yes, consult	☐ Yes ☑ No
15) At Risk Criteria: Serious chief complaint (chest pain, SOB, syncope)? If yes, consult	☐ Yes ☑ No
16) At Risk Criteria: Head injury with history of loss of consciousness? If yes, consult	☐ Yes ☑ No
17) At Risk Criteria: Significant MOI or high suspicion of injury? If yes, consult	☐ Yes ☑ No

18) At Risk Criteria: For minor/pediatric patients. ALTE, significant past medical history, or suspected intentional injury? If yes, consult	☐ Yes ☑ No
19) At Risk Criteria: Provider impression is that the patient requires hospital evaluation? If yes, consult	☐ Yes ☑ No
20) Providers: Did you perform an assessment (including exam) on this patient? If yes to # 20, skip to # 22	☐ Yes ☑ No
21) Providers: If unable to examine, did you attempt vital signs?	☐ Yes ☑ No
22) Providers: Did you attempt to convince the patient or guardian to accept transport?	☐ Yes ☑ No
23) Providers: Did you contact medical direction for patient still refusing service?	☐ Yes ☑ No
24) Patient: The patient or his or her representative refuses EMS examination.	☐ Yes ☑ No
25) Patient: The patient or his or her representative refuses EMS treatment.	☐ Yes ☑ No
26) Patient: The patient or his or her representative refuses EMS transport.	☐ Yes ☑ No

Patient Signature: **Printed Name:**

Patient Phone: **Date:** 18:24 11/24/2016

Final Disposition

Patient Refused Exam ☐	Patient Refused Treatment ☐	Patient Refused Transport ☑
Patient Accepted Exam ☑	Patient Accepted Treatment ☑	Patient Accepted Transport ☐
Auth. Decision Maker (ADM) Refused Exam ☐	Auth. Decision Maker (ADM) Refused Treatment ☐	Auth. Decision Maker (ADM) Refused Transport ☐

Provide in the patient's own words why he/she refused the above care/service:

"Patient reports that despite the damage to his vehicle, he has only a small laceration on his finger and no other symptoms. He eventually agreed to allow EMS to evaluate him and provide a bandage for a small finger laceration (index finger, right hand). He agreed to follow-up with his primary care MD later today. When offered transport to the hospital he indicated, "No. thanks. I will be fine." Discussed plan with Dr Smith at St Elsewhere ED who agreed with plan and recommended reiterating to Mr Smith the importance of close follow-up with his primary care MD for tetanus prophylaxis and consideration of laceration care to include sutures.

Incident #: 1122141 Date Printed: 11/24/2016 18:24

Figure 4-15 Even though competent adult patients have the right to refuse medical treatment, attempt to have them sign a refusal form to document their informed refusal.

Table 4-8 Components of a Thorough Patient Refusal Document

Complete assessment
Evidence the patient is able to make a rational, informed decision
Discussion with the patient as to what care/transportation EMS recommends
Discussion with the patient as to what may happen if he or she does not allow care or transportation. Typically these consequences should be listed and clear to include the possibility of severe illness/injury or death if care or transportation is refused.
Discussion with family/friend/bystanders to try to encourage the patient to allow care
Discussion with medical direction according to local protocol
Providing the patient with other alternatives: Going to see his or her family doctor, having a family member drive him or her to the hospital
Willingness of EMS to return if the patient changes his or her mind
Signatures: Have a family member, police officer, or bystander sign the form as a witness. If the patient refuses to sign the refusal form, have a family member, police officer, or bystander sign the form verifying that the patient refused to sign.
If the patient refused care or did not allow a complete assessment, document that the patient did not allow for proper assessment and document whatever assessments were completed.

Refusal of care not only includes patients who do not wish to be transported to the hospital, but also those who refuse a certain aspect of care. For example, a victim of a car crash may wish to be treated and transported but refuses to be appropriately immobilized. In these instances, you should carry out all other medical care and document the patient's refusal of spinal immobilization. Just because the patient refuses a cervical collar is no reason to deny oxygen. The same is true for the patient who wishes to use a local hospital when the injuries dictate transport to a trauma facility. Any time a patient refuses any part of the standard treatment, it needs to be documented in the PCR.

Special Reporting Situations

In some situations, you may be required to file special reports with appropriate authorities. These situations may involve gunshot wounds, dog bites, certain infectious diseases, or suspected physical or sexual abuse. Learn your local requirements for reporting these incidents. Failure to report them may have legal consequences. It is important that the report be accurate, objective, and submitted in a timely manner.

Another special reporting situation is a mass-casualty incident (MCI). The local MCI plan should have some means of temporarily recording important medical information (such as a triage tag that can be used later to complete the form). The standard for completing the form in an MCI is not the same as for a typical call. Your local plan should have specific guidelines. MCIs will be discussed in Chapter 39, *Incident Management.*

Communications Systems and Equipment

Radio and telephone communications link you and your team with other members of the EMS, fire, and law enforcement communities. This link helps the entire team to work together more effectively and provides an important layer of safety and protection for each member of the team. You must know what your system can and cannot do, and you must be able to use your system efficiently and effectively. You must be able to send precise, accurate reports about the scene, the patient's condition, and the treatment that you provide.

As an EMT, you must be familiar with two-way radio communications and have a working knowledge of the mobile and handheld portable radios that are used in your unit. You must also know when to use them and what to say when you are transmitting.

Base Station Radios

The dispatcher usually communicates with field units by transmitting through a fixed radio base station that is controlled from the dispatch center. A **base station** is any radio hardware containing a transmitter and receiver that is located in a fixed place. The base station may be used by an operator speaking into a microphone that is connected directly to the equipment. It also works remotely through telephone lines or by radio from a communications center. Base stations may include dispatch centers, fire stations, ambulance bases, or hospitals.

A two-way radio consists of two units: a transmitter and a receiver. Some base stations may have more than one transmitter and/or more than one receiver. They may also be equipped with one multi-channel transmitter and several single-channel receivers. A **channel** is an assigned frequency or frequencies used to carry voice and/or data communications. Regardless of the number of transmitters and receivers, they are commonly called *base radios* or *stations*. Base stations usually have more power (often 100 watts or more) and higher, more efficient antenna systems than mobile or portable radios. This increased broadcasting range allows the base station operator to communicate with field units and other stations at much greater distances.

The base radio must be physically close to its antenna. Therefore, the actual base station cabinet and hardware are commonly found on the roof of a tall building or at the bottom of an antenna tower. The base station operator may be miles away in a dispatch center or hospital, communicating with the base station radio by dedicated lines or special radio links. A **dedicated line**, also known as a *hotline*, is used for specific point-to-point contact. This type of phone, typically located within an ED, is not on the main switchboard. EMS personnel are able to call the number directly without being placed on hold or transferred. This type of line makes recording medical command conversations much easier.

Mobile and Portable Radios

In the ambulance, you will use both mobile and portable radios to communicate with the dispatcher and/or medical control. An ambulance will often have more than one mobile radio, each on a different frequency **Figure 4-16**. One radio may be used to communicate with the dispatcher or other public safety agencies. A second radio is often used for communicating patient information to medical control.

A mobile radio is installed in a vehicle and usually operates at lower power than a base station. Most **VHF (very high frequency)** mobile radios operate between 30 and 300 MHz. **UHF (ultra-high frequency)** mobile radios operate between 300 MHz and 3,000 MHz. Radios that operate at 800 MHz are increasingly common in EMS systems. These systems provide a great amount of system flexibility without the need for vast numbers of frequencies. What was once accomplished with 30 separate frequencies can be done with less than 10. Mobile antennas are much closer to the ground than base station antennas, so communications from the unit are typically limited to 10 to 15 miles over average terrain.

Figure 4-16 Some ambulances have more than one mobile radio to allow communications with hospitals, mutual aid jurisdictions, and other agencies.

Portable radios are hand-held devices that operate at 1 to 5 watts of power. Because the entire radio can be held in your hand, when in use, the antenna is often no taller than you. The transmission range of a portable radio is more limited than that of mobile or base station radios. Portable radios are essential in helping to coordinate EMS activities at the scene of an MCI. They are also helpful when you are away from the ambulance and need to communicate with dispatch, another unit, or medical control **Figure 4-17**.

Repeater-Based Systems

A **repeater** is a special base station radio that receives messages and signals on one frequency and then automatically retransmits them on a second frequency. Because a repeater is a base station (with a large antenna), it is able to receive lower power signals, such as those from a portable radio, from a long distance away. The signal is then rebroadcast with all the power of the base station **Figure 4-18**. EMS systems that use repeaters usually have outstanding systemwide communications and are able to get the best signal from portable radios. There are also mobile repeaters that may be found in ambulances or placed in various areas around an EMS system area.

Figure 4-17 A portable radio is essential if you need to communicate with the dispatcher or medical control when you are away from the ambulance.

At times, you may be able to communicate with a base station radio, but you will not be able to hear or transmit to another mobile unit that is also communicating with that base. Repeater base stations eliminate such problems. They allow two mobile or portable units that cannot reach each other directly to communicate through the repeater, using its greater power and antenna.

Digital Equipment

Although most people think of voice communications when they think of two-way radios, digital signals are also a part of EMS communications. With telemetry, electronic signals are converted into coded, audible signals. These signals can then be transmitted by radio or telephone to a receiver with a decoder at the hospital. The decoder converts the signals back into electronic impulses that can be displayed on a screen or printed, such as a fax message. New technology also allows for digital telemetry. For example, data from cardiac monitors can be transmitted via Bluetooth-enabled mobile devices to a monitoring center, where physicians can review the data and quickly contact patients, if needed. Rhythm strips and 12-lead ECGs are transmitted to the hospital to identify abnormal heart rhythms and critical cardiac information such as ST segment elevation myocardial infarction (or STEMI) alerts, allowing informed treatment decisions to be made during the prehospital phase. Digital signals are also used in some kinds of paging and tone alerting systems because they transmit faster than spoken words and allow more choices and flexibility.

Figure 4-18 A message is sent from the control center to the transmitter by a landline. The radio carrier wave is picked up by the repeater for rebroadcast to outlying units. Return radio traffic is picked up by the repeater and rebroadcast to the control center.

▶ Cellular/Satellite Telephones

Whereas dispatchers communicate with field units by transmitting through a fixed radio base station, it is common for EMTs to communicate with receiving facilities by **cellular telephone**. These telephones are simply low-power portable radios that communicate through a series of interconnected repeater stations called *cells* (hence the name *cellular*). Cells are linked by a sophisticated computer system and connected to the telephone network. Another option is a satphone or satellite phone. These phones use a satellite, which receives and relays the signals, instead of a cell.

Many cellular systems make equipment and air time available to EMS services at little or no cost as a public service. The public is often able to call 9-1-1 or other emergency numbers on a cellular telephone free of charge. However, this easy access may result in overloading and jamming of cellular systems in mass-casualty and disaster situations.

When using these systems, ensure that a reference of commonly called numbers is available. Local hospitals, poison control, police services, and the number to the dispatcher should be readily available. Cellular and satellite systems also have areas of bad reception. As an EMT, it is important to be aware of any areas in which your equipment will not work.

As with all repeater-based systems, a cellular or satellite telephone is useless if the equipment fails, if there is a loss of power, or if it is damaged by severe weather or other circumstances.

A **scanner** is a radio receiver that searches or "scans" across several frequencies, stops whenever it receives a radio broadcast on that frequency, and continues once the message is complete. Although cellular and satellite telephones are more private than most other forms of radio communications, keep in mind that these telephones use digital signals, which makes eavesdropping difficult but not impossible. Therefore, you must always be careful to appropriately respect patient privacy and to speak in a professional manner every time you use any form of an EMS communications system.

▶ Other Communications Equipment

Ambulances and other field units are usually equipped with an external public address system. This system may be a part of the siren or the mobile radio. The intercom between the cab and the patient compartment may also be a part of the mobile radio. These components do not involve radio wave transmission, but you must understand how they work and practice using them before you really need them.

EMS systems may use a variety of two-way radio hardware. Some systems operate VHF equipment in the **simplex** (push to talk, release to listen) mode. In this mode, radio transmissions can occur in either direction but not simultaneously in both.

When one party transmits, the other can only receive. Once one party finishes transmitting, the other party can then reply. Other systems conduct **duplex** (simultaneous talk–listen) communications on UHF frequencies and cellular telephones. In the full duplex mode, radios can simultaneously transmit and receive communications on one channel. This is sometimes called "a pair of frequencies." A third possible configuration for a communications system is **multiplex**. This design utilizes two or more frequencies, which enables more than one transmission to occur simultaneously and provides for the transmission of both audio and data signals via separate channels. This type of system is what allows paramedics to transmit a patient's electrocardiogram to the hospital from the scene or back of the ambulance. A number of VHF and UHF channels, commonly called **MED channels**, are reserved exclusively for EMS use. However, hundreds of other commercial, local government, and fire services frequencies are also used for EMS communications.

Trunking, or 800-MHz, systems take advantage of the latest technologies in communications. Instead of being assigned to one or two frequencies, in a trunking system, many frequencies are assigned to a group. As the radio conversation begins, a computer selects the next open frequency and you begin talking. When you speak a second time, you will likely be speaking on a different frequency because the computer is constantly monitoring for frequency load and reassigning transmissions to unused frequencies. These systems allow for greater traffic without greater numbers of frequencies. Therefore, you do not need to worry about being able to transmit or receive. In a trunking system, the computer will switch you to another channel without your knowledge and you will operate the radio as you normally do.

YOU are the Provider — PART 4

The patient agrees to EMS transport, is placed on the stretcher, and is loaded into the ambulance. You cover her with a blanket to keep her warm and proceed to a hospital located 15 miles away. En route, you reassess her condition.

Recording Time: 11 Minutes	
Level of consciousness	Conscious and alert
Respirations	20 breaths/min; regular and unlabored
Pulse	74 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	118/60 mm Hg
Spo_2	98% (on room air)

The patient's condition remains unchanged since your initial encounter. You contact the receiving facility and provide them with a radio report.

6. What are the components of a radio report to the hospital?
7. How does the oral report differ from the radio report?

Any large-scale emergency requires cooperative efforts from several agencies such as law enforcement, fire departments, and EMS. At times more than one jurisdiction is involved and effective communication between all of those involved becomes challenging. An **interoperable communications system** allows all of the agencies involved to share valuable information with each other in real time. This system utilizes a voice-over-Internet-protocol format to connect landlines, cell phones, and computers to create a seamless, reliable exchange of information between all parties.

Another type of communication system is a **mobile data terminal (MDT)** Figure 4-19. An MDT is a small computer terminal inside the ambulance that directly receives data from the dispatch center. MDTs allow for greatly expanded communication capabilities. Instead of asking the dispatcher to confirm whether he said 11345 Main Street or 11354 Main Street, you look at the terminal where the address is displayed. Satellite communications can track your progress to the scene and can provide important scene information, such as known violent calls to this address, the nature of those calls, and the number of times the ambulance has been called.

Your ability to effectively communicate with other units or medical control depends on how well the weaker radio can "talk back." Base and repeater station radios often have higher antennas and much greater power than mobile or portable units do. This increased power ensures that signals are generally heard and understood from a far greater distance than the signal produced from a mobile unit. Remember, when you are at the scene, you may be able to clearly hear the dispatcher or hospital on your radio, but you may not be heard or understood when you transmit.

Figure 4-19 A mobile data terminal.

Even small changes in your location can significantly affect the quality of your transmission. Also remember that the location of the antenna is critically important for clear transmission. Commercial aircraft flying at 37,000 feet can transmit and receive signals over hundreds of miles, yet their radios have only a few watts of power. The "power" comes from their antenna positioned at 37,000 feet.

The success of communications depends on the efficiency of your equipment. A damaged antenna or microphone often prevents high-quality communications. Check the condition and status of your equipment at the start of each shift, and then correct or report any problems.

Radio Communications

All radio operations in the United States, including those used in EMS systems, are regulated by the Federal Communications Commission (FCC). The FCC has jurisdiction over interstate and international telephone and telegraph services and satellite communications—all of which may involve EMS activity.

The FCC has five principal EMS-related responsibilities:

1. **Allocate specific radio frequencies for use by EMS providers.** Modern EMS communications began in 1974. At that time, the FCC assigned 10 MED channels in the 460- to 470-MHz (UHF) band to be used by EMS providers. These UHF channels were added to the several VHF frequencies that were already available for EMS systems. However, these VHF frequencies had to be shared with other "special emergencies" uses, including school buses and veterinarians.
2. **License base stations and assign appropriate radio call signs for those stations.** An FCC license is usually issued for 5 years, after which time it must be renewed. Each FCC license is granted only for a specific operating group. Often, the longitude and latitude (locations) of the antenna and the address of the base station determine the call signs.
3. **Establish licensing standards and operating specifications for radio equipment used by EMS providers.** Before it can be licensed, each piece of radio equipment must be submitted to the FCC by its manufacturer for type acceptance, based on established operating specifications and regulations.
4. **Establish limitations for transmitter power output.** The FCC regulates broadcasting power to reduce radio interference between neighboring communications systems.

5. **Monitor radio operations.** This includes making spot field checks to help ensure compliance with FCC rules and regulations.

The FCC's rules and regulations are written in technical and legal language and fill many volumes. Only a very small section (part 90, subpart C) deals with EMS communication issues. You are not responsible for reading these detailed and often confusing documents. For appropriate guidance on technical issues, contact your EMS system supervisor. In fact, many EMS systems look to radio and telephone communications experts for advice on technical issues.

Responding to the Scene

EMS communication systems may operate on several frequencies and use different frequency bands. Some EMS systems may even use different radios for various purposes. However, all EMS systems depend on the skill of the dispatcher. The dispatcher receives the first call to 9-1-1. You are part of the team that responds to calls once the dispatcher notifies your unit of an emergency.

The dispatcher has several important responsibilities during the alert and dispatch phase of EMS communications. The dispatcher must do all of the following:

- Properly screen and assign priority to each call (according to predetermined protocols)
- Select and alert the appropriate EMS response unit(s)
- Dispatch and direct EMS response unit(s) to the correct location
- Coordinate EMS response unit(s) with other public safety services until the incident is over
- Provide emergency medical instructions to the telephone caller (according to predetermined protocols) so that essential care (eg, CPR) may begin before the EMTs arrive

When the first call to 9-1-1 comes in, the dispatcher must judge its relative importance to begin the appropriate EMS response using emergency medical dispatch protocols. First, the dispatcher must find out the exact location of the patient and the nature and severity of the problem. The dispatcher asks for the caller's telephone number, the patient's name and age, and other information, as directed by local protocol. Next, the dispatcher asks for some description of the scene, such as the number of patients or special environmental hazards.

Using this information, the dispatcher will assign the appropriate EMS response unit(s) based on local protocols and the following factors:

- Dispatcher's determination of the nature and severity of the problem (Many emergency medical dispatch systems will determine this automatically based on a caller's answers to a defined series of questions.)
- Anticipated response time to the scene
- Level of training (EMR, EMT, AEMT, Paramedic) of available EMS response unit(s)
- Need for additional EMS units, fire suppression, rescue, a hazardous materials team, air medical support, or law enforcement

The dispatcher's next step is to alert the appropriate EMS response unit(s) **Figure 4-20**. Alerting these units may be done in a variety of ways. The dispatcher may use the dispatch radio system to contact units that are already in service and monitoring the channel. Dedicated lines (hotlines) between the control center and the EMS station may also be used.

The dispatcher may also page EMS personnel. Pagers are commonly used in EMS operations to alert on-duty and off-duty personnel. **Paging** involves the use of a coded tone or digital radio signal and a voice or display message that is transmitted to pagers (beepers) or desktop monitor radios. Paging signals may be sent to alert only certain personnel or may be blanket signals that will activate all the pagers in the EMS service. Pagers and monitor radios are convenient because they are usually silent until their specific paging code is received. Alerted personnel contact the dispatcher to confirm the message and receive details of their assignments.

Figure 4-20 You will be assigned to a call by the dispatcher.

Once EMS personnel have been alerted, they must be properly dispatched and sent to the incident. Every EMS system should use a standard dispatching procedure. The dispatcher should give the responding unit(s) the following information:

- Nature and severity of the injury, illness, or incident
- Exact location of the incident
- Number of patients
- Responses by other public safety agencies
- Special directions or advisories, such as adverse road or traffic conditions, severe weather reports, or potential scene hazards
- Time at which the unit or units are dispatched

Your unit must confirm with the dispatcher that you have received the information and are en route to the scene. Local protocol will dictate whether it is the job of the dispatcher or your unit to notify other public safety agencies that you are responding to an emergency. In some areas, the ED is also notified when an ambulance responds to an emergency.

You should report to the dispatcher any problems during your response. You should also inform the dispatcher when you have arrived at the scene. The arrival report to the dispatcher should include any obvious details that you see during scene size-up. For example, you might say, "Dispatcher, BLS Unit Two is on scene at 3010 Mitchell Street. It is a blue house with a long driveway." This information is particularly useful if additional units are responding to the same scene.

All radio communications during dispatch, as well as during other phases of operations, must be brief and easily understood. Speak in plain English and do not use code words in your transmissions. The use of ten-codes is specifically discouraged because they vary by jurisdiction and decrease the understandability of a transmission. Your tone and pace should be slow, relaxed and clear. You do not need to use excessively polite language. Also, avoid wordiness. An example of an excessively wordy communication is: "Good morning dispatch, this is Ambulance 6-3-1. We are responding to 381 South Main Street. Have a good day." Although this sounds pleasant (and you should try to foster a good working environment with the dispatcher), this wastes radio time. Remember, the dispatcher's job is to field hundreds of calls an hour; therefore, you need to only report important information so that he or she can focus on what to do next. Table 4-9 lists common instances for which EMS providers will need to use the radio to communicate with dispatch.

Table 4-9 Typical EMS Communications With Dispatch

Phase of EMS Call	EMS Unit Communication
Initial receipt of call	Acknowledge call Respond to the call
En route to call	Request assistance with directions, when needed Request additional resources, when needed
On scene	Report arrival at scene Check in; often a system will require EMS units to transmit every 20 minutes as a safety measure Request additional resources, when needed Report leaving scene
Arrival at hospital (or point of transfer)	Notify dispatch of arrival at point of transfer
Return to service	Notify dispatch when the unit is available for another call
Miscellaneous	Some systems require EMS units to notify dispatch anytime they are not in station

Table 4-10 lists tips to using the radio. Although these may change slightly from department to department, they provide a good foundation from which to begin.

Communicating With Medical Control and Hospitals

The principal reason for radio communication is to facilitate communication between you and medical control (and the hospital). Medical control may be located at the receiving hospital, another facility, or sometimes even in another city or state. You must, however, consult with medical control to notify the hospital of an incoming patient, request advice or receive orders, or advise the hospital of special situations.

It is important to plan and organize your radio communication before you push the transmit button. Remember, a concise, well-organized report is the best method of accurately and thoroughly describing the patient and his or her medical condition to the providers who will be receiving the patient. It also demonstrates your competence and professionalism to all who hear your report. Well-organized radio communications with the hospital will engender confidence in the receiving facility's physicians and nurses, as well as others who are listening. In addition, the patient and family will be comforted by your organization and ability to communicate clearly. A well-delivered radio report puts you in control of the information, which is correct procedure.

Hospital notification is the most common type of communication between you and the hospital. The purpose of these calls is to notify the receiving facility of the patient's chief complaint and condition Figure 4-21. On the basis of this information, the ED is able to appropriately prepare staff and equipment to receive the patient. This is primarily a one-way form of communication. You are telling the ED what to expect. You are not asking for advice or orders; you are simply notifying them.

Giving the Patient Report

The patient report should follow a standard format established by your EMS system. The report commonly includes the following nine elements:

1. Your unit identification and level of services. Example: "Columbus Fire 2-BLS."
2. The receiving hospital and your estimated time of arrival. Example: "Columbus Community Hospital, ETA 10

minutes," or "patient transport code" according to local protocols.

YOU are the Provider PART 5

With an estimated time of arrival at the hospital of 20 minutes, you reassess the patient and note that her condition has remained unchanged.

Recording Time: 16 Minutes	
Level of consciousness	Conscious and alert
Respirations	18 breaths/min; regular and unlabored
Pulse	72 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	120/60 mm Hg
Spo_2	99% (on room air)

You arrive at the hospital and give your oral report to the charge nurse. After answering the nurse's questions, you complete your patient care report and return to service.

8. What functions does the patient care report serve?

Table 4-10 Tips When Using EMS Radio Communications

Turn radio on and adjust volume.
Ensure a clear frequency before speaking.
To speak, use the "press-to-talk" button, and wait 1 second before speaking.
Hold the microphone 2 in. to 3 in. from your mouth.
Address the unit you are calling, and provide the name of your unit.
The unit you call will signal that you can begin your transmission.
Use a clear, calm, and monotone voice and speak at a reasonable pace.
Keep the transmission brief.
Use clear text.
Avoid the use of codes or agency-specific terms.
Avoid using slang or unapproved abbreviations.
Do not use useless or meaningless phrases, such as "be advised."
Limit saying "please," "thank you," and "you're welcome."
When transmitting numbers, such as an address, provide both the number and the individual digits ie, "Respond to 1381, 1-3-8-1, Main Street."
Remember that the airwaves are public and the use of scanners is popular.
Do not use names; protect the privacy of patients.
Remain objective and impartial in describing patients.
Never use profanity; always be professional.
Use the words "affirmative" and "negative" instead of "yes" or "no."
Use the standard format for transmission of information.
When you are finished transmitting, indicate this by saying "over."
Do not provide a diagnosis of the patient's problem.
Use EMS frequencies only for EMS communications.
Monitor background noise.

3. The patient’s age and gender. Example: “An 86-year-old woman.” The patient’s name should not be given over the radio because it may be overheard. This would be a violation of the patient’s privacy.
4. The patient’s chief complaint or your perception of the problem and its severity. Example: “Patient reports severe pelvic and less severe back pain.”
5. A brief history of the patient’s current problem. Example: “Patient fell into bathtub at 0300 this morning and wasn’t able to get out.” Other important history information that may pertain to the current problem should also be included, such as “The patient has diabetes and takes insulin.”

Figure 4-21 The patient report should be given in an objective, accurate, and professional manner.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

6. A brief report of physical findings. This report should include level of consciousness, the patient’s general appearance, pertinent abnormalities noted, and vital signs. Example: “The patient is alert and oriented, has pale skin color, and is cold to the touch. We noted crepitus in the pelvic girdle. Her blood pressure is 112/84, pulse is 72, and respirations 14.”
7. A brief summary of the care given and any patient response. Example: “We have immobilized her onto a backboard. She still has pulse, motor, and sensory function distally in all four extremities.”
8. A brief description of the patient’s response to the treatment provided.
9. Determine whether the receiving facility has any additional questions or orders.

Be sure you report all patient information in an objective, accurate, and professional manner. Remember that people with scanners are listening. You could be successfully sued for slander if you describe a patient in a way that injures his or her reputation.

The Role of Medical Control

The delivery of EMS involves an impressive array of assessments, stabilization, and treatments. In some cases, you may assist patients in taking medications. AEMTs and paramedics go beyond this level by initiating medication therapy based on the patient's presenting signs. For logical, ethical, and legal reasons, the delivery of such sophisticated care must be done in association with physicians. For this reason, every EMS system needs input and involvement from physicians, including your system or department medical director, providing medical direction (medical control) for your EMS system. Medical control is either off-line (indirect) or online (direct), as authorized by the medical director. Medical control guides the treatment of patients in the system through protocols, direct orders, advice, and postcall review.

Depending on how the protocols are written, you may need to call medical control for direct orders (permission) to administer certain treatments, to determine the transport destination of patients, or to be allowed to stop treatment and/or not transport a patient. In these cases, the radio or cellular phone provides a vital link between you and the expertise available through the base physician.

To maintain this link 24 hours a day, 7 days a week, medical control must be readily available on the radio at the hospital or on a mobile or portable unit when you call **Figure 4-22**. In most areas, medical control is provided by the physicians who work at the receiving hospital. However, many variations have developed across the country. For example, some EMS units receive medical direction from one hospital even though they are taking the patient to another hospital. In other areas, medical direction may come from a freestanding center or even from an individual physician. Regardless of your system's design, your link to medical control is vital to maintain the high quality of care your patient requires and deserves.

Figure 4-22 Medical control must be readily available on the radio at the hospital.

Words of Wisdom

Some EMS systems will assign roles in their units: a primary person to speak on the radio and a primary person to administer patient care. In these systems, all members of the crew must communicate very closely to make this process work. In reality, EMTs are involved in every role, but the partial division of responsibilities can be efficient and effective. This approach is most common in systems that use extensive online medical control.

Calling Medical Control

You can use the radio in your unit or a portable radio to call medical control. A cellular telephone can also be used. Regardless of the type of communication, you should use a channel that is relatively free of other radio traffic and interference and one that will be recorded. Medical command communications create medical legal requirements that such conversations should be recorded. There are a number of ways to control access on ambulance-to-hospital channels. In some EMS systems, the dispatcher monitors and assigns appropriate, clear medical control channels. Other EMS systems rely on special communications operations, such as centralized medical emergency dispatch or resource coordination centers, to monitor and allocate the medical control channels.

Because of the large number of EMS calls to medical control, your radio report must be precise and well organized and must only contain important information. In addition, because you need specific directions on patient care, the information that you provide to medical control must be accurate. Remember, the physician on the other end bases his or her instructions on the information you provide.

As discussed earlier, you should use proper medical terminology when giving your report. Never use codes when communicating with medical control unless you are directed by local protocol to do so. Most medical control systems handle many EMS agencies and will most likely not know your unit's special codes or signals.

To ensure complete understanding, once you receive an order from medical control, such as an order for a medication or the denial of a request for a particular treatment, you must repeat the order back, word for word, and then receive confirmation. This helps to eliminate confusion and the possibility of poor patient care. Orders that are unclear or seem inappropriate or incorrect should be questioned. Do not blindly follow an order that does not make sense to you. The physician may have misunderstood or may have missed part of your report. In that case, he or she may not be able to respond appropriately to the patient's needs. The role of medical control will be discussed further in Chapter 11, *Principles of Pharmacology*.

Words of Wisdom

Orders that are unclear or seem inappropriate or incorrect should be questioned. Do not blindly follow an order that does not make sense to you.

Information About Special Situations

Depending on your system's procedures, you may initiate communication with one or more hospitals to advise them of an extraordinary call or situation. For instance, a small rural hospital may be better able to respond to multiple victims of a highway crash if it is notified when the ambulance is first responding. At the other extreme, an entire hospital system must be notified of any disaster, such as a plane or train crash, as early as possible to enable activation of its staff call-in system. These special situations may also include hazardous materials situations, rescues in progress, MCIs, or any other situation that could require special preparation on the part of the hospital. In some areas, mutual aid frequencies may be designated in MCIs so that responding agencies can communicate with one another on a common frequency.

When notifying the hospital(s) of any special situations, keep the following in mind: The earlier the notification, the better. You should ask to speak to the charge nurse or physician in charge, as he or she is best able to mobilize the resources necessary to respond. Also, whenever possible, provide an estimate of the number of people who may be transported to the facility. Be sure to identify any conditions the patient(s) may have that require special needs, such as burns or hazardous materials exposure, to assist the hospital in preparation. In many cases, hospital notification is part of a larger disaster or hazardous materials plan. Follow the plan for your system.

Maintenance of Radio Equipment

Like all other EMS equipment, radio equipment must be serviced by properly trained and equipped personnel. Remember that the radio is your lifeline to other public safety agencies (who function to protect you), as well as to medical control, and it must perform under emergency conditions. Radio equipment that is operating properly should be serviced at least once a year. Any equipment that is not working properly should be immediately removed from service and sent for repair. Outdated equipment should be removed from service as new equipment becomes available.

When you are beginning your shift, it is typical to check the ambulance to ensure that it is ready to go. You cannot assume that the crew before you left the ambulance well stocked and in operational readiness. The radio is also an important component that needs to be checked to ensure that it is operating correctly and using the correct frequency.

Sometimes, radio equipment will stop working during a run. Your EMS system must have several backup plans and options for this scenario. The goal of a backup plan is to make sure you can maintain contact when the usual procedures do not work. There are quite a few options.

The simplest backup plan relies on written standing orders. **Standing orders** are written documents that have been signed by the EMS system's medical director. These orders outline specific directions, permissions, and sometimes prohibitions regarding patient care. By their very nature, standing orders do not require direct communication with medical control. When properly followed, standing orders or formal protocols have the same authority and legal status as orders given over the radio. They exist to one extent or another in every EMS system and can be applied to all levels of EMS providers. Other backup plans can involve using a cell phone and calling the ED directly. The problem with this approach is that the conversation will probably not be recorded. Medical command conversations are often recorded for the purpose of quality improvement.

YOU are the Provider — SUMMARY

1. What information should you ask the dispatcher to obtain from the caller?

A "sick person" could be anyone from a patient with the flu to a patient in cardiac arrest. For all you know, the patient could be experiencing a psychiatric crisis, in which case law enforcement should be dispatched to secure the scene before your arrival. After determining the nature of the patient's illness and gathering information that will maximize your own safety, your next priority is to determine if the patient is conscious and breathing. Try to ascertain the patient's age and gender, if possible. Although you will truly not know what you are dealing with until you arrive at the scene and assess the patient, you should capitalize on the fact that the dispatcher still has the caller on the phone. The more information you obtain prior to arrival at the scene, the better prepared you will be to care for the patient.

2. Why is effective communication between the responding EMS unit and the dispatcher so important?

Effective communication between the dispatcher and the EMS unit is important because accurate, thorough communication results in quicker and more effective care for the patient at the scene as possible. Once you respond to a scene, you will confirm with the dispatcher that you are en route. Should there be any delay in your unit's response, your communication with the dispatcher allows adjustments to the response as needed.

During an emergency call, you will communicate with the dispatcher regarding any problems. Depending on your local protocol, the dispatcher will inform other public agencies that you are responding, and coordinate efforts with them to ensure that needed resources are mobilized.

3. How can you maximize successful communication with a patient who is hard of hearing?

First, determine the degree of the patient's hearing loss; her hearing aids may allow her to hear normally. Do not assume she is totally deaf! Remember, most patients who are hard of hearing have a normal intelligence level. Provided you successfully communicate with them, they usually understand what is going on around them.

Many patients who are hard of hearing can read lips to some extent; therefore, you should position yourself where the patient can see your lips. Never shout in the ear of a patient who is hard of hearing. Listen carefully, ask short questions, and give short answers whenever possible.

If your efforts to verbally communicate with the patient are unsuccessful, write down your questions on paper and ask the patient to write down her response. Print legibly, so your handwriting is not a communication barrier.

Learn some simple phrases in sign language, such as "hurt," "sick," and "help" in case you cannot communicate in any other way.

4. Should your general approach to the assessment process be any different for this patient versus a younger patient? Why or why not?

As a result of the natural process of aging, older patients may not react to pain the same as younger patients. An older person who has fallen, for example, may not report any pain, despite the presence of an obvious injury.

Assess the patient just as you would a younger patient; however, you may need to allow extra time for her to answer your questions. As with any patient, she should feel confident that everything possible is being done for her.

5. What techniques can facilitate the process of interviewing an older patient?

Many of the same techniques used to interview younger patients can be used effectively to interview older patients. When interviewing an older patient, however, patience is even more important. Identify yourself; do not assume that an older person—or any person for that matter—knows who you are. Remain aware of how you present yourself; frustration and impatience can be conveyed through body language.

When communicating with an older patient, look directly at her and speak slowly and distinctly. Do not increase the volume of your voice based on the assumption that the patient is hard of hearing. After asking the patient a question, allow her ample time to answer it and then *actively listen* to her response. As with any patient, show respect. Refer to her as Mrs. or Miss, unless she asks to be addressed otherwise.

Do not talk about the patient in front of her; doing so gives the impression that she has no choice in her medical care. Again, this may only escalate her fear of losing independence.

6. What are the components of a radio report to the hospital?

The purpose of the radio report is to inform the receiving facility that you are transporting to its location and to provide an overview of the patient's condition so it can adequately prepare to receive the patient. Your radio report to the receiving hospital should be concise—brief in length, yet comprehensive in scope.

Identify your EMS system and unit number and then advise the nurse or physician that you are prepared to give a radio report. After he or she confirms that he or she can hear you, begin your radio report with the patient's age, gender, chief complaint, and level of consciousness. Next, provide a brief elaboration of the patient's chief complaint (eg, the history of present illness), your assessment findings, SAMPLE history, initial vital signs, and the most recent set of vital signs. Summarize any treatment that you provided and the patient's response, if any, to your treatment. Finally, give the hospital your estimated time of arrival and transport mode.

7. How does the oral report differ from the radio report?

Patient care transfer occurs during your oral report, not your radio report. Once a hospital staff member is ready to take responsibility for the patient, you should provide that person with a formal oral report of the patient's condition.

Unlike your radio report, which should be brief and concise, your oral report should be more comprehensive. In many cases, your oral report is given at the same time the nurse or physician is providing care for the patient, such as assessing the patient or helping you move the patient from the stretcher to the hospital bed. Therefore, you must report important information in a complete, precise manner. The following components should be included in your oral report:

- The patient's name and the chief complaint, nature of illness, or mechanism of injury
- Detailed information, such as pertinent negatives and findings of a more detailed physical exam
- Any medical history not already given
- The patient's response to treatment given en route. It is especially important to report any changes in the patient's condition or the treatment provided after your radio report.
- The vital signs assessed during transport and after your radio report
- Any other information that you obtained en route and after your radio report; for example, a list of medications that the patient is currently taking, or any known allergies to medications or food.

8. What functions does the patient care report (PCR) serve?

In addition to your radio and oral reports, you should also complete a formal PCR before you leave the hospital or shortly thereafter depending on your local jurisdictional protocol. There are two types of PCRs: written and electronic. A copy of the report, whether written or transmitted electronically, must be left at the hospital.

The PCR describes the nature of the patient's injuries or illness at the scene, the treatment you provided initially and en route, vital signs, and the patient's condition on arrival at the hospital. The PCR serves the following functions:

- Continuity of care

- Legal documentation
- Education
- Administrative information (ie, billing)
- Essential research information
- Evaluation and continuous quality improvement

The information in the PCR confirms that you provided proper patient care. In some cases, it also shows that you properly handled unusual or uncommon situations. You should include both objective (what you find) and subjective (what the patient tells you) information in the PCR. A well-written, neat, and concise PCR—including correct spelling and grammar—reflects good patient care. If the report looks sloppy, the care you provided may be assumed to have been the same.

Narrative

Dispatched for a "sick person." Arrived on scene to find the patient, an 83-year-old woman, sitting on the couch in her living room. She was conscious and alert; her airway was patent and her breathing was adequate. The patient reported light-headedness and nausea that had started approximately one hour earlier. Patient denied chest pain, shortness of breath, abdominal pain, headache, or significant medical problems. Only medications are vitamins; no prescribed medications or known drug allergies. Assessment did not reveal any gross abnormalities. Her blood glucose level was assessed and noted to be 112 mg/dL. Obtained vital signs and prepared patient for transport. Applied blanket because the patient stated that she was cold. Began transport and monitored patient's mental status and vital signs en route. Her condition remained unchanged. The patient wears hearing aids in both ears but was easy to communicate with. Arrived at the hospital and transferred patient care without incident. Oral report was given to staff nurse. Returned to service at 0655.**End of report**

Prep Kit

Ready for Review

- The Shannon–Weaver model of communication is a valuable tool in understanding the variables involved in human communication.
- There are many verbal and nonverbal factors and strategies that are necessary for therapeutic communication.

- Excellent communication skills are crucial in relaying pertinent information to the hospital before arrival.
- It is important to remember that people who are sick or injured may not understand what you are doing or saying. Therefore, your body language and attitude are very important in gaining the trust of both the patient and family. You must also take special care of people such as children, older adults, patients who are hard of hearing, patients who are visually impaired, and non–English-speaking patients.
- As an EMT, you must have excellent verbal communication skills. You should be able to interact with the patient and any family members, friends, or bystanders.
- You must aim to complete a patient care report before you leave the hospital. This is a vital part of providing emergency medical care and ensuring the continuity of patient care. This information guarantees the proper transfer of responsibility, complies with the requirements of health departments and law enforcement agencies, and fulfills your agency's administrative needs.
- Radio and telephone communications link you and other members of the EMS, fire, and law enforcement communities. This enables your entire team to work together more effectively.
- Understand and be able to use different forms of communication. Be familiar with two-way radio communications and have a working knowledge of mobile and hand-held portable radios. You must know when to use them and what type of information you can transmit.
- Know what your communication system can and cannot handle. You must be able to communicate effectively by sending precise, accurate reports about the scene, the patient's condition, and the treatment that you provide.
- Remember, the lines of communication are not always exclusive; therefore, speak in a professional manner at all times and protect patient privacy.
- Your reporting and record-keeping duties are essential, but they should never come before the care of a patient.

Vital Vocabulary

base station Any radio hardware containing a transmitter and receiver that is located in a fixed place.

cellular telephone A low-power portable radio that communicates through an interconnected series of repeater stations called "cells."

channel An assigned frequency or frequencies that are used to carry voice and/or data communications.

closed-ended questions Questions that can be answered in short or single word responses.

communication The transmission of information to another person—verbally or through body language.

cultural imposition When one person imposes his or her beliefs, values, and practices on another because he or she believe his or her ideals are superior.

dedicated line A special telephone line that is used for specific point-to-point communications; also known as a *hotline*.

documentation The recorded portion of the EMT's patient interaction, either written or electronic. This becomes part of the patient's permanent medical record.

duplex The ability to transmit and receive simultaneously.

ethnocentrism When a person considers his or her own cultural values as more important when interacting with people of a different culture.

Federal Communications Commission (FCC) The federal agency that has jurisdiction over interstate and international telephone and telegraph services and satellite communications, all of which may involve EMS activity.

interoperable communications system A communication system that uses voice-over-Internet-protocol (VoIP) technology to allow multiple agencies to communicate and transmit data.

MED channels VHF and UHF channels that the Federal Communications Commission has designated exclusively for EMS use.

mobile data terminal (MDT) A small computer terminal inside the ambulance that directly receives data from the dispatch center.

multiplex The ability to transmit audio and data signals through the use of more than one communications channel.

noise Anything that dampens or obscures the true meaning of a message.

open-ended questions Questions for which the patient must provide detail to give an answer.

paging The use of a radio signal and a voice or digital message that is transmitted to pagers ("beepers") or desktop monitor radios.

patient care report (PCR) The legal document used to record all patient care activities. This report has direct patient care functions but also administrative and quality control functions. PCRs are also known as *prehospital care reports*.

rapport A trusting relationship that you build with your patient.

repeater A special base station radio that receives messages and signals on one frequency and then automatically retransmits them on a second frequency.

scanner A radio receiver that searches or "scans" across several frequencies until the message is completed; the process is then repeated.

simplex Single-frequency radio; transmissions can occur in either direction but not simultaneously in both; when one party transmits, the other can only receive, and the party that is transmitting is unable to receive.

standing orders Written documents, signed by the EMS system's medical director, that outline specific directions, permissions, and sometimes prohibitions regarding patient care; also called *protocols*.

telemetry A process in which electronic signals are converted into coded, audible signals; these signals can then be transmitted by radio or telephone to a receiver with a decoder at the hospital.

therapeutic communication Verbal and nonverbal communication techniques that encourage patients to express their feelings and to achieve a positive relationship.

trunking Telecommunication systems that allow a computer to maximize utilization of a group of frequencies.

UHF (ultra-high frequency) Radio frequencies between 300 and 3,000 MHz.

VHF (very high frequency) Radio frequencies between 30 and 300 MHz; the VHF spectrum is further divided into "high" and "low" bands.

Assessment *in Action*

You are dispatched at 0130 hours to an apartment complex for a gunshot wound. While you are en route, dispatch informs you that law enforcement has arrived and secured the scene. Upon arrival, you observe a law enforcement officer kneeling next to a teenager while two other officers interview witnesses. The patient is a 17-year-old boy with a single gunshot wound to the left upper leg. He is screaming in pain and states, "I can't believe he did this to me! I didn't know she was his sister!" You locate the wound and control the bleeding with direct pressure. Assessment of his vital signs shows a pulse rate of 96 beats/min; a respiratory rate of 22 breaths/min; blood pressure of 104/76 mm Hg; an Spo_2 of 98% on room air; and his skin is pink, warm, and dry.

1. Encouraging this patient to provide more information about his injury is an example of which therapeutic communication technique?

   A. Facilitation
   B. Clarification
   C. Reflection
   D. Interpretation

2. Which of the following actions should you avoid while interviewing this patient?

   A. Being empathetic
   B. Asking leading or biased questions
   C. Clarifying information
   D. Giving the patient time to answer the question

3. If this patient refuses to be transported to the hospital, you should:

   A. contact medical control.
   B. ask law enforcement to take him into custody.
   C. immediately stop patient care and leave.
   D. find another person to continue medical care.

4. As you radio the hospital to give a report on your patient, remember to:

   A. provide as much detail as possible.
   B. use code words to protect the patient's identity.
   C. speak as quickly as possible.
   D. remain objective and impartial.

5. What information should you include in your report to the hospital?

   A. Your estimated time of arrival
   B. The patient's full name and date of birth
   C. The address of the location you are coming from
   D. Your personal opinion of the patient's condition

6. As you write your narrative for this call, it is important to include:

   A. your personal opinions.
   B. many abbreviations.
   C. physical assessment findings.
   D. the address of your location.

7. After you submit the electronic PCR for this call, you realize that you accidentally documented the wrong vital signs. You should:

   A. leave the record as it is and seek legal advice.
   B. notify your agency's information technology department.
   C. follow your agency's directions for making an amendment.
   D. say nothing and hope that the error goes unnoticed.

8. Your partner takes several photos of the patient and the scene to post online to share with friends. This could be a violation of:

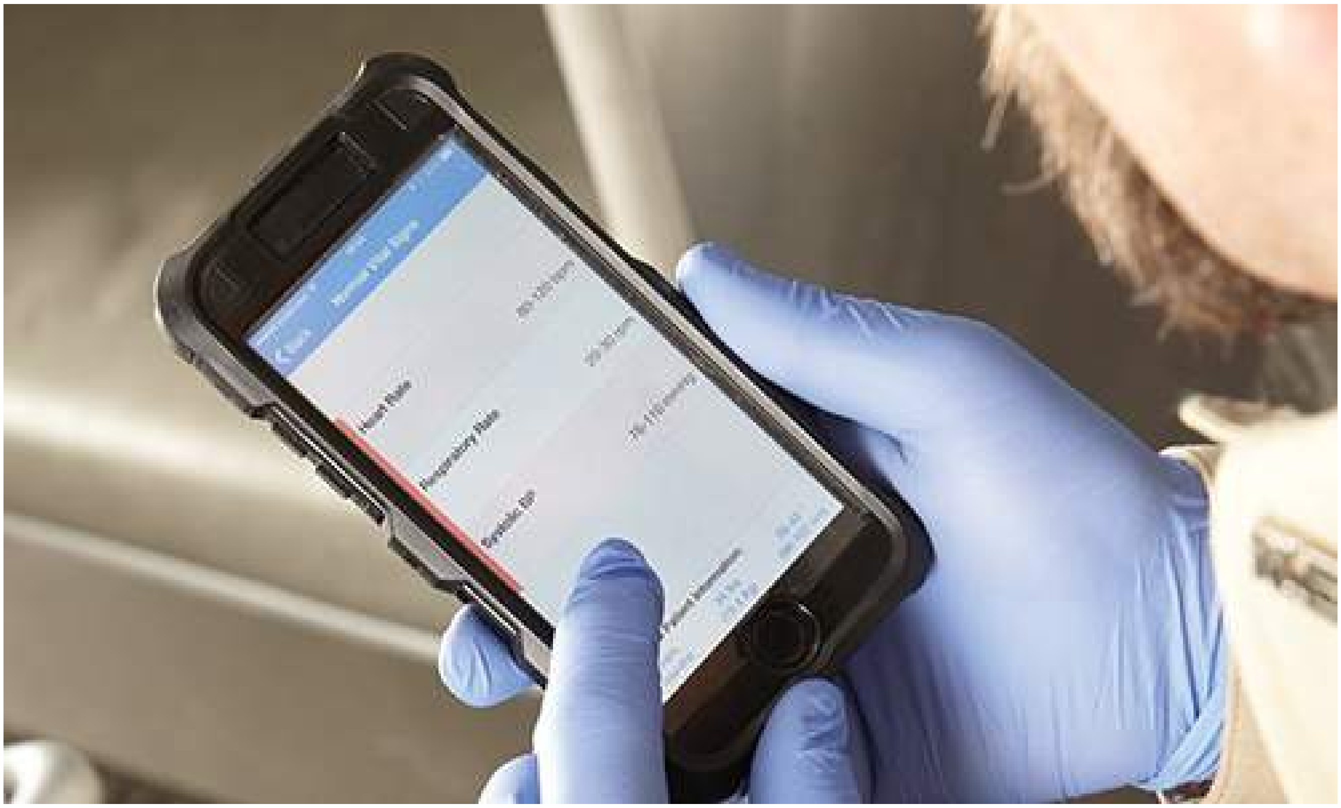
   A. Internet laws.
   B. patient care report protocol.
   C. NEMSIS.
   D. HIPAA.

9. Describe some of the administrative information that can be found on a PCR.

10. Describe the importance of the administrative information.

CHAPTER 5

Medical Terminology



National EMS Education Standard Competencies

Medical Terminology

Uses foundational anatomical and medical terms and abbreviations in written and oral communication with colleagues and other health care professionals.

Knowledge Objectives

1. Explain the purpose of medical terminology. (p 153)
2. Identify the four components that comprise a medical term. (p 153)
3. Describe the following directional terms: anterior (ventral), posterior (dorsal), right, left, superior, inferior, proximal, distal, medial, lateral, superficial, and deep. (pp 158–161)
4. Describe the prone, supine, Fowler, and semi-Fowler positions of the body. (p 161)
5. Break down the meaning of a medical term based on the components of the term. (p 162)
6. Identify error-prone medical abbreviations, acronyms, and symbols. (p 162)
7. Interpret selected medical abbreviations, acronyms, and symbols. (p 163)

Skills Objectives

There are no skills objectives for this chapter.

Introduction

As an EMT, it is essential that you have a strong working knowledge of medical terminology. Understanding key terms, acronyms, symbols, and abbreviations is important for effective communication and documentation. Understanding how terms are formed and the definitions for the various parts of a medical term will help you determine the meaning of an unknown term by breaking the word apart. Once you understand medical jargon, you will be able to communicate effectively with other members of the EMS, health care, and public safety teams.

Anatomy of a Medical Term

Medical terms are made of distinct parts that perform specific functions. Changing or deleting any of those parts can significantly change the function (or meaning) of a word. Components that comprise medical terms include the:

- **Word root** – the foundation of the word
- **Prefix** – what occurs before the root word
- **Suffix** – what occurs after the root word
- **Combining vowels** – vowels that join one or more word roots to other components of a term

How the parts of a term are combined determines its meaning. Accurate spelling, especially when some words are pronounced almost the same way, is essential in medical terminology. For example, the suffix *-phasia* means speaking, whereas *-phagia* means eating or swallowing. The prefix *dys-* means difficult or painful. Combining those two parts, *dysphasia* means difficulty speaking, while *dysphagia* means difficulty eating or swallowing. These are very different terms and the two words, although spelled differently, sound almost identical. Likewise, the terms *ilium* and *ileum* are pronounced exactly the same, but refer to different anatomic parts. The ilium is the largest bone of the pelvis, and the ileum is the last part of the small intestine. Knowing anatomy and the context of how these words are used will help you correctly determine (and spell) the term in a given situation.

Word Roots

The main part or stem of a word is called a word root. Some books use the term *word root*; others use *root word*. The terms are synonymous. A word root conveys the essential meaning of the word and frequently indicates a body part. Most terms have at least one word root, and some have more than one word root. Adding a prefix or suffix to the word root creates a term. Changing the prefix or suffix will change the meaning of the term.

A frequently used medical term is CPR, which stands for cardiopulmonary resuscitation. *Cardiopulmonary* breaks down as follows: *cardio* is a word root meaning "heart," and *pulmon* is a word root meaning "lungs." By performing CPR you introduce air into the lungs and circulate blood by compressing the heart to resuscitate the patient. Some word roots may also be used as prefixes or suffixes for other terms.

Examples of some word roots are shown in **Table 5-1**.

YOU are the Provider — PART 1

It is almost the end of your shift when you get a call for a routine transfer from the nursing home to the hospital for a 79-year-old woman with constipation and abdominal pain. Upon your arrival, you are met by a nurse who informs you the patient is new to the facility. She hands you the medical record, which includes the following information:

Patient Hx: AAA; HTN; CVA in 2009; AMI in 2010; GERD; and type 1 DM.

Your patient is pale and her skin is wet. When you gently palpate her abdomen you feel a pulsing mass in the area of her umbilicus. Your partner has placed a nonrebreathing oxygen mask on the patient at 12 L/min and obtained vital signs.

1. What can you determine about the patient's medical history based on the acronyms in the record?

See the tables at the end of this chapter for more common word roots. Combining forms are discussed later in the chapter.

Prefixes

A prefix is the part of a term that appears at the beginning of a word. It generally describes location and intensity. Prefixes are frequently found in general language (ie, *auto*pilot, *sub*marine, *tri*cycle), as well as in medical and scientific terminology. Not all medical terms have prefixes.

A prefix gives the word root a specific meaning. When a medical word contains a prefix, the meaning of the word is altered. For example, *pnea* is the word root for breathing. Adding the prefix *a-* (without), *brady-* (slow), or *tachy-* (rapid) to a word creates three very different terms:

- a/pnea – without breathing
- brady/pnea – slow breathing
- tachy/pnea – rapid breathing

Some common prefixes are shown in Table 5-2.

By learning to recognize a few of the more commonly used medical prefixes, you can figure out the meaning of terms that may not be immediately familiar to you. See the tables at the end of the chapter for more common prefixes.

Suffixes

Suffixes are placed at the end of words and usually indicate a procedure, condition, disease, or part of speech.

A commonly used suffix is *-itis*, which means "inflammation." When this suffix is paired with the word root *arthro-*, meaning joint, the resulting word is arthritis, an inflammation of the joints.

Some common suffixes are listed in Table 5-3. See the tables at the end of this chapter for more common suffixes.

Table 5-1 Common Word Roots in EMS

Root	Meaning	Example	Definition of Example
cardi	heart	tachycardia	fast heart rate
hepat	liver	hepatomegaly	enlargement of the liver
nephr	kidney	nephropathy	disease of the kidney
neur	nerves	neurologist	physician who specializes in diseases of the nervous system
psych	mind	psychology	study of the mind
thorac	chest	thoracic	pertaining to the chest or thorax

Table 5-2 Common Prefixes in EMS

Prefix	Meaning	Example	Definition of Example
hyper-	over, excessive, high	hyperventilation	fast ventilations
hypo-	under, below normal	hypoperfusion	below normal blood flow to vital organs
tachy-	rapid, fast	tachycardia	fast heart rate
brady-	slow	bradypnea	slow breathing
pre-	before	prenatal	occurring before birth
post-	after, behind	postsurgical	occurring after surgery

Table 5-3 Common Suffixes in EMS

Suffix	Meaning	Example	Definition of Example
-al	pertaining to	syncopal	pertaining to syncope
-algia	pertaining to pain	arthralgia	joint pain
-ectomy	surgical removal of	appendectomy	surgical removal of the appendix
-ic	pertaining to	diaphoretic	pertaining to diaphoresis
-itis	inflammation	epiglottitis	inflammation of the epiglottis
-logy	study of	cardiology	the study of the heart
-logist	specialist	pulmonologist	specialist in diseases of the lung
-megaly	enlargement	cardiomegaly	enlargement of the heart
-meter	measuring instrument	sphygmomanometer	instrument to measure blood pressure
-oma	tumor (usually referring to cancer)	lymphoma	cancer of the lymphatic system
-pathy	disease	nephropathy	diseases of the kidneys

Combining Vowels

A combining vowel is the part of a term that connects a word root to a suffix or other word root. In most cases, the combining vowel is an *o*; however, it may also be an *i* or an *e*. A combining vowel is usually used when joining a suffix that begins with a consonant or when joining another word root. For example, take the term *gastroenterology*, the study of diseases of the stomach and small intestines:

- gastr/o + enter/o + logy
- stomach + small intestines + the study of

In this term, *gastr* and *enter* are both word roots, *-logy* is the suffix, and *o* is the combining vowel (used twice). The combining vowel helps ease the pronunciation of the term. Without the vowel, the term would be rather difficult to pronounce—*gastrenterlogy*.

Refer to the tables at the end of this chapter for combining vowels associated with common word roots. A combining vowel shown with the word root is called a combining form. Here are a few of the most common combining forms you will see:

- cardi/o (heart)
- gastr/o (stomach)
- hepat/o (liver)
- arthr/o (joint)
- oste/o (bone)
- pulmon/o (lungs)

YOU are the Provider — PART 2

ALS assistance is 15 minutes away, so after administering oxygen you prepare the patient for transport. En route to the hospital you call with a report:

"EMT 123 to Regional Medical Center. We are en route to your facility with a 79-year-old woman reporting abdominal pain that started 2 hours ago. History of abdominal aortic aneurysm, hypertension, cerebrovascular accident in 2009; acute myocardial infarction in 2010, gastroesophageal reflux disease, and type 1 diabetes. Patient's skin is pale and wet and there is a pulsing mass in the periumbilical area. BP is 80/50 mm Hg; pulse 128 BPM; respirations 24 per minute. Patient is on NRB mask at 12 L/min; Our ETA is 10 minutes."

2. How did the use of acronyms assist in delivering your report to the hospital?
3. What other acronyms or abbreviations could have been used in this report?

Word Building Rules

When building or taking apart a medical term, it is helpful to understand some basic rules. The following summarizes the rules covered thus far:

1. The prefix is always at the beginning of a term; however, not all terms will have a prefix.
2. The suffix is always at the end of the term.
3. When a suffix begins with a consonant, a combining vowel is used between the word root and suffix to make pronunciation easier.
4. When a term has more than one word root, a combining vowel must be placed between the two word roots, even if the second root begins with a vowel.

Plural Endings

To change a term from a singular to plural form, certain rules apply. In some cases, you simply add a *s* to the word (lung becomes lungs). However, for some medical terms, making the plural form is more complicated. Rules you may encounter when converting terms from singular to plural are:

1. Singular words that end in *a* change to *ae* when plural.
   - Example: vertebra becomes vertebrae.
2. Singular words that end in *is* change to *es* when plural.
   - Example: diagnosis becomes diagnoses.
3. Singular words that end in *ex* or *ix* change to *ices*.
   - Example: apex becomes apices.
4. Singular words that end in *on* or *um* change to *a*.
   - Examples: ganglion becomes ganglia, ovum becomes ova.
5. Singular words that end in *us* change to *i*
   - Example: bronchus becomes bronchi.

Special Word Parts

As already described, prefixes appear at the beginning of a word, before the word root. Prefixes used to indicate numbers, colors, and directions are described as follows. Look at the prefixes, meanings, and examples. Can you think of other terms using the same prefix with another root? Do you see how it changes the meaning?

Numbers

Several prefixes are used to indicate if a term involves a number such as half, one or two or more parts or sides. Common prefixes for numbers are listed in Table 5-4.

Colors

Several word roots are used to describe color. The most common include those listed in Table 5-5.

Positions and Directions

Prefixes can also be used to describe a position, direction, or location. The most common include those listed in Table 5-6.

Table 5-4 Common Number Prefixes

Prefix	Meaning	Example	Definition of Example
uni-	one	unilateral	one side
dipl-	two; double	diplopia	double vision
null-	none	nullipara	never given birth
primi-	first	primigravida	pregnant for the first time
multi-	many	multiparous	giving birth to more than one offspring at a time
bi-	two	bilateral	pertaining to both sides
tri-	three	trigeminy	irregular heartbeat of two normal beats followed by one premature beat
quad-	four	quadriplegic	paralysis of all four extremities
tetra-	four	tetralogy of Fallot	a congenital defect involving four anatomic abnormalities of the heart
quint-	five	quintipara	five pregnancies resulting in five live births
sexti-	six	sextuplets	six offspring of the same pregnancy
septi-	seven	septuplets	seven offspring of the same pregnancy
oct-	eight	octigravida	pregnant for the eighth time
nona-	nine	nonan	occurring on the ninth day
deca-	ten	decagram	measurement of ten grams
semi-	half; partial	semiconscious	partially conscious
hemi-	half; one sided	hemiplegia	paralysis on one side of the body
ambi-	both	ambidextrous	able to use either hand equally well
pan-	all, entire	pandemic	an epidemic over a wide area

Table 5-5 Word Roots That Describe Color

Root	Meaning	Example	Definition of Example
cyan/o	blue	cyanosis	bluish discoloration of the skin
leuk/o	white	leukocyte	white blood cells that fight infection
erythr/o	red	erythrocyte	red blood cells that contain hemoglobin to carry oxygen
cirrh/o	yellow-orange	cirrhosis	inflammation of the liver causing yellow-orange pigmentation of the liver
melan/o	black	melena	black, tarry stool typically caused by upper GI bleeding
poli/o	gray	poliomyelitis	an acute viral disease that attacks the motor neurons of the central nervous system (brain and spinal cord)
alb	white	albino	a person lacking skin pigmentation (very white hair, very pale skin, and nonpigmented iris)
chlor/o	green	chlorophyll	green pigment in leaves used in photosynthesis

Table 5-6 Prefixes That Describe Position

Prefix	Meaning	Example	Definition of Example
To/From			
ab-	away from	abduction	away from the point of reference
ad-	to, toward	adduction	toward the center
Above/Below/Around			
de-	down from, away	decay	to waste away
circum-	around, about	circumferential burn	a burn around an entire area (arm, chest, abdomen, etc)
peri-	around	pericardium	the sac around the heart
trans-	across, through, beyond	transvaginal	across or through the vagina
epi-	above, upon, on	epigastric	above or over the stomach
supra-	above, over	suprasternal notch	top of the sternum
retro-	behind	retroperitoneal	the area behind the peritoneum
sub-	under, beneath	subcutaneous	beneath the skin
infra-	below, under	infraclavicular	below the clavicle
para-	near, beside, beyond, apart from	parasternal	beside the sternum
contra-	against, opposite	contraindicated	something that is not indicated
Outside/Inside			
ecto-	out, outside	ectopic pregnancy	pregnancy where the embryo attaches outside of the uterus
endo-	within	endoscopy	examining inside someone's body (with an endoscope)
extra-	outside, in addition	extraneous	outside the organism and not belonging to it
intra-	inside, within	intrauterine	within the uterus
ipsi-	same	ipsilateral	on or affecting the same side

Common Direction, Movement, and Position Terms

Directional Terms

When discussing where an injury is located or how pain radiates in the body, you need to know the correct directional terms Figure 5-1. Table 5-7 provides the basic terms used in medicine. Notice how directional terms are paired as "opposites."

Right and Left

The terms *right* and *left* refer to the patient's right and left sides, not to your right and left sides.

Superior and Inferior

The **superior** part of the body, or any body part, is the portion nearer to the head from a specific reference point. The part nearer to the feet is the **inferior** portion. These terms are also used to describe the relationship of one structure to another. For example, the knee is superior to the foot and inferior to the pelvis.

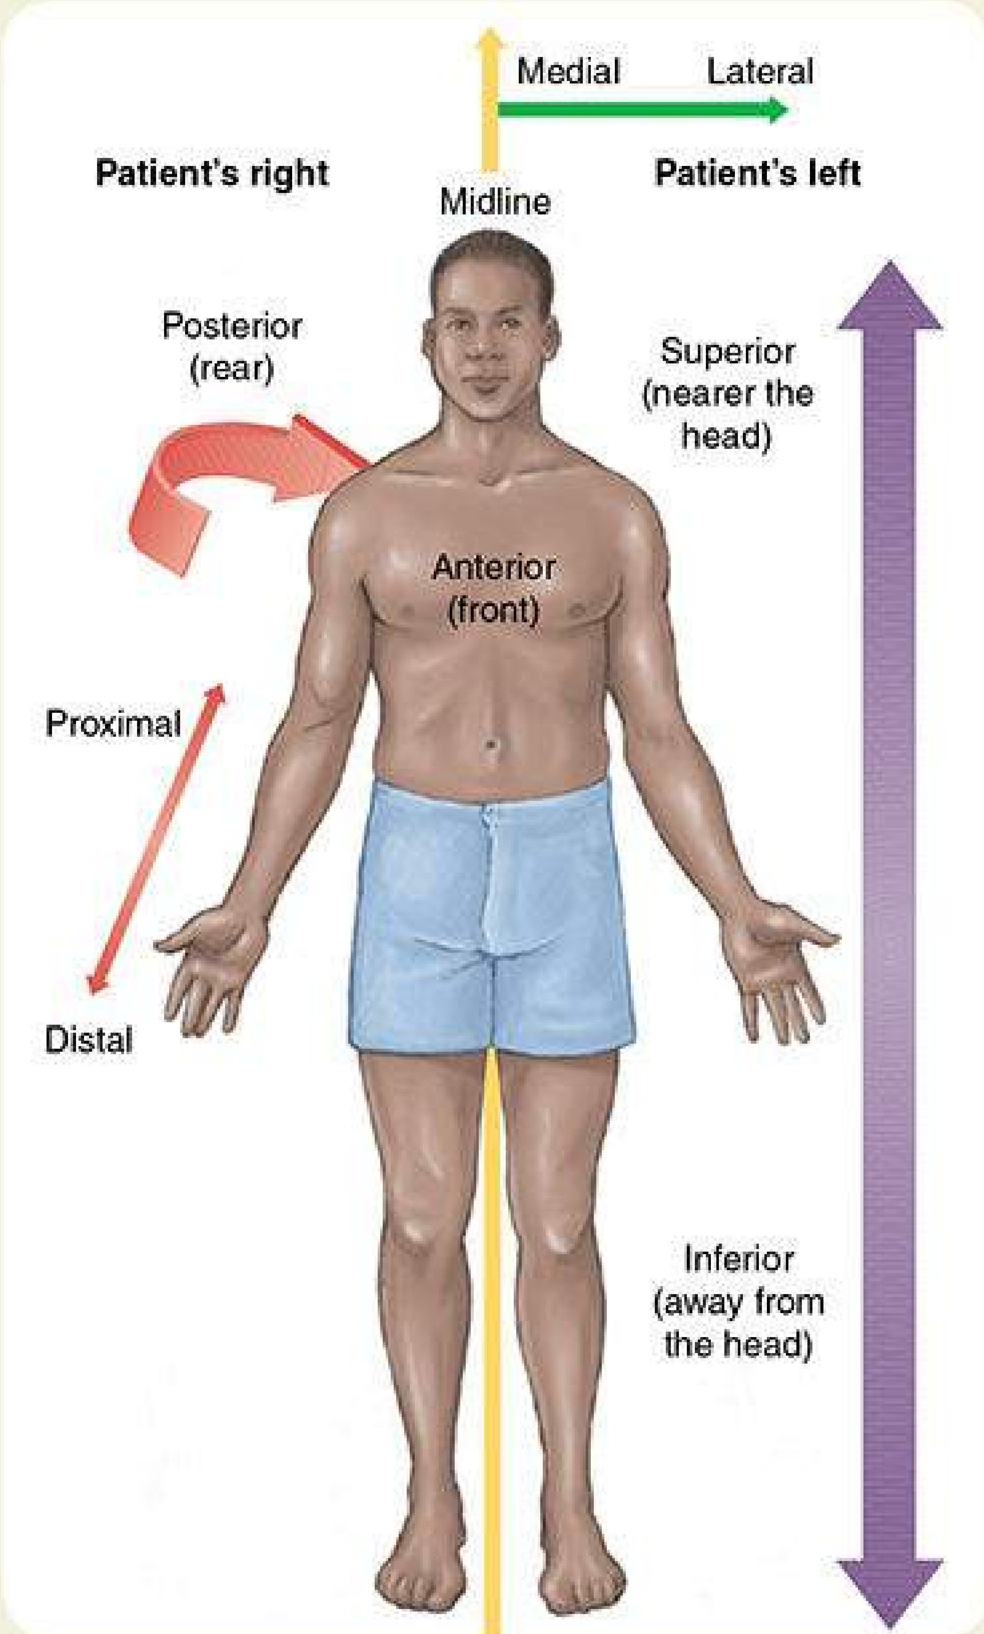


Figure 5-1 Directional terms indicate distance and direction from the midline.

Lateral and Medial

Parts of the body that lie farther from the midline are called **lateral** (outer) structures. The parts that lie closer to the midline are called **medial** (inner) structures. For example, the thigh has medial (inner) and lateral (outer) surfaces. In general terms, *lateral* means side. For example, lying on the left side is called left lateral recumbent. Something that occurs on both sides is referred to as *bilateral*. When describing the location of an injury, the terms *medial* and *lateral* help pinpoint an exact location. For example, the patient has a 2-inch (5 cm) laceration on the medial aspect of the thigh (toward the inside).

Table 5-7 Directional Terms

Common Term	Directional Term	Definition
Front and back	Anterior (ventral) Posterior (dorsal)	The front surface of the body The back surface of the body
Right and left	Right Left	The patient's right The patient's left
Top and bottom	Superior Inferior	Closest to the head Closest to the feet
Closest and farthest	Proximal Distal	Closest to the point of attachment Farthest from the point of attachment
Middle and side	Medial Lateral	Closest to the midline Farthest from the midline
In and out	Superficial Deep	Closest to the surface of the skin Farthest from the surface of the skin

Proximal and Distal

The terms *proximal* and *distal* are used to describe the relationship of any two structures on an extremity. **Proximal** describes structures that are closer to the trunk. **Distal** describes structures that are farther from the trunk or nearer to the free end of the extremity. For example, the elbow is distal to the shoulder and proximal to the wrist and hand.

Superficial and Deep

Superficial means closer to or on the skin. **Deep** means farther inside the body or tissue and away from the skin. For example, a superficial burn involves only the top layer of skin, similar to a sunburn. An abrasion is a superficial wound, similar to "scraping your knee," whereas a deep laceration involves a cut deeper into the tissue such as with a knife.

Ventral and Dorsal

Ventral refers to the belly side of the body, or the anterior surface of the body. **Dorsal** refers to the spinal side of the body, or the posterior surface of the body, including the back of the hand. These terms are used less frequently than the terms **anterior** (the front surface of the body) and **posterior** (the back surface of the body). An easy way to remember *dorsal* is to think of the dorsal fin on a dolphin, which is on its back (posterior) side.

Palmar and Plantar

The front region of the hand is referred to as the palm or **palmar** surface. The bottom of the foot is referred to as the **plantar** surface.

Apex

The **apex (plural apices)** is the tip of a structure. For example, the apex of the heart is the bottom (inferior portion) of the ventricles in the left side of the chest.

Movement Terms

The following terms relate to movement Figure 5-2:

- **Flexion** is the bending of a joint.
- **Extension** is the straightening of a joint.
- **Adduction** is motion toward the midline.
- **Abduction** is motion away from the midline.

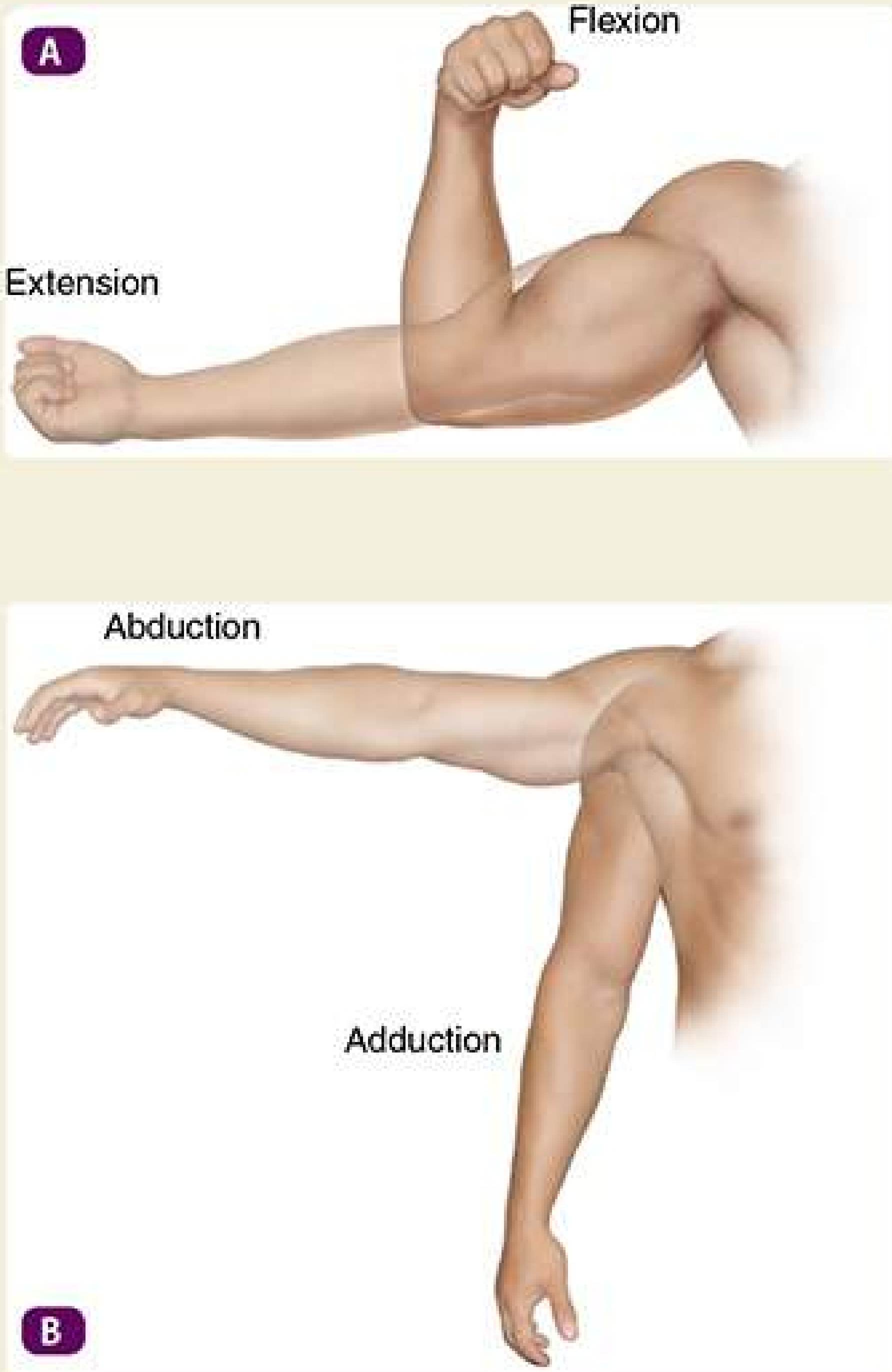

Figure 5-2 **A.** Flexion and extension at the elbow. **B.** Adduction and abduction at the shoulder.

Words of Wisdom

Using the correct anatomic terminology in your patient care report improves patient care by making the report more useful to hospital personnel and enhances your professional image as an EMT.

▶ Other Directional Terms

Many structures of the body occur bilaterally. A body part that appears on both sides of the midline is **bilateral**. For example, the eyes, ears, hands, and feet are bilateral structures, meaning there is one on each side of the midline. This is also true for structures inside the body, such as the lungs and kidneys. Something that appears on only one side of the body is said to occur *unilaterally*. For example, unilateral chest expansion means that only one lung is expanding with inhalation (such as with a pneumothorax). Pain that occurs on only one side of the body could be called unilateral pain.

As part of the assessment process, you will palpate the abdomen and report findings. Therefore, it is important that you are able to describe the exact location of areas of the abdomen. The way to describe the sections of the abdominal cavity is by **quadrants**. Imagine two lines intersecting at the umbilicus, dividing the abdomen into four equal areas **Figure 5-3**. These are referred to as the right upper quadrant, left upper quadrant, right lower quadrant, and left lower quadrant. Remember that here, too, right and left refer to the patient's right and left, not yours.

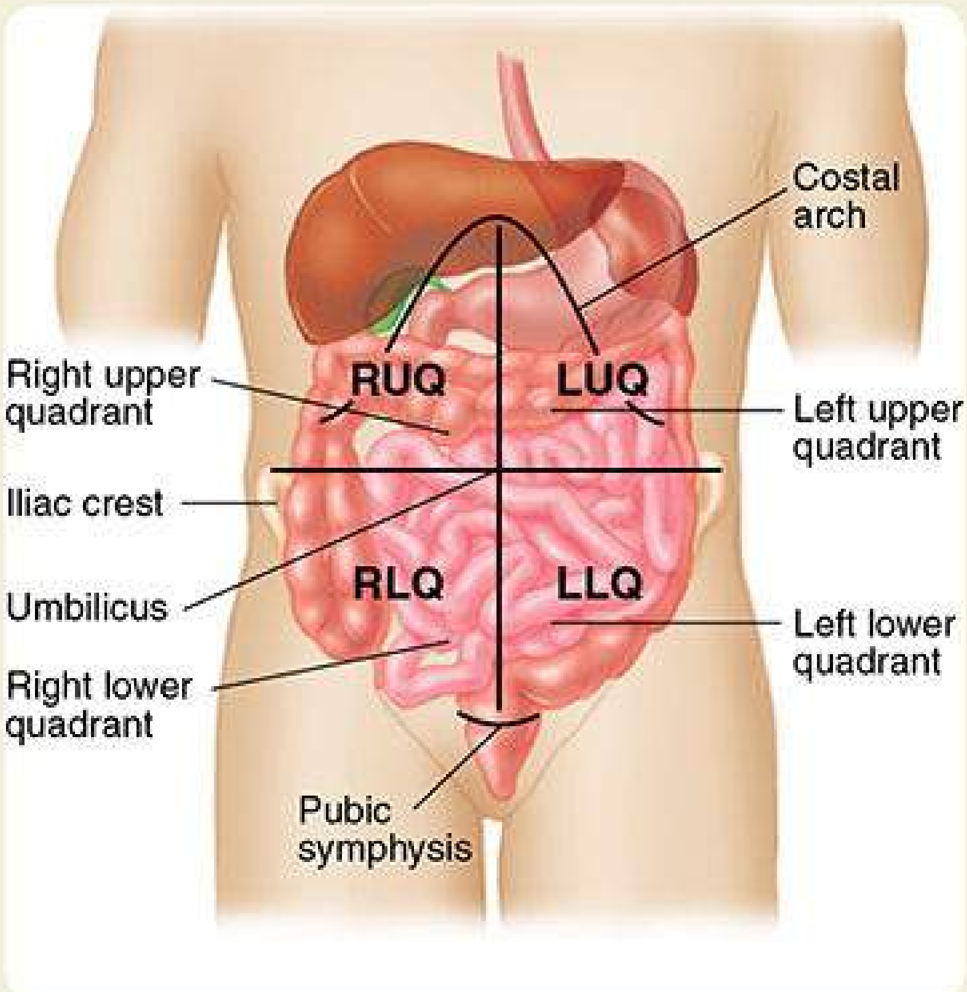

Figure 5-3 The abdomen is divided into four quadrants. RUQ indicates right upper quadrant; LUQ, left upper quadrant; RLQ, right lower quadrant; and LLQ, left lower quadrant.

It is important to learn all of these terms and concepts so you can describe the location of any injury or assessment findings. When you use these terms properly, any other medical personnel who care for the patient will know immediately where to look and what to expect.

Anatomic Positions

There are many terms used to describe the position of the patient upon your arrival or during transport to the emergency department **Figure 5-4**.

Prone and Supine

These terms describe the position of a body. The body is in the **prone** position when lying face down; the body is in the **supine** position when lying faceup.

Fowler Position

The **Fowler position** was named after a US surgeon, George R. Fowler, MD, at the end of the 19th century. Dr. Fowler placed his patients in a semireclining position with the head elevated to help them breathe easier and to control the airway. A patient who is sitting upright is therefore said to be in the Fowler position. Some refer to semi-Fowler position as sitting with the back of the stretcher at a 45-degree angle and high-Fowler position as sitting at a 90-degree angle.

Figure 5-4 **A.** Fowler position. **B.** Supine. **C.** Prone. **D.** Recovery position.

Breaking Terms Apart

Just as you use parts of terms to build new words, you can use knowledge of the meaning of parts to decipher the meaning of a term. When trying to define a term, begin with the suffix and work backward. If the term also contains a prefix, define the suffix, then the prefix, and then the word root. Here are some examples:

- nephropathy
  nephr/o/pathy
  -pathy (suffix meaning "disease")
  o (combining form)
  nephr (word root meaning "kidney")
  nephropathy = disease of the kidney
- dysuria
  dys/ur/ia
  -ia (suffix meaning "condition of")
  dys- (prefix meaning "difficult, painful, or abnormal")
  ur (word root meaning "urine")
  dysuria = painful urination (pain when urinating) or difficulty urinating
- hyperemesis
  hyper/emesis
  hyper- (prefix meaning "excessive")
  emesis (word root meaning "vomiting")
  hyperemesis = excessive vomiting
- analgesic
  an/alges/ic
  -ic (suffix meaning "pertaining to")
  an- (prefix meaning "without" or "absence of")
  alges (word root meaning "pain")
  analgesic = pertaining to no pain

Abbreviations, Acronyms, and Symbols

Medical abbreviations, acronyms, and symbols are a type of shorthand used to communicate in the medical world. They came about for the same reason that people send text messages and tweets using text shorthand—you can communicate faster using this method. It is important, however, not to trade speed for accuracy. Use only commonly understood acronyms and abbreviations to minimize misinterpretations and errors. The Joint Commission and the Institute for Safe Medication Practices are considered two authorities on abbreviations; both organizations provide do-not-use lists identifying abbreviations that lead to errors.

There is a slight difference in meaning between abbreviations and acronyms. When you shorten a word using an abbreviation, you pronounce each letter of the abbreviation separately and distinctly. For example, emergency medical technician is abbreviated to EMT (you say it E–M–T). When you use an acronym, you are shortening several words, usually using the first letter of each word to make the acronym. Acronyms are pronounced as their own word (for example, SAMPLE history is pronounced like the word *sample*), by reading the letters one by one (for example, EMS is pronounced "E-M-S"), or by a combination of the two (for example, DCAP-BTLS is pronounced "D-cap-B-T-L-S," and the acronym for Urban Search and Rescue (USAR) is pronounced ū-săr.

Misunderstanding and errors will occur if everyone involved in the emergency care of a patient does not understand the meaning of abbreviations or acronyms. For this reason, some agencies limit the use of abbreviations.

YOU are the Provider — PART 3

Within 10 minutes of arriving at the hospital, your patient is in the operating room having her ruptured abdominal aortic aneurysm repaired. You sit down to carefully document your care, and start with: "EMT123 arrived to find a 79 yo female, A&O, supine in hospital bed. CC: Periumbilical abdominal pain. Skin is pale and wet. On palpation, noted a pulsing midline abdominal mass in the epigastric region approximately 2 inches superior to the umbilicus..."

4. What do the abbreviations or acronyms in this portion of the report mean?
5. What other abbreviations, acronyms, or symbols could you have used in this portion of the report?

Abbreviations

Abbreviations take the place of words to shorten notes or documentation. When using abbreviations on patient care reports, remember to use only standard, accepted abbreviations to avoid confusion and errors. See the tables at the end of this chapter for a list of commonly used abbreviations. This list is intended to help you decipher documents written by other health care professionals. Before using any abbreviations in your own reports, be familiar with accepted use of abbreviations in your local jurisdiction or service area.

Words of Wisdom

There are many medical terms, acronyms, abbreviations, and symbols used by medical professionals. The material in this chapter provides only a small sample. You may find it helpful to invest in a phone app or pocket reference guide to assist you when you encounter unfamiliar terms.

Symbols

Like abbreviations, symbols are sometimes used as a shortcut in communication and documentation. As with abbreviations, it is important to use only the symbols that are widely understood and accepted Table 5-8.

Master Tables

Table 5-9 through Table 5-12 provide a thorough reference list of common word roots, combining forms, prefixes, suffixes, and abbreviations.

Table 5-8 Common Symbols

1°	first, first degree, primary
2°	secondary, second degree
↑	increase(d)
↓	decrease(d)
Ⓡ	right
Ⓛ	left
μ	micro
α	alpha
β	beta
~	approximately
N	normal
×2	times two
/	per
≠	not equal
>	greater than
<	less than
?	questionable, possible
Δ	change
—	negative
♀	female
♂	male

Note: The forward slash mark ("/") is included for explanatory purposes, but its use is not recommended by the Institute for Safe Medication Practices.

YOU are the Provider — PART 4

Knowing that the abbreviations related to the patient's history point to severe cardiovascular disease helps direct the assessment and subsequent field impression to abdominal aortic aneurysm. The ability to call in the report using common abbreviations helps save precious time so you can return to the care of your patient. Using medical terminology correctly to document the call increases your professionalism as an EMT.

Table 5-9 Common Word Roots and Combining Forms

Root	Meaning	Root	Meaning	Root	Meaning
abdomin/o	abdomen	bronch/i	airway, bronchus	corne/o	cornea
acou/o; acoust/o	hear	bucc/o	cheek	cost/o	rib
aden/o	gland	burs/o	pouch or sac	crani/o	cranium, skull
adip/o	fat	calc/i	calcium	crin/o	to secrete
alb/o	white	carcin/o	cancer	cubitus	elbow
alges/o	pain	cardi/o	heart	cutane/o	skin
andr/o	man, male	carp/o	wrist	cyan/o	blue
angi/o	vessel	cartil/o	cartilage, gristle	cycl/o	circle or cycle
angin/o	blood vessel	caud/o	tail	cyst/o	bladder
ankyl/o	fused, stiff	cec/o	blind intestine, cecum	cyt/o	cell
anter/o	front	cel/o	hernia, protrusion	derm(at)/o	skin
aort/o	aorta	cent/e	to puncture (a body cavity)	digit	finger or toe
append/o	appendix	cent/i	a fraction in the metric system; one hundredth or 100	dipl/o	two, double
arteri/o	artery	cephal/o	head	dips/o	thirst
arthr/o	joint	cerebr/o	brain, cerebrum	disk/o	flat shape, intervertebral disk
asthen/o	weak	cervic/o	neck	dist/o	distant, away
atel/o	incomplete	chol/e	bile	diverticul/o	diverticulum, a small blind pouch
ather/o	fat	chondr/o	cartilage	dors/o	back
atri/o	atrium	chrom/o	color	duct/o	lead, move
audi/o	to hear	chron/o	time	duoden/o	duodenum
aur/o	ear	cirrh/o	yellow-orange	ech/o	to bounce, sound
aut/o	self	cleid/o	clavicle	ede	swelling
bacteri/o	bacteria	col/o	colon	elast/o	change shape
bi	life; also two	colp/o	vagina	electr/o	electricity
bil/i	bile	condyl/o	knuckle of a joint	embol/o	a plug
blast/o	germ, bud, developing cell	cor/o	pupil	embry/o	embryo
blephar/o	eyelid			emesis	vomit
brachi/o	arm				

Root	Meaning
emmetr/o	according to measure
enchephal/o	brain
enter/o	small intestine
episi/o	vulva
erythr/o	red
esthesi	sensation or perception
febr	fever
flex	bend
foramen	opening
fract	break
gastr/o	stomach
gest	carry, produce, congestion
glyc/o	sugar, sweet
gno	know
gyn/o	woman, female
hem(at)/o	blood
hepat/o	liver
heter/o	other, different
hom/o	the same
hydr/o	water
idi/o	person, self
lact/o	milk
leuk/o	white
lingu/o	tongue
mal/o	abnormal, bad
medi/o	middle
melan/o	black, dark
men/o	month, menstruation

Root	Meaning
mening/o	membrane, usually refers to the meninges
myel/o	marrow or spinal cord
my/o	muscle
nephr/o	kidney
neur/o	nerve
ocul/o	eye
ophthalm/o	eye
oste/o	bone
ot/o	ear
ov/o	egg
palpate	to examine by touch
path/o	disease
ped/o	child or foot
percuss	to examine by striking
phag/o	eat
pharyng/o	throat
phot/o	light
pleur/o	rib, side
pneum(at)/o	lungs, air
pneumo(n)/o	lung
pod(i)	foot
pseud/o	false
psych/o	mind
pto	fall
ptyal/o	saliva
pulmon/o	lungs
pur, py	pus
pyr/o	fire, heat

Root	Meaning
quadr/o; quar	four
ren/o	kidney
rhin/o	nose
sangui(n)o	blood
scler/o	hard
sebum	a fatty secretion of the sebaceous glands
sect/o	cut
sept/o	wall, divider; also seven
serum	the clear portion of body fluids, including blood
sinus	cavity, channel, or hollow space
som(a)	body
spir/o	coil, to breathe
stern(o)-	sternum (breastbone)
stomat/o	mouth
thorac/o	chest
tom/o	cut
toxic/o	poisonous
trich/o	hair
ur/o	urine
uter/o	uterus, womb
varic/o	dilated vein
vas/o	blood vessel
viscer/o	internal organs
xen/o	foreign (material)
xer/o	dry

Table 5-10 Common Prefixes

Prefix	Meaning	Prefix	Meaning	Prefix	Meaning
a-	without, lack of	hemi-	half	pan-	all, entire
ab-	away from	hyper-	over, excessive, high	para-	near, beside, beyond, apart from
ad-	to, toward	hypo-	under, below normal	per-	through
an-	without, lack of	in-	in, into, not, without	peri-	around
ana-	up, back, again	infra-	below, under	poly-	many
ante-	before, forward	inter-	between	post-	after, behind
anti-	against, opposed to	intra-	inside, within	pre-	before
auto-	self	ipsi-	same	primi-	first
bi-	two	iso-	equal	pro-	before, in front of
brady-	slow	macro-	large	quadr(i)-	four
circum-	around, about	mal-	bad or abnormal	re-	back
contra-	against, opposite	mega-	large	retro-	backward, behind
de-	down from, away	meta-	after, change	semi-	half, partial
di-	twice, double	micro-	small	sub-	under, below
dia-	through, completely	mono-	one, single	super-	above, excessive, or more than normal
dys-	difficult, painful, abnormal	multi-	many	supra-	above, upper
ect(o)-	out, outside	neo-	new	sym-	together, joined
end(o)-	within	noct-	night	syn-	together, joined
epi-	upon, over, above	nulli-	none	tachy-	rapid, fast
eu-	easy, good, normal	olig(o)-	little, deficient	tetra-	four
ex(o)-	outside, away from	ortho-	straight or normal	trans-	across, through, beyond
extra-	outside, in addition			tri-	three
				uni-	one

Table 5-11 Common Suffixes

Suffix	Meaning	Suffix	Meaning	Suffix	Meaning
-al	pertaining to	-ia	condition of	-pnea	pertaining to breathing
-algia	pertaining to pain	-ic	pertaining to	-ptosis	drooping
-asthenia	weakness	-itis	inflammation	-rrhage	abnormal or excessive flow or discharge
-blast	immature cell	-lysis	decline, disintegration, or destruction	-rrhagia	abnormal or excessive flow or discharge
-cele	pertaining to a tumor or swelling	-megaly	enlargement of	-rrhaphy	suture of; repair of
-centesis	pertaining to puncturing an organ or body cavity, often to drain excess fluid or obtain a sample for analysis	-meter	measuring instrument	-rrhea	flow or discharge
-cyte	cell	-ology	science or study of	-scope	instrument for examination
-ectomy	surgical removal of	-oma	tumor	-scopy	examination with an instrument
-emesis	vomiting	-osis	pertaining to a disease process (*see also* -sis)	-sis	a process, action, or condition (*see also* -osis)
-emia	pertaining to the presence of a substance in the blood	-ostomy	surgical creation of an opening	-stasis	slowing or stopping of the normal flow of a fluid, such as blood
-esthesia	pertaining to sensation or perception	-pathy	disease or a system for treating disease	-taxis	order, arrangement of
-genic	causing	-phagia	pertaining to eating or swallowing	-trophic	pertaining to nutrition
-gram	record	-phasia	pertaining to speech		
-graph	a record or the instrument used to create the record	-phobia	pertaining to an irrational fear		
		-plasty	plastic surgery		
		-plegia	paralysis		

Table 5-12 Common Abbreviations*

Abbreviation	Meaning	Abbreviation	Meaning	Abbreviation	Meaning
A&P	anatomy and physiology	abd	abdomen	ACLS	advanced cardiac life support
ā	before	ABC, ABCs	airway, breathing, circulation	ADL, ADLs	activities of daily living
AAA	abdominal aortic aneurysm	ac	before meals		

Abbreviation	Meaning
ad lib	as desired
AED	automated external defibrillator
AF, A-fib	atrial fibrillation
AICD	automated implantable cardioverter defibrillator
AIDS	acquired immuno-deficiency syndrome
AK	above the knee
AKA	above the knee amputation
AMA	against medical advice
amb	ambulatory
AMI	acute myocardial infarction
ant	anterior
AO × 4, A/O × 4	alert and oriented to person, place, time, and self
AP	anteropo-sterior, front-to-back, action potential, angina pectoris, anterior pituitary, arterial pressure
ARDS	adult respiratory distress syndrome
ASA	aspirin (acetylsalicylic acid)

Abbreviation	Meaning
ASHD	arteriosclerotic or atherosclerotic heart disease
BGL	blood glucose level
bid/b.i.d./BID	twice daily
BKA	below the knee amputation
BM	bowel movement
BP, B/P	blood pressure
BPM	beats per minute
BS	blood sugar, breath sounds, bowel sounds, bachelor of science (degree)
BSA	body surface area
BVM	bag-valve mask
bx	biopsy
c̄	with
°C	degrees Celsius (centigrade)
CA	cancer, cardiac arrest, chronologic age, coronary artery, cold agglutinin
CABG	coronary artery bypass graft
CAD	coronary artery disease
CBC	complete blood cell count
CC or C/C	chief complaint
CCU	coronary care unit

Abbreviation	Meaning
C diff	*Clostridium difficile*
CHF	congestive heart failure
cm	centimeter
CNS	central nervous system
c/o	complaining of
CO	cardiac output, carbon monoxide
CO_2	carbon dioxide
COLD	chronic obstructive lung disease
COPD	chronic obstructive pulmonary disease
CP	chest pain, chemically pure, cerebral palsy
CPR	cardiopul-monary resuscitation
CRNA	certified registered nurse anesthetist
CRT	capillary refill time, cathode ray tube
CSF	cerebrospinal fluid
CVA	cerebrovascular accident
DM	diabetes mellitus
DNR	do not resuscitate
DOA	dead on arrival
DOE	dyspnea on exertion
DON	director of nursing

Abbreviation	Meaning
DPT	diphtheria and tetanus toxoids and pertussis vaccine, Doctor of Physical Therapy
DSD	dry sterile dressing
DtaP	diphtheria and tetanus toxoids and acellular pertussis vaccine
DTP	diphtheria and tetanus toxoids and pertussis vaccine
DTs	delirium tremens
DVT	deep venous thrombosis
Dx	diagnosis
ECG	electro-cardiogram
ED	emergency department, erectile dysfunction
EDC	estimated date of confinement
EEG	electroen-cephalogram
EKG	electro-cardiogram
ENT	ears, nose, and throat
EOC	Emergency Operations Center
ER	emergency room
ET, ETT	endotracheal tube, endotracheal
ETA	estimated time of arrival
ET_{CO_2}	end-tidal carbon dioxide
ETOH	ethyl alcohol
°F	degrees Fahrenheit
F_{IO_2}	fraction of inspired oxygen
FBS	fasting blood sugar
Fe	iron
FHR	fetal heart rate
FHx	family history
fl or fld	fluid
fx	fracture
GB	gallbladder
GCS	Glasgow Coma Scale
GERD	gastroesophageal reflux disease
GI	gastrointestinal
GSW	gunshot wound
gtt	drop(s)
GTT	glucose tolerance test
GU	genitourinary
gyn	gynecology
h	hour
H&P	history and physical
HA, H/A	headache
Hb, Hgb	hemoglobin
HBV	hepatitis B virus
Hct	hematocrit
HCV	hepatitis C virus
HH	hiatal hernia
HIV	human immuno-deficiency virus
H_2O	water
HPI	history of present illness
HR	heart rate
hr	hour
HTN	hypertension
Hx	history
I&O	intake and output
ICP	intracranial pressure
ICS	incident command system, intercostal space
ICU	intensive care unit
IDDM	insulin-dependent diabetes mellitus
IM	intramuscular
IMS	incident management system
IO	intraosseous
IPPB	intermittent positive-pressure breathing
IUD	intrauterine (contraceptive) device
IV	intravenous
JVD	jugular venous distention
kg	kilogram
LE	lower extremity, left eye, lupus erythematosus
LLL	left lower lobe of the lung

Abbreviation	Meaning
LLQ	left lower quadrant of the abdomen
L/M, LPM	liters per minute
LMP	last menstrual period
LOC	level of consciousness, loss of consciousness
LUL	left upper lobe of the lung
LUQ	left upper quadrant of the abdomen
LVAD	left ventricular assist device
MAE	moves all extremities
MAEW	moves all extremities well
mg	milligram
MI	myocardial infarction
MICU	mobile intensive care unit; medical intensive care unit
min	minute
mL	milliliter
mm	millimeter
mm Hg	millimeters of mercury
MOI	mechanism of injury
MRI	magnetic resonance imaging
MRSA	methicillin-resistant *Staphylococcus aureus*
MVA	motor vehicle accident
MVC	motor vehicle crash

Abbreviation	Meaning
MVP	mitral valve prolapse
NA, N/A	not applicable
NAD	no apparent distress, no appreciable disease
NC	nasal cannula
NG	nasogastric
NICU	neonatal intensive care unit
NIDDM	non–insulin-dependent diabetes mellitus
NKA	no known allergies
NKDA	no known drug allergies
NPA	naso-pharyngeal airway
NPO	nil per os (nothing by mouth)
NRB, NRBM	nonre-breathing mask
NS	normal saline
NSR	normal sinus rhythm
NTG	nitroglycerin
N/V	nausea and vomiting
N/V/D	nausea, vomiting, and diarrhea
O_2	oxygen
OB	obstetrics
OBS	organic brain syndrome
OD	overdose, right eye, optical density, outside diameter, doctor of optometry

Abbreviation	Meaning
OP	outpatient
OPA	oropharyngeal airway
OR	operating room
OS	left eye
OU	both eyes
oz	ounce
$\bar{p}$	after
pc	after meals
Pco_2	partial pressure of carbon dioxide
PDR	*Physicians' Desk Reference*
PE	pulmonary embolism, physical examination
PEARL or PERL	pupils equal and reactive to light
PEARLA	pupils equal and reactive to light and accommodation
PEARRL	pupils equal and round, regular in size, react to light
ped or peds	pediatric
PEEP	positive end-expiratory pressure
PERRL	pupils equal, round, and reactive to light
PID	pelvic inflammatory disease
PMH	past medical history
PND	paroxysmal nocturnal dyspnea
po	per os (by mouth)

Abbreviation	Meaning
PO	postoperative, post-op
PRN	pro re nata (as needed)
psi	pounds per square inch
PSVT	paroxysmal supraventricular tachycardia
pt	patient
PT	physical therapy, prothrombin time
PTA	prior to admission, plasma thromboplastin antecedent
PTT	partial thromboplastin time
PVC	premature ventricular contraction, polyvinyl chloride
PVD	peripheral vascular disease
q	every
RA	rheumatoid arthritis, right atrium
RAD	reactive airway disease, right axis deviation
RBC	red blood cell
Rh	Rhesus blood factor, rhodium
RLL	right lower lobe of the lung
RLQ	right lower quadrant of the abdomen
RN	registered nurse
R/O	rule out
ROM	range of motion, rupture of membranes
RUL	right upper lobe of the lung
RUQ	right upper quadrant of the abdomen
Rx	prescription
$\bar{s}$	without
Sao_2	oxygen saturation
SC	subcutaneous
SICU	surgical intensive care unit
SIDS	sudden infant death syndrome
SL	sublingual
SOB	shortness of breath
Spo_2	saturation of peripheral oxygen
S/S, S&S	signs and symptoms
stat	immediately
STD	sexually transmitted disease
STEMI	ST-segment elevation myocardial infarction
subcut	subcutaneous
SVT	supraventricular tachycardia
sym or Sx	symptoms
T	temperature
tab	tablet
TB	tuberculosis
TBA	to be admitted, to be announced
tech	technician, technologist
TIA	transient ischemic attack
tid/t.i.d./TID	three times a day
Tx	treatment
UA	urinalysis
UE	upper extremity
URI	upper respiratory infection
UTI	urinary tract infection
VD	venereal disease
VF/V fib	ventricular fibrillation
VRE	vancomycin-resistant enterococcus
VS	vital signs
VT/V tach	ventricular tachycardia
W/	with
WBC	white blood cell
WMD	weapon of mass destruction
WNL	within normal limits
W/O	without
wt	weight
$\bar{x}$	except
yo; y/o	year old

*Abbreviations are sometimes written with periods (for example, abd. and a.c.), and different capitalization might be used that may convey a different meaning. This table does not include all possible meanings. If you are uncertain, always ask the person using the abbreviation.

YOU are the Provider SUMMARY

1. What can you determine about the patient's medical history based on the acronyms in the record?

You can determine that the patient has a significant past medical history. The record indicates the patient has had an abdominal aortic aneurysm, hypertension, a cerebrovascular accident (stroke), acute myocardial infarction (heart attack), gastroesophageal reflux disease, and type 1 diabetes.

2. How did the use of acronyms assist in delivering your report to the hospital?

When providing a verbal report to the hospital, it is important to be as succinct as possible. Using abbreviations will help you deliver the most information in the minimum amount of time. For this report, stating the BP is 80/50, rather than "the blood pressure is...," the pulse is 128 BPM rather than beats per minute, and using ETA rather than estimated time of arrival, all help to shorten the time for providing a verbal report. Time in an emergency can be critical, so providing a quick report of essential information is sometimes valuable.

3. What other acronyms or abbreviations could have been used in this report?

You can use acronyms when reporting most of the past medical history. Appropriate acronyms for this report include *AAA, CVA, AMI,* and *GERD*. Abbreviations are useful in written and verbal reports. Also, *LPM* could be used in place of *L/min* when documenting oxygen flow.

4. What do the abbreviations or acronyms in this portion of the report mean?

The abbreviations in this report include *EMT* for Emergency Medical Technician, *A&O* meaning "alert and oriented," and *CC* meaning chief complaint. The abbreviation yo is used for years old.

5. What other abbreviations, acronyms, or symbols could you have used in this portion of the report?

The acronym *AAA*, for abdominal aortic aneurysm, could be used. Acceptable abbreviations include *abd* for abdomen and *min* for minute. An appropriate use of a symbol in this report is ♀, meaning female.

EMS Patient Care Report (PCR)

Date: 6-10-17	**Incident No.:** 060109	**Nature of Call:** Constipation and abdominal pain		**Location:** Friends Acre Nursing Home, 322 Azalea Trail

Oxygen @ 12 **L/min via (circle one):** **NC** **NRM** **BVM**		**Assisted Ventilation**	**Airway Adjunct**	**CPR**
Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** Position of comfort

Narrative

Dispatched for a female patient c/o constipation and abdominal pain. On arrival at the scene, found the patient, a 79-year-old female, lying on her side in bed with her knees drawn up into her abdomen. She was conscious and alert; her airway was patent, and breathing adequate. Skin was pale and wet. Patient states the pain (8 on a 0-to-10 scale) began suddenly approximately 20 minutes ago. Her medical history is significant for AAA, HTN, CVA in 2009, AMI in 2010, GERD, and type 1 diabetes. Applied oxygen at 12 L/min via nonrebreathing mask and obtained vital signs. Further assessment of patient's abdomen revealed an anterior, periumbilical pulsating mass; it was point tender to palpation of the RUQ. Patient denies chest pain, shortness of breath, nausea or vomiting, and any other symptoms. She further denies radiating and referred pain. Patient was placed onto the stretcher in a position of comfort, loaded into the ambulance, and transported to the hospital. En route, continued to monitor patient's condition, which remained unchanged. Vital signs reassessed and noted above. Shortly before arrival at the hospital, reassessment of the patient revealed that her vital signs remained stable and that her pain had decreased in severity. Transferred care of patient to receiving hospital without incident and gave verbal report to charge nurse. Departed the hospital and returned to service.**End of report**

Prep Kit

Ready for Review

- Knowledge of medical terminology is essential for health care team members to effectively communicate and document calls.
- Understanding how terms are formed, and the definitions for the various parts of a medical term, will help you determine the meaning of an unknown term.
- Parts that can make up a word include the word root, prefix, suffix, and combining vowels. Not every part is included in every word. Each part can significantly change the meaning of a word.
- The word root is the stem of the word and conveys the core meaning. It frequently indicates a body part. Most terms have at least one word root.
- A prefix and/or suffix can be added to the word root to create a term. Changing the prefix or suffix will change the meaning of the term.
- A prefix is the part of a term that appears at the beginning of a word. It generally describes location and intensity.
- A suffix is placed at the end of a word to change the original meaning. In medical terminology, a suffix usually indicates a procedure, condition, disease, or part of speech.
- A combining vowel is the part of a term that connects a word root to a suffix or other word root to make it easier to pronounce.
- To make some terms plural, an s is added to the term. Other terms use other plural forms.
- Prefixes can also indicate numbers, colors, or direction.
- Directional terms indicate distance and direction from the midline. These include right, left, superior, inferior, lateral, medial, proximal, distal, superficial, deep, ventral, dorsal, palmar, plantar, and apex.
- Terms related to movement include flexion, extension, adduction, and abduction.
- Anatomic position refers to the position of the body; for example, the position the patient is in when you arrive on scene. Anatomic positions include prone, supine, and Fowler.
- Abbreviations, acronyms, and symbols are used as shorthand to communicate and document in a concise manner. To avoid potentially dangerous misinterpretation of your documentation, be sure to use only abbreviations that are commonly understood; avoid using abbreviations that are not recommended.

Vital Vocabulary

abduction Motion of a limb away from the midline.

adduction Motion of a limb toward the midline.

anterior The front surface of the body; the side facing you in the standard anatomic position.

apex (plural apices) The pointed extremity of a conical structure.

bilateral A body part or condition that appears on both sides of the midline.

combining vowel The vowel used to combine two word roots or a word root and suffix.

deep Farther inside the body and away from the skin.

distal Further from the trunk or nearer to the free end of the extremity.

dorsal The posterior surface of the body, including the back of the hand.

extension The straightening of a joint.

flexion The bending of a joint.

Fowler position An inclined position in which the head of the bed is raised.

inferior Below a body part or nearer to the feet.

lateral Parts of the body that lie farther from the midline; also called outer structures.

medial Parts of the body that lie closer to the midline; also called inner structures.

palmar The forward facing part of the hand in the anatomic position.

plantar The bottom surface of the foot.

posterior The back surface of the body; the side away from you in the standard anatomic position.

prefix Part of a term that appears before a word root, changing the meaning of the term.

prone Lying face down.

proximal Closer to the trunk.

quadrants Describes the sections of the abdominal cavity, in which two imaginary lines intersect at the umbilicus, dividing the abdomen into four equal areas.

suffix The part of a term that comes after the root word, at the end of the term.

superficial Closer to or on the skin.

superior Above a body part or nearer to the head.

supine Lying face up.

ventral The anterior surface of the body.

word root The main part of a term that contains the primary meaning.

Assessment *in Action*

You are dispatched to a motor vehicle crash involving a motorcycle. Upon your arrival, you find a 17-year-old male patient lying face down on the ground. The patient's breath smells of alcohol. He reports a headache and weakness on one side. He also reports seeing double. Upon examination, you find a 2-inch (5 cm) laceration above the left upper quadrant of his abdomen and a gunshot wound to his right leg, above the thigh. The patient is coughing up blood. His blood pressure is 100/60 mm Hg. His heart rate was 90 beats/min. His pupils are equal, round, and reactive to light and accommodation. His breath sounds are clear and equal on both sides. He has no known allergies and a history of hypertension. You treat the patient by placing him on oxygen at 12 L/min via a nonrebreathing mask. You begin transport of the patient on his left side with an estimated time of arrival of 10 minutes.

1. What is the term for the position in which you found the patient?

   A. Recumbent
   B. Fowler
   C. Prone
   D. Supine

2. As you document this call, you note the patient is in pain. What is the root word for *pain*?

   A. alges
   B. angi
   C. asthen
   D. centesis

3. You note the patient reports weakness. What is the root word for *weakness*?

   A. alges
   B. angi
   C. asthen
   D. centesis

4. The patient reports weakness on one side. What is the term for *on one side*?

   A. Bilateral
   B. Hemilateral
   C. Lateral
   D. Unilateral

5. The patient does not appear to have any allergies. What is the acronym for this?

   A. NA
   B. ANK
   C. NKA
   D. ANN

6. The patient is seeing double. What medical term means *double vision*?

   A. Bioccular
   B. Bioptic
   C. Dioccular
   D. Diplopia

7. The patient is coughing up blood. What is the medical term for *coughing up blood*?

   A. Hemogastritis
   B. Hematuria
   C. Hematemesis
   D. Hemoptysis

8. The patient has a history for hypertension. What is the abbreviation for hypertension?

   A. HPT
   B. HTN
   C. ATN
   D. AHTN

9. Rewrite the scenario above using abbreviations and symbols whereever possible.

10. What is the danger of using abbreviations?

CHAPTER
6

The Human Body

Courtesy of SynDaver Labs.

National EMS Education Standard Competencies

Preparatory

Applies fundamental knowledge of the emergency medical services (EMS) system, safety/well-being of the emergency medical technician (EMT), medical/legal and ethical issues to the provision of emergency care.

Anatomy and Physiology

Applies fundamental knowledge of the anatomy and function of all human systems to the practice of EMS.

Pathophysiology

Applies fundamental knowledge of the pathophysiology of respiration and perfusion to patient assessment and management.

Knowledge Objectives

1. Identify the body's topographic anatomy, including the anatomic position and the planes of the body. (pp 179–180)
2. Identify the anatomy and physiology of the skeletal system. (pp 180–181)
3. Describe the anatomy and physiology of the musculoskeletal system. (pp 186–187)
4. Discuss the anatomy and physiology of the respiratory system. (pp 187–196)
5. Discuss the anatomy and physiology of the circulatory system. (pp 196–208)
6. Discuss the anatomy and physiology of the nervous system. (pp 208–212)
7. Describe the anatomy and the physiology of the integumentary system. (pp 212–214)
8. Explain the anatomy and physiology of the digestive system. (pp 214–218)
9. Describe the anatomy and physiology of the lymphatic system. (p 218)
10. Discuss the anatomy and physiology of the endocrine system. (pp 218–220)
11. Describe the anatomy and physiology of the urinary system. (pp 220–221)
12. Discuss the anatomy and physiology of the genital system. (pp 221–223)
13. Describe the life support chain, aerobic metabolism, and anaerobic metabolism. (pp 223–224)
14. Define pathophysiology. (p 224)

Skills Objectives

There are no skills objectives for this chapter.

Introduction

A working knowledge of human anatomy is important for you as an EMT. By using the proper medical terms, you will be able to communicate correct information to other medical professionals with the least possible confusion. At the same time, you need to be able to communicate with laypeople who may not understand medical terms. Balancing these two approaches is one of the most challenging aspects of your job. A basic understanding of human anatomy, physiology, and pathophysiology is essential so that you can meet these challenges.

This chapter begins with a discussion of topographic anatomy, or the landmarks on the surface of the body. The various parts of the body, or its anatomy, are then described. This information will provide you with the correct medical terms you will use in the field. Physiology, or the functions of the body or any of its parts, is also covered. Finally, pathophysiology is discussed, which describes how normal physiologic processes are affected by disease.

Topographic Anatomy

The surface of the body has many definite visible features that serve as guides or landmarks to the structures that lie beneath them. You must be able to identify the superficial landmarks of the body—its **topographic anatomy**—to perform an accurate assessment. But how do you know that everyone is looking at the body in the same orientation?

To accomplish this, the terms that are used to describe the topographic anatomy are applied to the body when it is in the **anatomic position**. This is a position of reference in which the patient stands facing you, arms at the side, with the palms of the hands forward. The anatomic position is used as a common starting point so that health care providers refer to the body in the same way. Directional terms are always from the patient's perspective. For example, you are looking at a person who reports pain in the left arm. Which left do you use—your left or the patient's left? To be consistent, use the patient's left as the reference point.

The Planes of the Body

The anatomic planes are imaginary straight lines that divide the body **Figure 6-1**. There are three main axes of the body depending on how it is divided. The frontal or **coronal plane** divides the body into a front and back portion. The **transverse (axial) plane** divides the body into a top and bottom portion. The **sagittal (lateral) plane** divides the body into left and right (but not necessarily equal) portions.

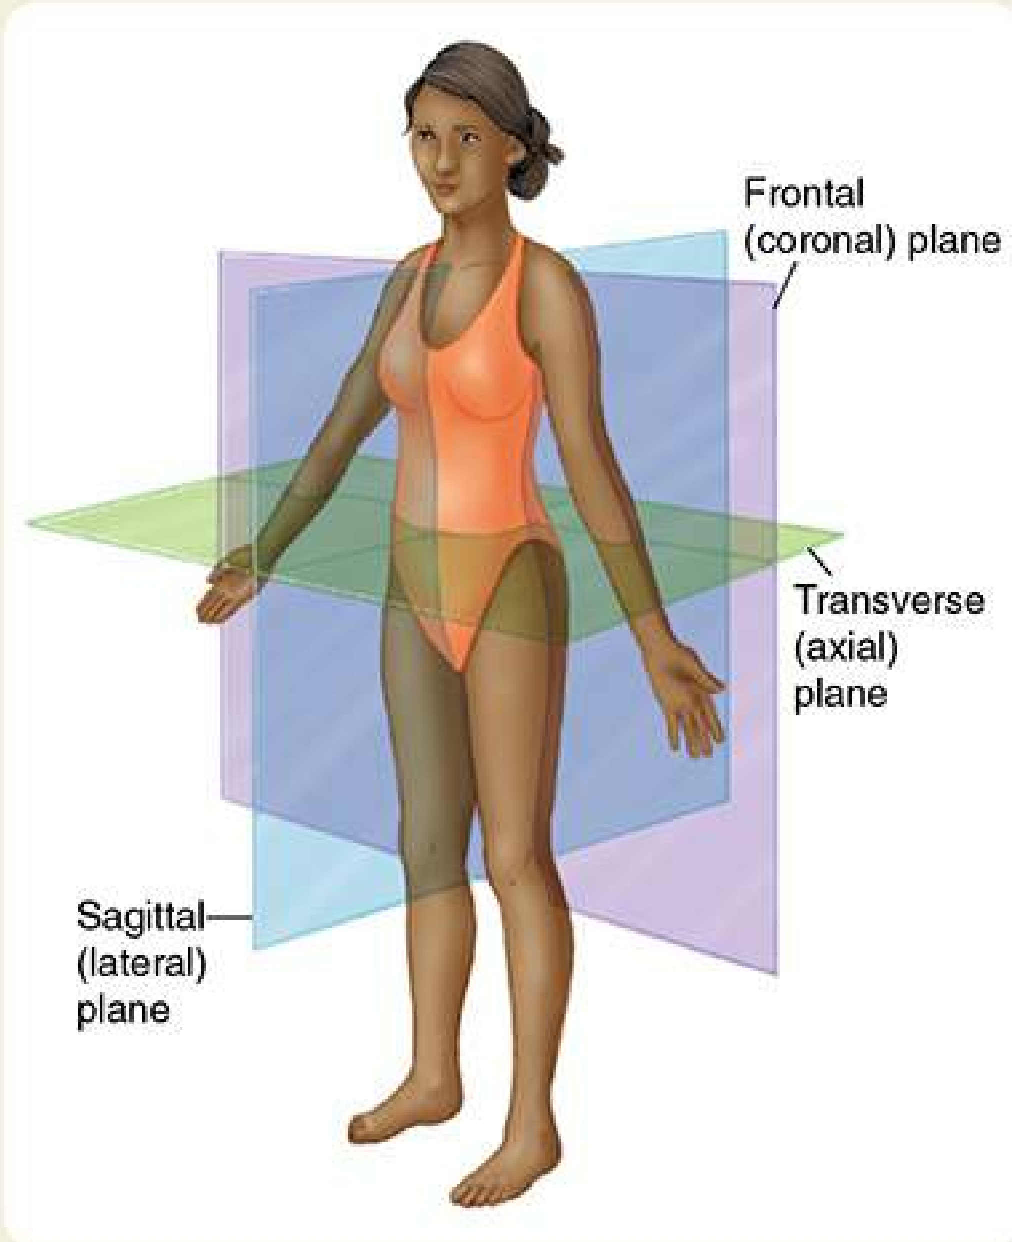

Figure 6-1 Planes of the body.

YOU are the Provider — PART 1

At 1740 hours, you are dispatched to 322 Azalea Trail for a 60-year-old man with severe abdominal pain. The weather is overcast, the traffic is heavy, and your response time to the scene is approximately 6 minutes.

1. How will knowledge of anatomy and physiology help you provide appropriate patient care?

Table 6-1 Planes of the Body	
Plane of the Body	**Description**
Coronal (frontal)	Front and back
Transverse (axial)	Top and bottom
Sagittal (lateral)	Left and right
Midsagittal (midline)	Left and right (equal halves)

The **midsagittal plane (midline)** is a type of sagittal plane where the body is divided into equal left and right halves. Your nose and navel are found along this imaginary line. These planes help you to identify the location of internal structures and understand the relationships between and among the organs Table 6-1.

The Skeletal System: Anatomy

The **skeleton** gives the body its recognizable human form and protects the vital internal organs. The 206 bones of the skeleton constitute the major structure of the skeletal system and provide a framework for the attachment of muscles. The skeleton is designed to allow motion of the body. Bones come into contact with one another at joints where, with the help of muscles, the body is able to bend and move. **Ligaments** are fibrous tissues that connect bones to each other. **Tendons** are ropelike structures that connect muscles to bones. Finally, **cartilage** is the smooth connective tissue that covers the ends of bones at mobile joints Table 6-2.

The skeletal system is divided into two main portions: the axial skeleton and the appendicular skeleton. The **axial skeleton** forms the foundation to which the arms and legs are attached. The axial skeleton is composed of the skull, facial bones, **thoracic cage**, and vertebral column. The arms and legs, their connection points, and the pelvis make up the **appendicular skeleton** Figure 6-2. The brain lies within the skull. The heart, lungs, and great vessels are enclosed in the **thorax**, which is part of the torso. Much of the liver and spleen are protected by the lower ribs. The spinal cord is contained within and protected by a bony spinal canal formed by the vertebrae.

Table 6-2 Support Structures Within the Skeletal System

Name	Function
Ligament	Connects bone to bone
Tendon	Connects muscle to bone
Cartilage	Cushion between bones

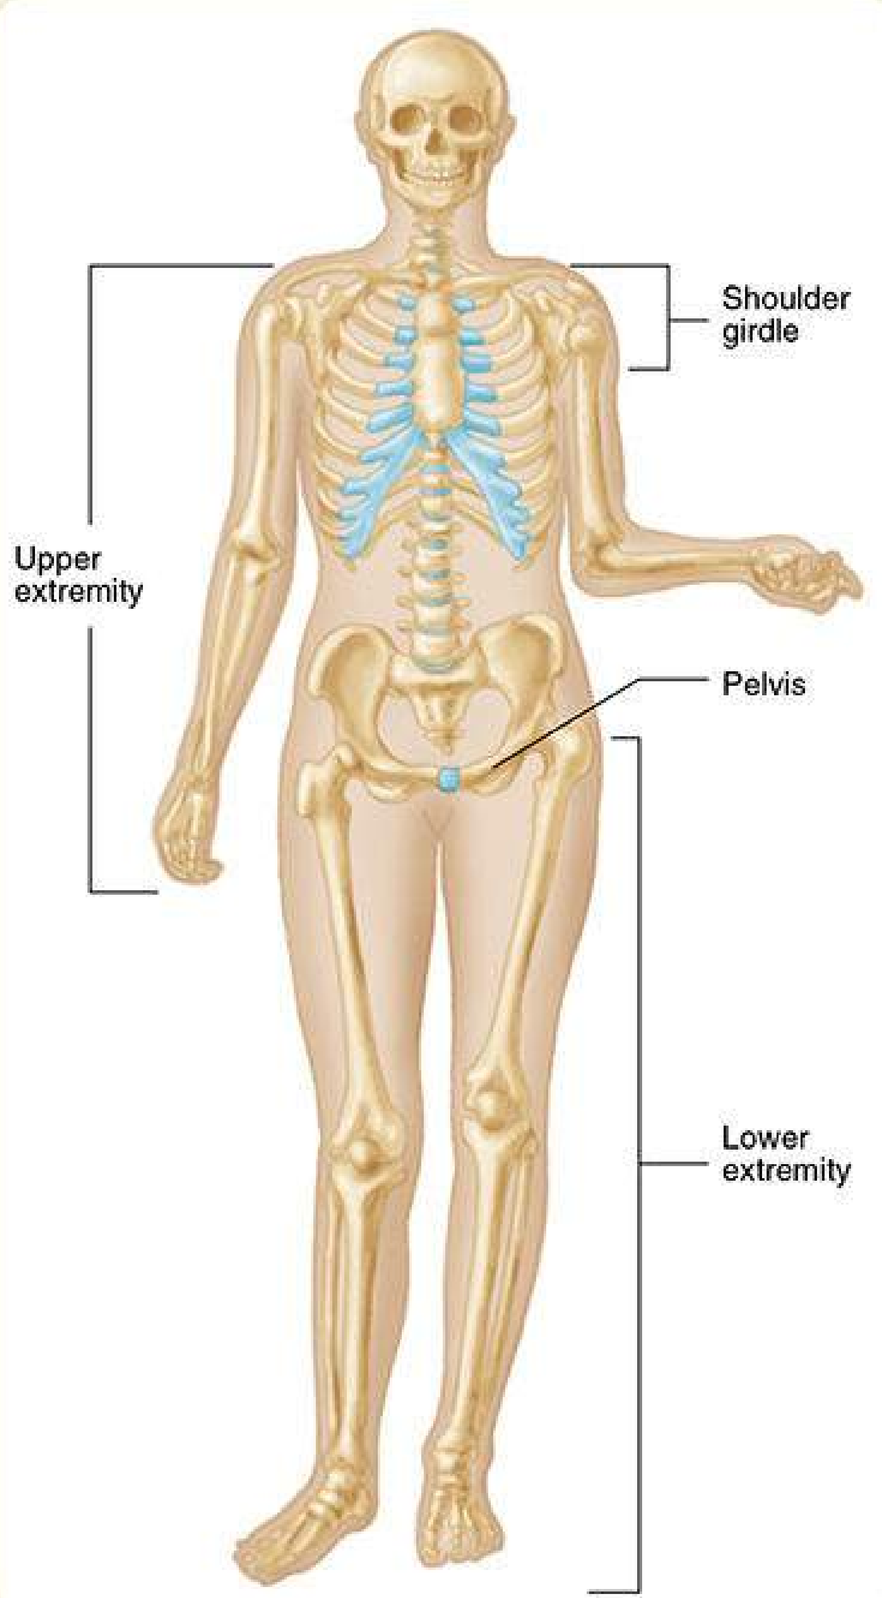

Figure 6-2 The 206 bones of the skeleton give the body its form, protect the vital organs, and allow the body to move. The axial skeleton runs in a straight line from the head to the pelvis. The appendicular skeleton is made up of the arms and legs and the pelvis.

The Axial Skeleton

The Skull

The head is a great place to start this discussion since it is at the top of the body. The skull is composed of two groups of bones: the cranium and the facial bones. The **cranium** is composed of a number of thick bones that fuse together to form a shell above the eyes and ears that holds and protects the brain **Figure 6-3**. The brain connects to the spinal cord through a large opening at the base of the skull called the **foramen magnum** (Latin for "great opening").

Four major bones make up the cranium. The most posterior portion of the cranium is the **occiput**. On each side of the cranium, the lateral portions are the temples or **temporal bones**. Between the temporal regions and the occiput lie the **parietal bones**. The forehead is the **frontal bone**. If you have ever felt an infant's head, you may have noticed the soft spots on top of the head. These gaps are where the separate bones have yet to fuse together. This allows the infant's head to be molded without breaking during the birthing process.

The face is composed of 14 bones. The upper, non-moveable jawbones are the **maxillae**, the cheek bones are the **zygomas**, and the **mandible** is the lower, moveable portion of the jaw. The **orbit** (eye socket) is made up of two facial bones: the maxilla and the zygoma. The orbit also includes the frontal bone of the cranium. Together, these bones form a solid, bony rim that protrudes around the eye to protect it. If you look at the face from the side, you can see that the eyeball sits back in the orbit. Finally, one-third of the nose is made up of very short bones that form the bridge of the nose; the rest of the nose is made of flexible cartilage.

The Spinal Column

The spinal column is the central supporting structure of the body and is composed of 33 bones, each called a vertebra (plural: vertebrae). The **vertebrae** are named according to the section of the spine in which they are located and are numbered from top to bottom **Figure 6-4**. From the top down, the spine is divided into five sections:

- **Cervical spine**. The first seven vertebrae (C1 through C7) in the neck form the cervical spine. The skull rests on and attaches to both the first cervical vertebra (the atlas) and the second cervical vertebra (the axis). The vertebrae fit together but move separately, allowing the head to turn in multiple directions.
- **Thoracic spine**. The next 12 vertebrae make up the thoracic spine. One pair of ribs is attached to each of the thoracic vertebrae.
- **Lumbar spine**. The next five vertebrae form the lumbar spine.

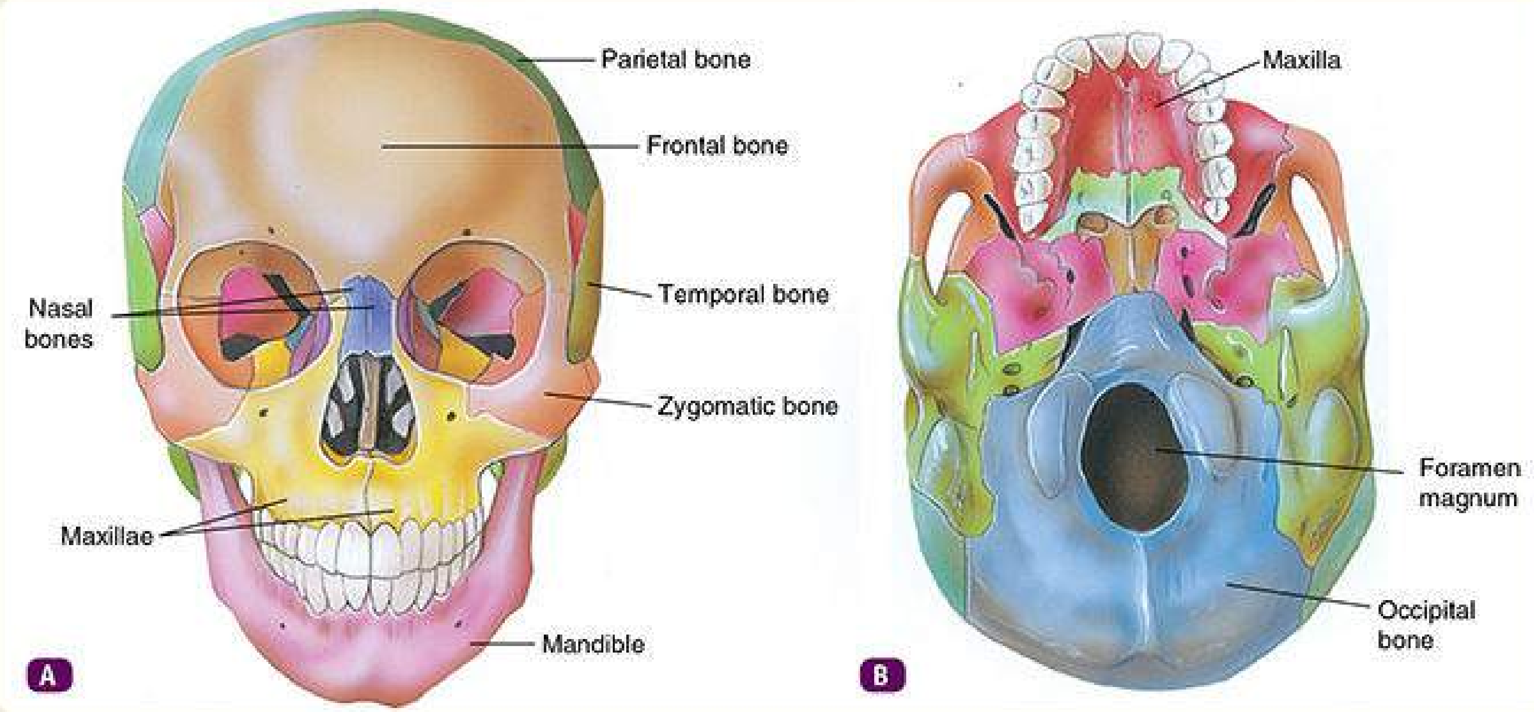

Figure 6-3 The skull. **A.** Anterior view. **B.** Inferior view.

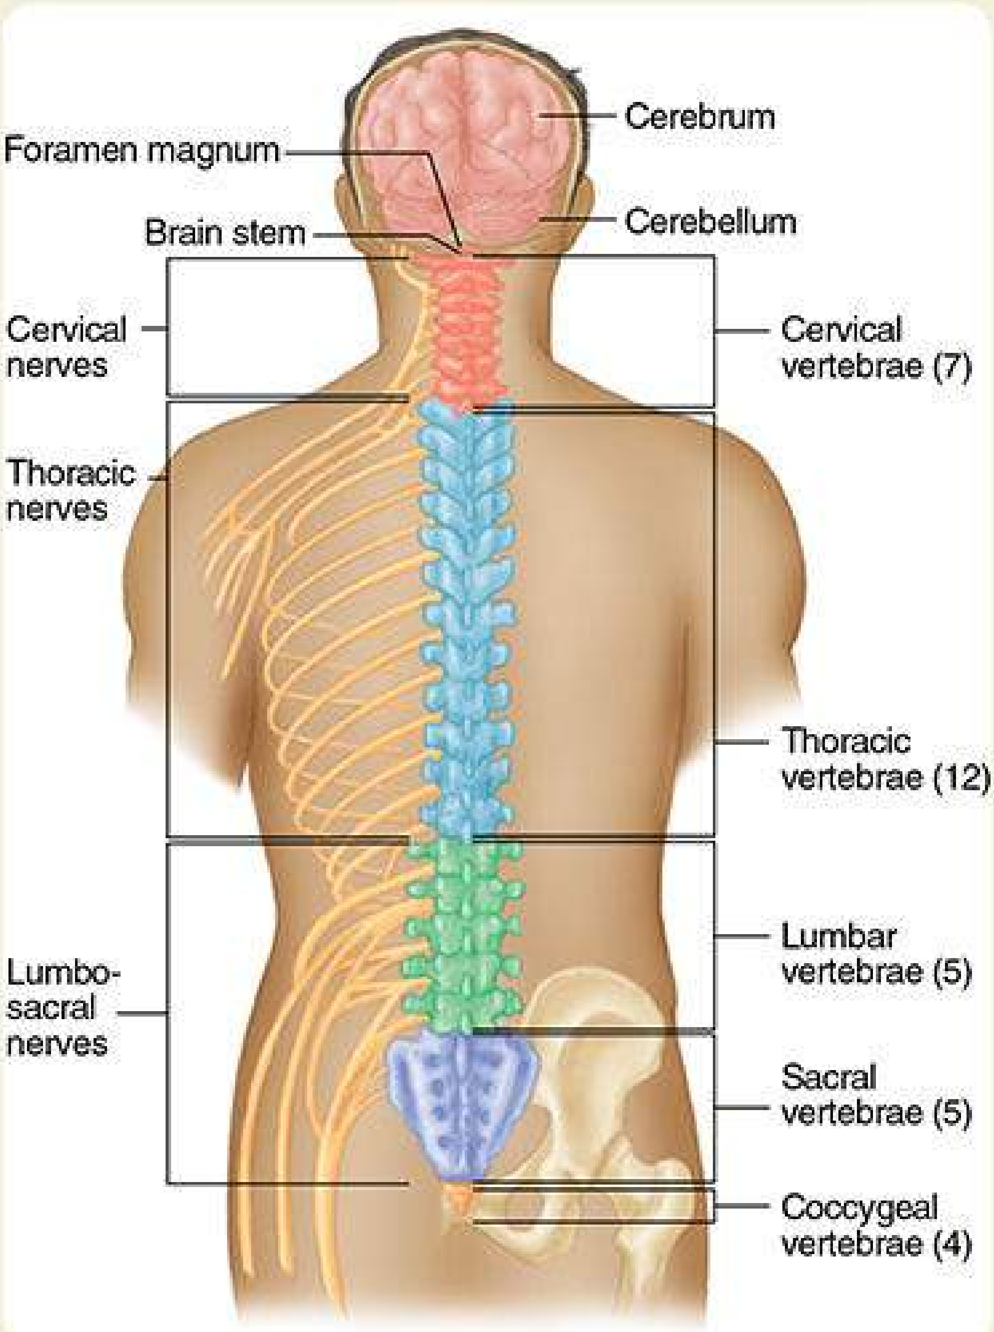

Figure 6-4 The spinal column is composed of 33 bones divided into five sections.

- **Sacrum**. The five sacral vertebrae are fused together to form one bone called the sacrum. The sacrum is joined to the iliac bones of the pelvis with strong ligaments at the sacroiliac joints to form the pelvis.
- **Coccyx**. The last four vertebrae, also fused together, form the coccyx, or tail bone.

The vertebrae are connected by ligaments, and between each vertebra is a cushion called the intervertebral disk. These ligaments and disks allow some motion so the trunk can bend forward (flex) and back (extend), and they allow for rotation and lateral movement. However, they also limit motion of the vertebrae to protect the spinal cord against injury. An injury to the spine may damage part of the spinal cord and its nerves. Therefore, you must use extreme caution in caring for patients with any spinal injury to prevent further injury to the spinal cord.

The Thorax

The thorax (chest) contains the heart, lungs, esophagus, and great vessels (the aorta and two venae cavae). It is formed by the 12 thoracic vertebrae (T1 through T12) and their 12 pairs of ribs.

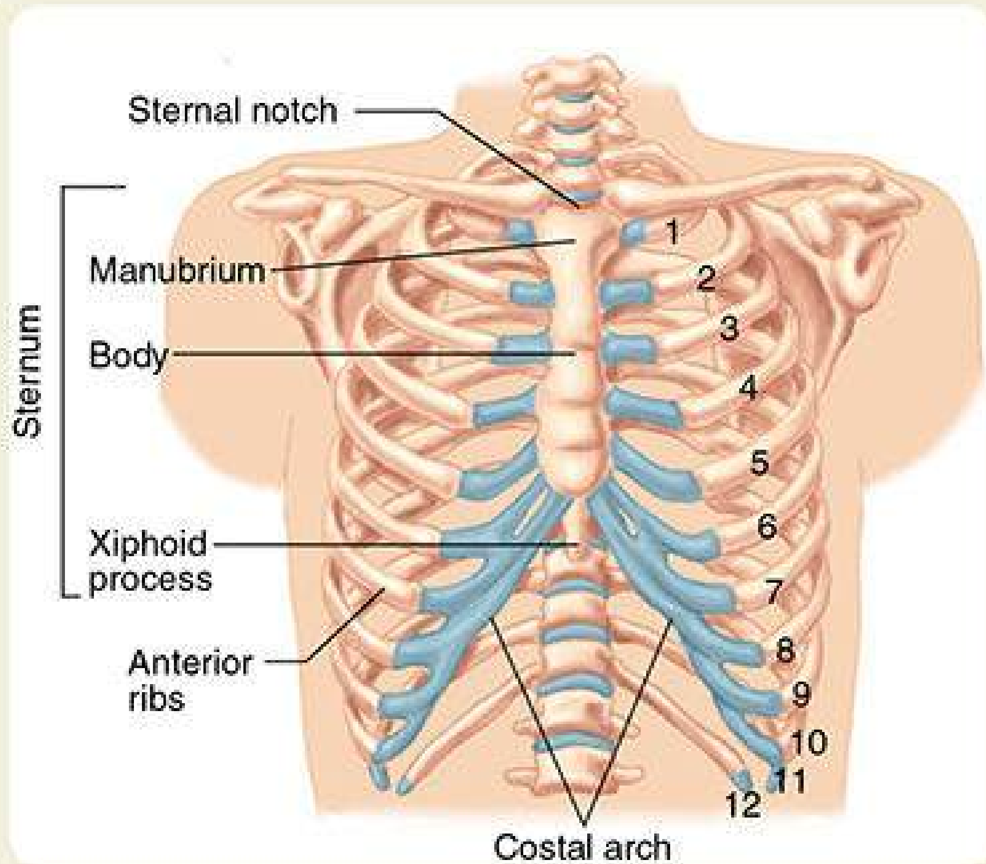

Figure 6-5 The thorax.

Anteriorly, in the midline of the chest is the **sternum**. The superior border of the sternum forms the easily palpable sternal notch. This is the location where the trachea enters the chest. The sternum has three components: the manubrium, the body, and the xiphoid process. The upper section of the sternum is called the **manubrium**. The body comprises the rest of the sternum except for a narrow, cartilaginous tip inferiorly, which is called the **xiphoid process** Figure 6-5.

The Appendicular Skeleton

Joints

Wherever bones come in contact, a **joint (articulation)** is formed. A joint consists of the ends of the bones that make up the joint and the surrounding connecting and supporting tissue Figure 6-6. Most joints in the body are named by combining the names of the bones that form that joint. For example, the sternoclavicular joint is the articulation between the sternum and the clavicle. Most joints allow motion—for example, the knee, hip, and elbow—whereas some bones fuse with one another at joints to form a solid, immobile, bony structure, such as the skull. Some joints have slight, limited motion in which the bone ends are held together by fibrous tissue. Such a joint is called a **symphysis**.

The bone ends of a joint are held together by a fibrous sac called the **joint capsule**. This sac is composed of connective tissue (connecting bone to bone). At certain points around the circumference of the joint, the capsule is lax and thin so motion can occur. In other areas, it is thick and resists stretching or bending. A joint such as the **sacroiliac joint** that is virtually surrounded by tough, thick ligaments will have little motion, whereas a joint such as the shoulder, with few ligaments, will be free to move in almost any direction (and will, as a result, be more prone to dislocation). In moving joints, the ends of the bones are covered with a thin layer of cartilage known as **articular cartilage**. This cartilage is a pearly white substance that allows the ends of the bones to glide easily. On the inner lining of the joint capsule is the **synovial membrane**. This special tissue is responsible for making a thick lubricant called **synovial fluid**. This oil-like substance allows the ends of the bones to glide over each other as opposed to rubbing and grating over each other.

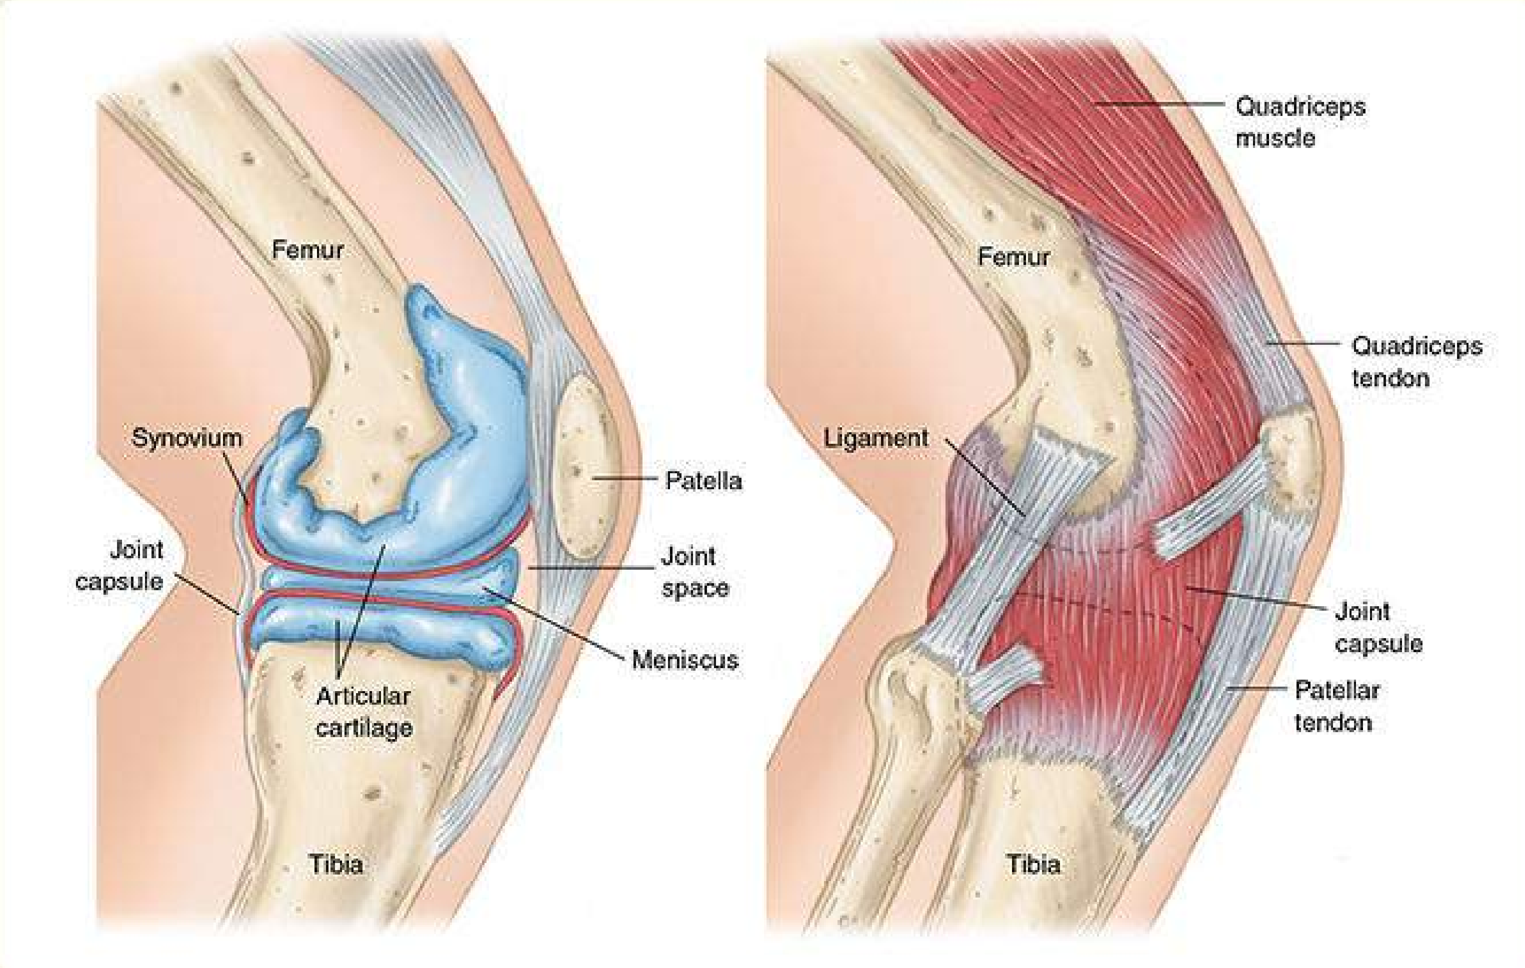

Figure 6-6 A joint consists of bone ends, the fibrous joint capsule, the synovial membrane, and ligaments. The degree to which a joint can move is determined by how the ligaments hold the bone ends and by the configuration of the bones themselves.

The degree to which a joint can move is determined by the extent to which the ligaments hold the bone ends together and also by the configuration of the bone ends themselves. The shoulder joint is a **ball-and-socket joint**, which allows rotation and bending **Figure 6-7**. The finger joints, elbow, and knee are **hinge joints**, with motion restricted to **flexion** (bending) and **extension** (straightening) **Figure 6-8**. Rotation is not possible because of the shape of the joint surfaces and the strong restraining ligaments on both sides of the joint. Although the amount of motion varies from joint to joint, all joints have a definite limit beyond which motion cannot occur. When a joint is forced beyond this limit, damage to some structure must occur. Either the bones that form the joint will break, or the supporting capsule and ligaments will be disrupted.

The Upper Extremities

The upper extremities extend from the shoulder girdle to the fingertips and are composed of the arm, forearm, hand, and fingers. The joints are the shoulder, elbow, wrist, and finger joints. The arm extends from the shoulder to the elbow, the forearm from the elbow to the wrist, and the hand from the wrist to the fingertips.

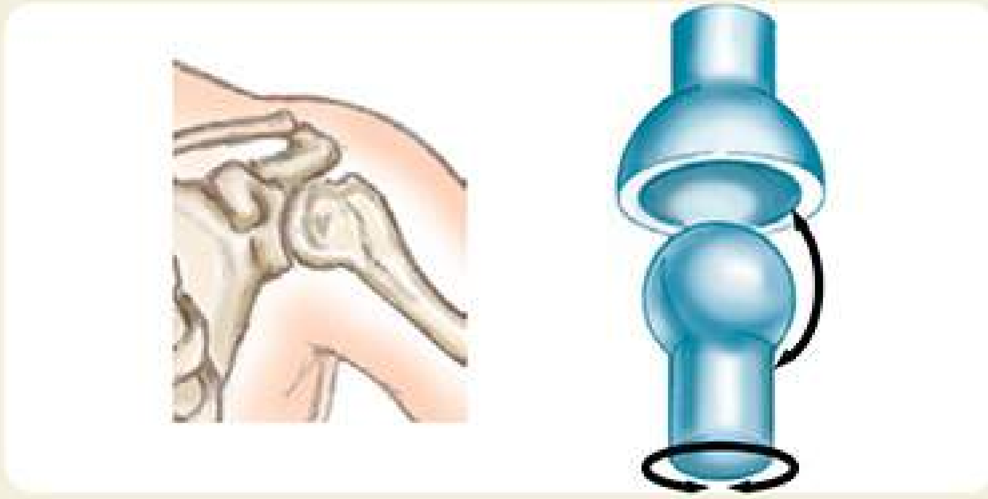

Figure 6-7 The shoulder is an example of a ball-and-socket joint.

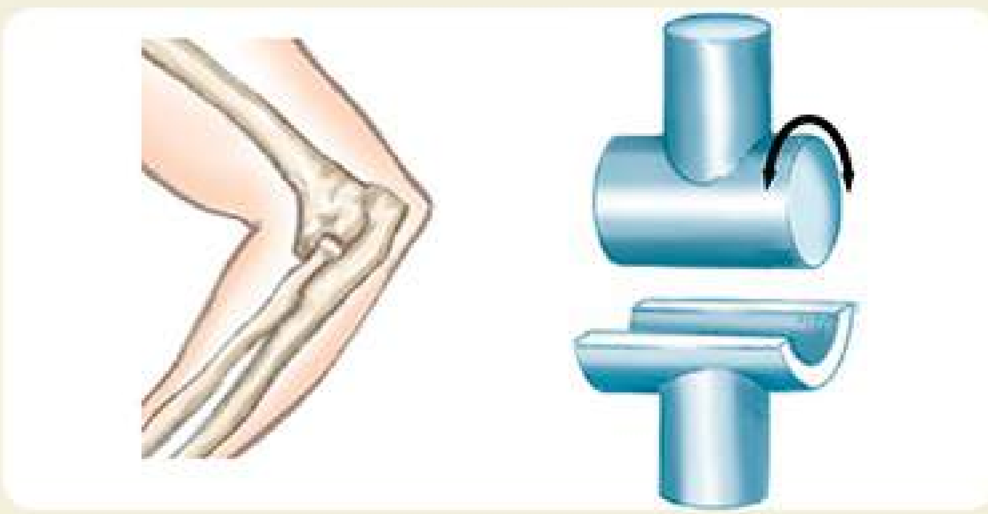

Figure 6-8 The elbow joints are hinge joints, which allow motion in only one plane (flexion and extension).

Shoulder Girdle

The **shoulder girdle** is where three bones come together, allowing the arm to move. These three bones are the **clavicle**, the scapula, and the humerus **Figure 6-9**. The clavicle (collar bone) overlies the superior boundaries of the thorax in front and articulates (joins) posteriorly with the **scapula** (shoulder blade), which lies in the muscular tissue of the posterior thoracic wall.

Arm

The supporting bone of the arm is the **humerus**. Its long, straight shaft serves as an effective lever for heavy lifting. The forearm is composed of the radius and the ulna. The **ulna** is larger in the proximal forearm, and helps to form the elbow joint. The **radius** is larger in the distal forearm. The radius lies on the lateral, or thumb, side of the forearm, and the ulna is on the medial, or little finger, side.

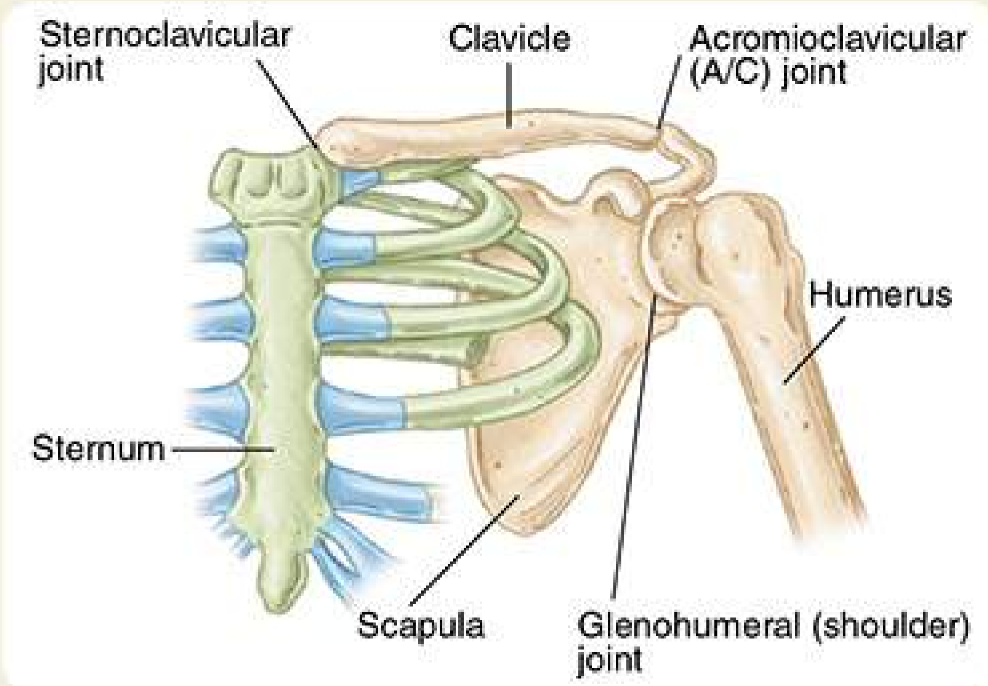

Figure 6-9 The bones of the shoulder girdle include the clavicle, the scapula, and the humerus.

Wrist and Hand

The wrist is a modified ball-and-socket joint formed by the ends of the radius and ulna and several small wrist bones **Figure 6-10**. There are eight bones in the wrist, called carpal bones. Extending from the carpal bones are five metacarpals which make up the hand. The anterior surface of the hand is referred to as the palm, while the back is referred to as the dorsal surface of the hand. The five fingers or digits are composed of bones called the phalanges. The thumb is composed of two phalanges; the other four digits each contain three phalanges.

The Pelvis

The pelvis is a closed, bony ring that consists of three bones: the sacrum and the two pelvic bones **Figure 6-11**. Each pelvic bone is formed by the fusion of three separate bones: the **ilium**, the **ischium**, and the **pubis**. These bones are joined together posteriorly by the sacrum. On the anterior side of this ring, the left pubis and the right pubis are joined. This area, the **pubic symphysis**, has cartilage within it that allows for slight motion of one side of the pelvis over the other. Pressure on the symphysis pubis during the physical examination can reveal fractures in the pelvis. These fractures can lead to life-threatening bleeding. The part of the pelvis where the leg connects to the hip joint is the **acetabulum** and is formed where the ilium, ischium, and pubic bones meet.

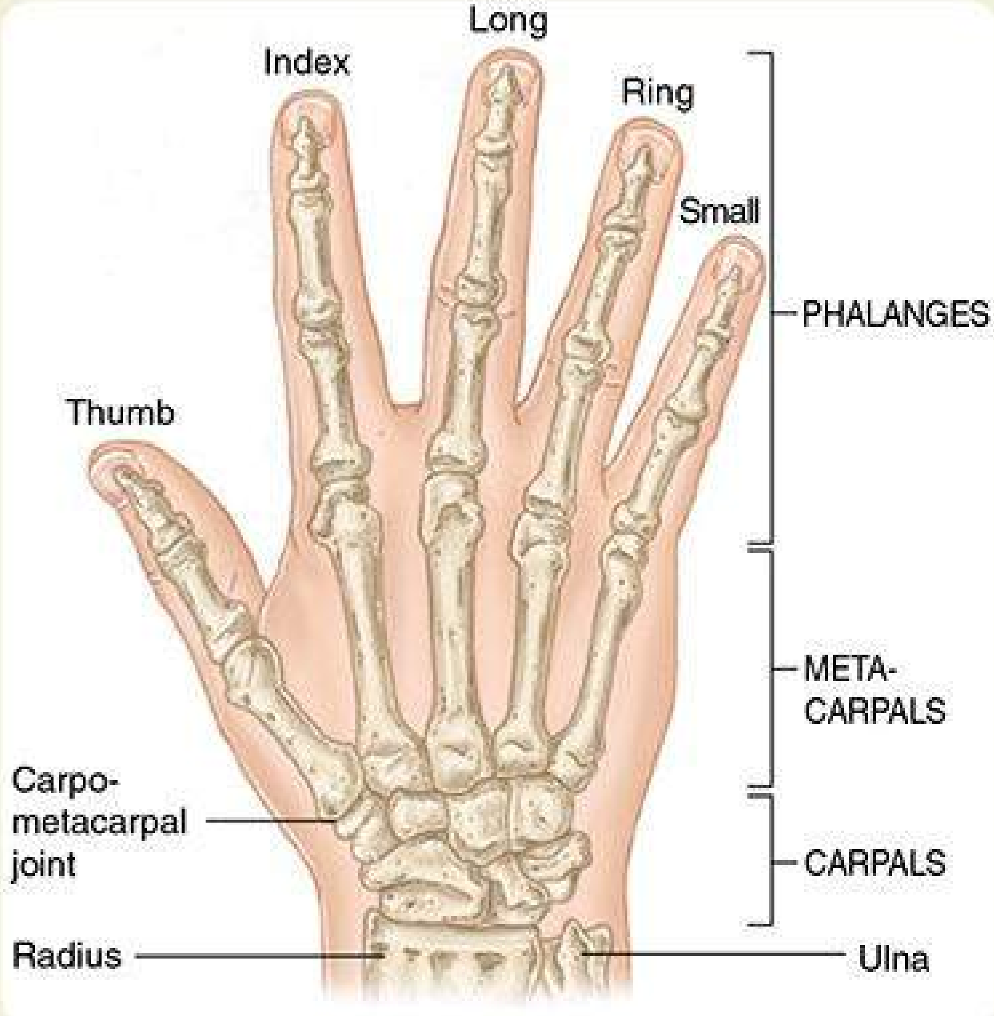

Figure 6-10 The major bones in the wrist and hand include the carpals, the metacarpals, and the phalanges.

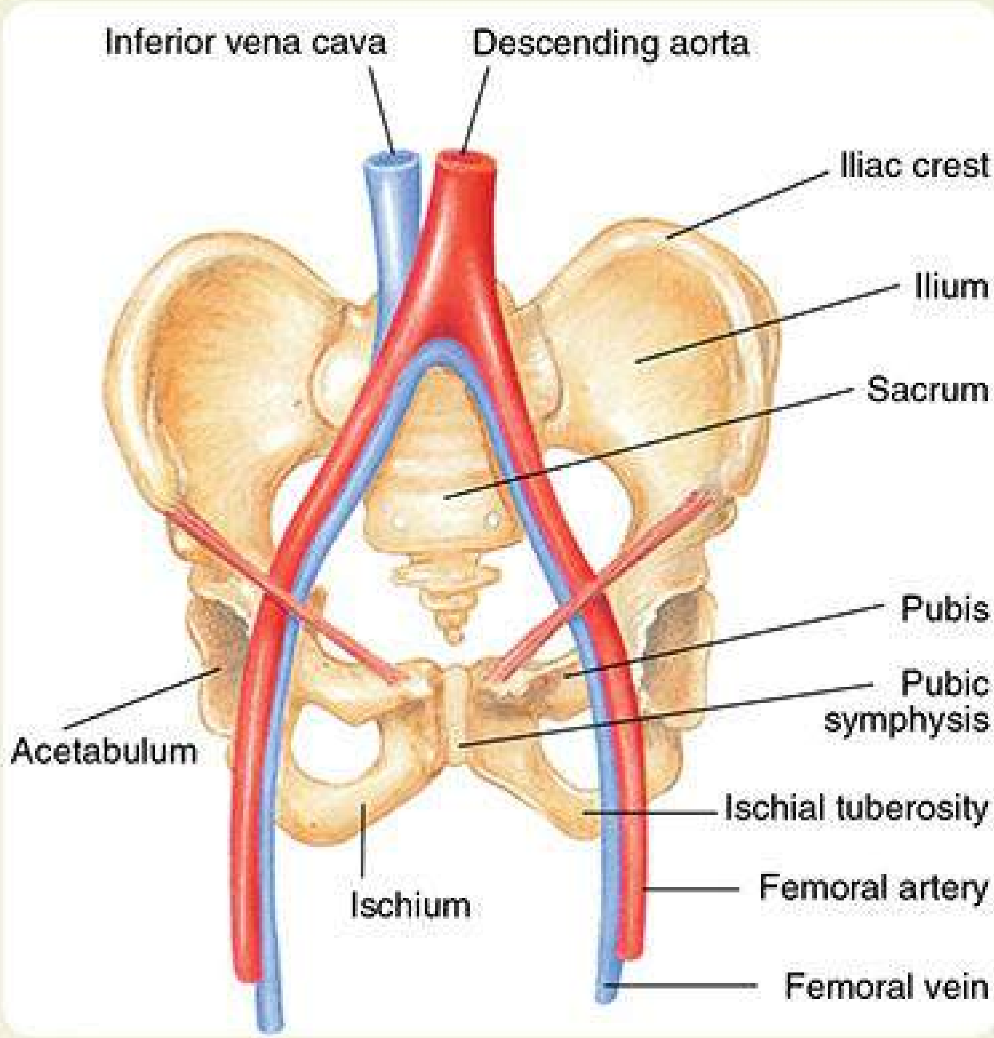

Figure 6-11 The pelvis is a closed, bony ring that consists of the sacrum, ilium, ischium, pubis, acetabulum, and pubic symphysis.

The Lower Extremities

The **femur** (*thighbone*) is the longest and one of the strongest bones in the body. At the superior end of the bone is a round structure called the **femoral head**. This is where the femur connects into the acetabulum (pelvic girdle) by a ball-and-socket joint. The femoral head attaches to the shaft of the femur through the femoral neck. The femur has two projections **Figure 6-12**. The projection on the lateral/superior portion of the junction between the femoral neck and shaft is the **greater trochanter**. The projection on the medial/inferior portion of the junction between the femoral neck and shaft is the **lesser trochanter**. Both projections are anchor points where the major muscles of the thigh connect to the femur.

The joint that connects the upper leg to the lower leg is the knee. The knee is a hinge joint, allowing only flexion and extension between the distal femur and the proximal tibia. Anterior to the knee is a specialized bone called the **patella** (knee cap). The lower leg lies between the knee and the ankle joint and is composed of the tibia and the fibula. The **tibia** (shinbone) is the larger bone and lies in the anterior of the leg. You can palpate the entire length of the tibia on the anterior surface of the leg just under the skin. The fibula lies on the lateral side of the leg. You can palpate the head of the fibula on the lateral aspect of the knee joint.

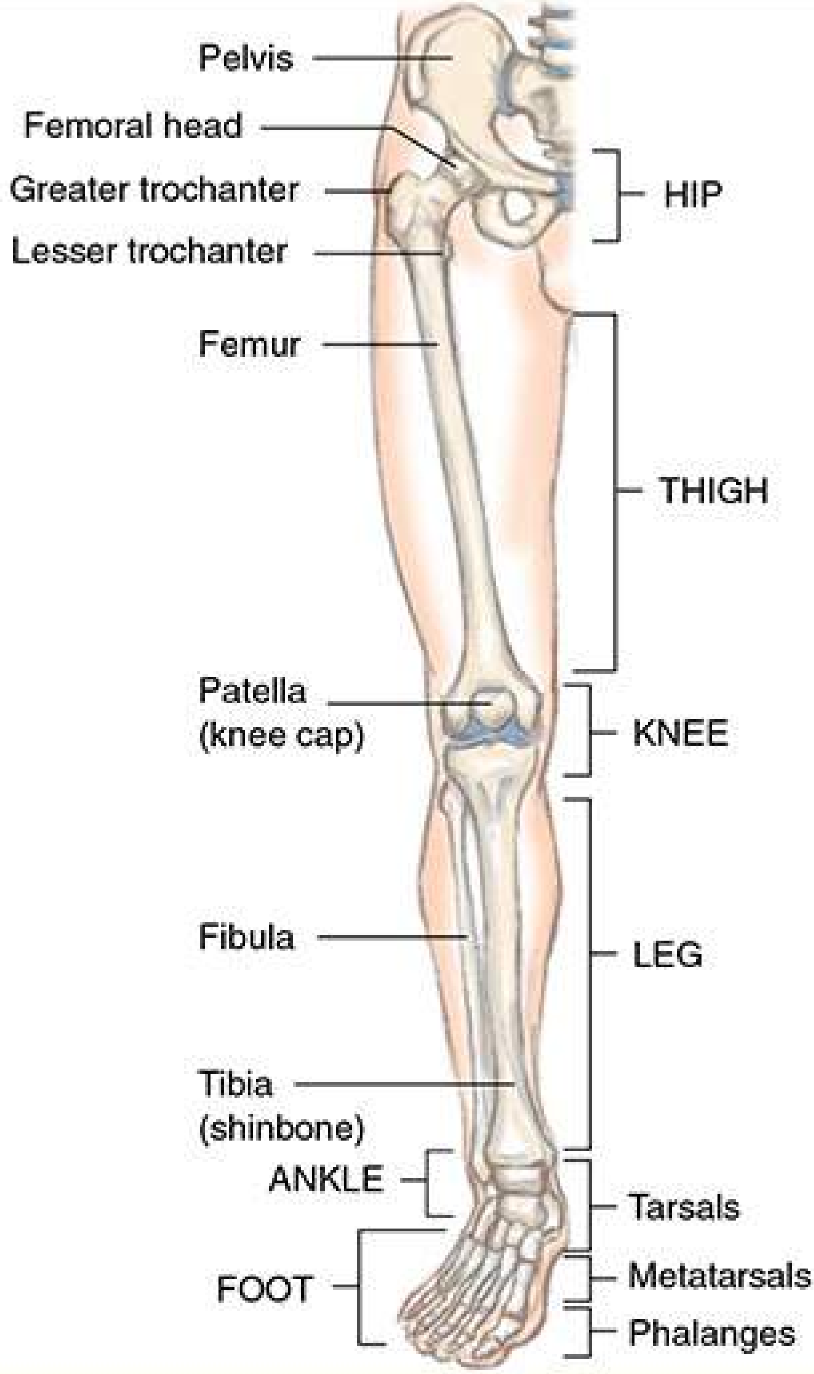

Figure 6-12 The major parts of the lower extremities include the femur, femoral head, greater and lesser trochanters, patella, tibia, and fibula.

Ankle and Foot

The ankle is a hinge joint that allows flexion and extension of the foot on the leg **Figure 6-13**. The foot contains seven tarsal bones. The talus is the second largest tarsal bone and joins with the distal tibia and fibula to form the ankle joint. The calcaneus, which forms the prominence of the heel, is the largest tarsal bone. Five metatarsal bones form the middle of the foot. The bottom surface of the foot is referred to as the plantar surface, while the top of the foot is described as the dorsum. The five toes are formed by 14 phalanges—two in the great toe and three in each of the smaller toes.

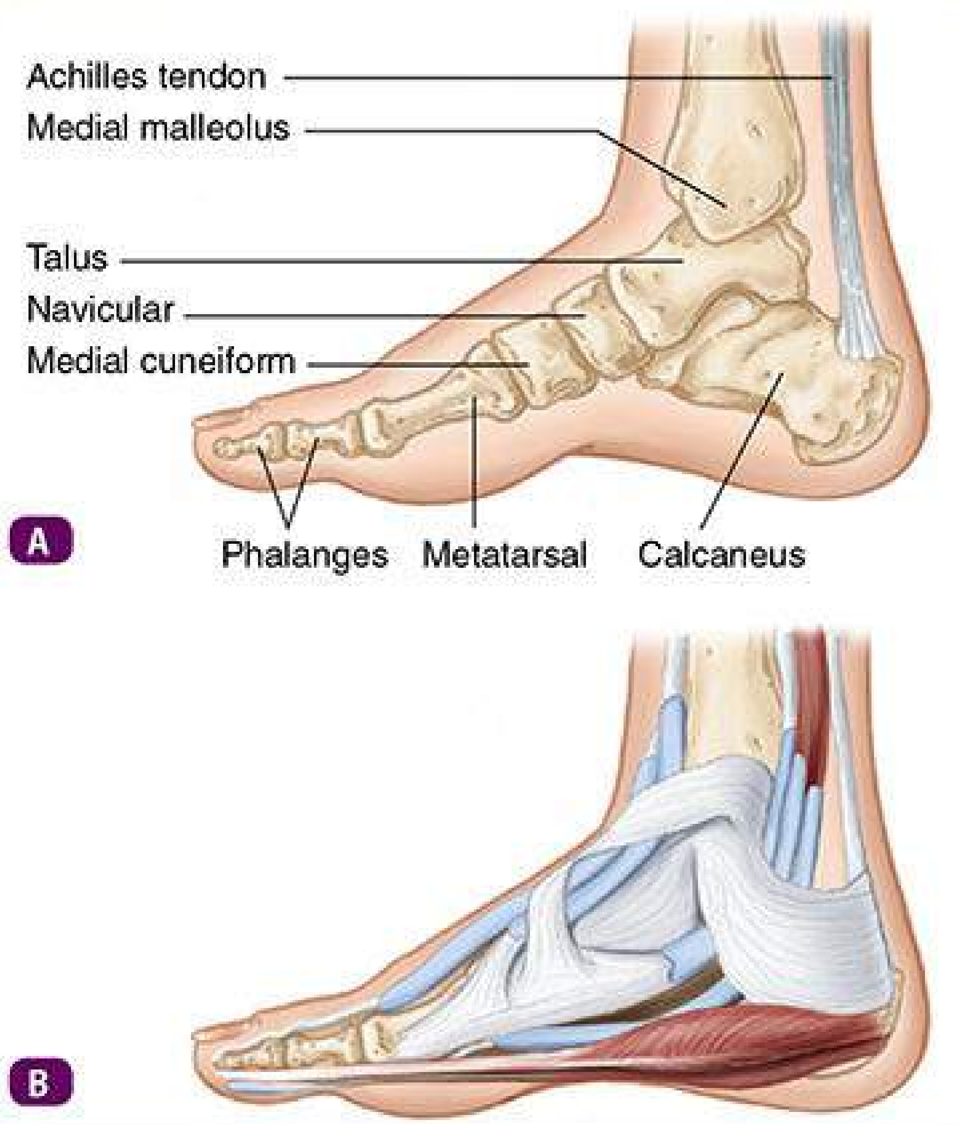

Figure 6-13 **A.** The surface landmarks of the foot, including the talus, the calcaneus, and the phalanges. **B.** Soft tissue of the ankle.

Safety Tips

As you gain a better understanding of the anatomy and physiology of the body, remember that these systems work together and not in isolation. A person who falls and breaks a leg may appear to have an isolated injury of the skeletal system. But then ask yourself the following questions: Is there bleeding inside the leg? Is there damage to the nerves, tendons, or ligaments? Has the injury disrupted the skin and is there now a risk of infection? A seemingly simple illness or injury can involve several body systems. Always perform a thorough patient assessment.

The Skeletal System: Physiology

The skeletal system is responsible for several functions: it gives the body shape, provides protection of fragile organs, and allows for movement. Another function of the skeletal system is the storage of calcium. Calcium is a mineral that helps to build hard and resilient bones. The bones are constantly being made and destroyed as stress is applied to them. Calcium is also important for other body systems and helps the heart, muscles, and nerves work properly.

The skeletal system also helps with the creation of various types of blood cells. Special cells are present in the marrow of certain types of bones that can transform themselves into red blood cells, white blood cells, and platelets. The cells, when stimulated, help to replace worn out cells in the blood.

The Musculoskeletal System: Anatomy

The human body is a well-designed system whose form, upright posture, and movement are provided by the **musculoskeletal system**. The term musculoskeletal refers to the bones and voluntary muscles of the body. The musculoskeletal system also protects the vital internal organs of the body. Muscles are a form of tissue that allow body movement. The three types of muscles are skeletal, smooth, and cardiac. **Skeletal muscle**, so named because it attaches to the bones of the skeleton, forms the major muscle mass of the body. **Smooth muscle** is found within blood vessels and intestines. For example, when you hear your stomach growling, you are hearing the rhythmic contractions of the smooth muscles of your intestines. **Cardiac muscle** is found only within the heart **Figure 6-14** and is able to create and conduct its own electrical impulses.

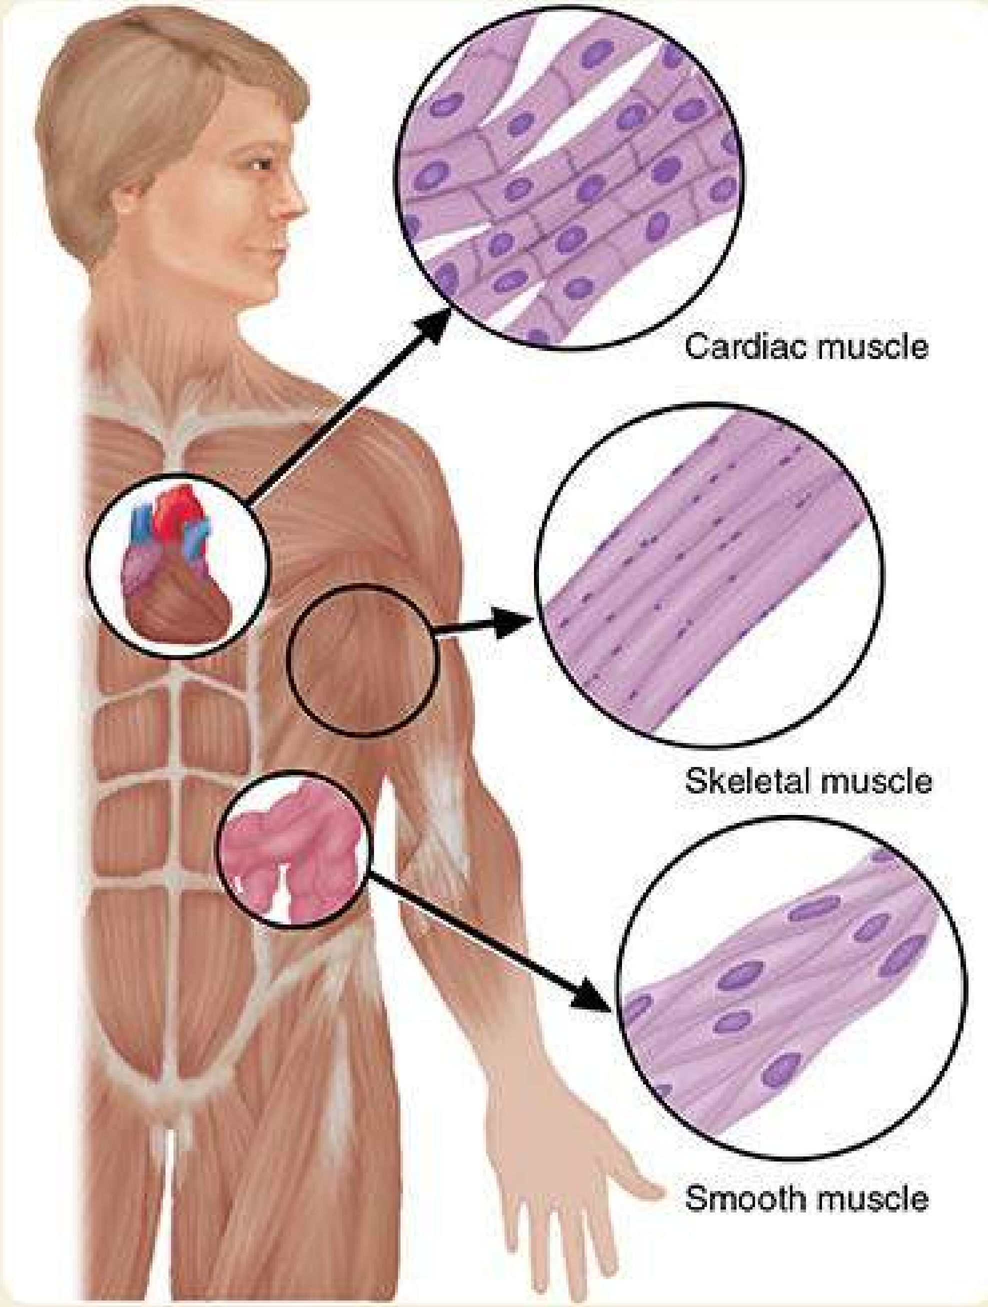

Figure 6-14 The three types of muscle are skeletal, smooth, and cardiac.

▶ Skeletal Muscle

Skeletal muscle is also called **voluntary muscle**, because all skeletal muscle is under direct voluntary control of the brain and can be stimulated to contract or relax at will. (By contrast, **involuntary muscle** is a muscle over which you have no conscious control, such as the heart.) Skeletal muscle is also called striated muscle because of its characteristic stripes. Movement of the body, like waving or walking, results from skeletal muscle contraction or relaxation. Usually, a specific motion is the result of several muscles contracting and relaxing simultaneously.

Most muscles within the body operate on the principle of antagonistic pairs. The muscles of the upper arm include the **biceps** muscle, which is located on the anterior aspect of the humerus. This muscle moves the lower part of the arm toward the head. If the muscle was working alone, you would have little control over the speed of that movement. The way the body achieves control and fine movement is to have the biceps compete against another muscle group. The biceps competes with the **triceps** muscle, which is called the three-headed muscle of the arm because there are three bundles of muscle that join together at the elbow. Without the triceps, you would slap yourself in the face every time you bend your arm. The biceps works to slow the movement of the triceps as the arm is extended.

There are more than 600 muscles in the musculoskeletal system. **Figure 6-15** and **Table 6-3** show the major muscles, their locations, and their functions.

The Musculoskeletal System: Physiology

The muscluloskeletal system has several functions. Your ability to move and be able to manipulate your environment is made possible by the contraction and relaxation of this system. A by-product of this movement is heat. When you get cold, your muscles involuntarily shake, or shiver, to produce heat and maintain homeostasis (a balance of all systems in the body). Shivering is an essential function. Muscles also protect the structures under them. For example, the intestines are protected by the rectus abdominus muscles.

The Respiratory System: Anatomy

The **respiratory system** consists of all the structures of the body that contribute to respiration, or the process of breathing **Figure 6-16**. It includes the nose, mouth, throat, larynx, trachea, bronchi, and bronchioles, which are all air passages or airways. The system also includes the lungs, where oxygen is passed into the blood and carbon dioxide removed. Finally, the respiratory system includes the diaphragm, the muscles of the chest wall, and accessory muscles of breathing, which permit normal respiratory movement. In this text, “airway” usually refers to the upper airway or the passage above the larynx (voice box).

The Upper Airway

The structures of the upper airway are located anteriorly and at the midline. The upper airway includes the nose, mouth (oral cavity), tongue, jaw (mandible), pharynx, and larynx. The larynx is typically considered the dividing line between the upper and lower airway. The larynx is a complex arrangement of tiny bones, cartilage, muscles, and two vocal cords. The larynx does not tolerate any foreign solid or liquid material, and any contact will result in a violent episode of coughing and spasm of the vocal cords. The nose and mouth lead to the oropharynx (throat). The pharynx is composed of the nasopharynx, oropharynx, and the laryngopharynx. The nostrils lead to the **nasopharynx** (above the roof of the mouth and soft palate), and the mouth leads to the oropharynx. The nasal passages and nasopharynx warm, filter, and humidify air as you breathe. Air enters through the mouth more rapidly and directly. As a result, it is less moist than air that enters through the nose.

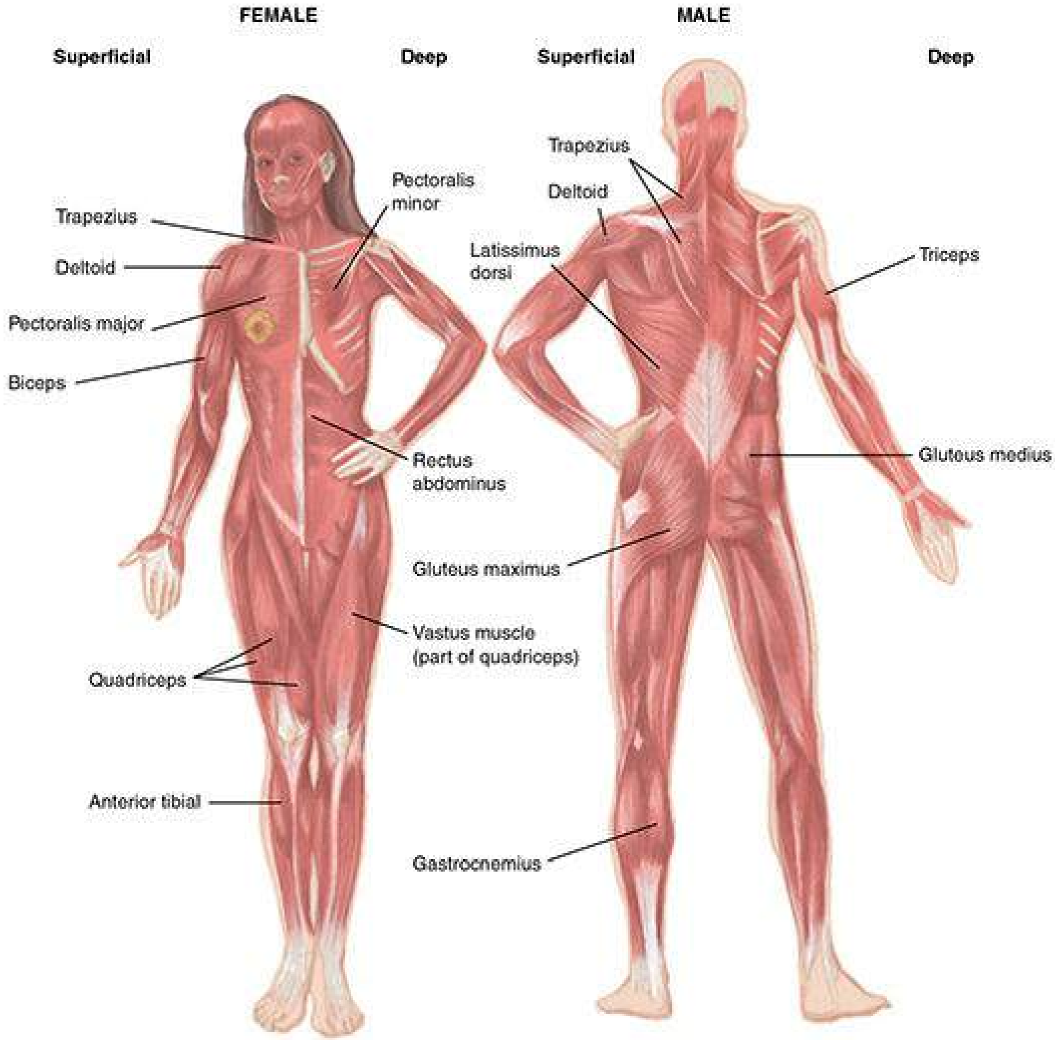

Figure 6-15 The major muscle groups.

Table 6-3 Muscles: Locations and Functions

Muscle Name	Location	Function
Biceps	Anterior, humerus	Flexes lower arm
Triceps	Posterior, humerus	Extends lower arm
Pectoralis	Anterior, thorax	Flexes and rotates arm
Latissimus dorsi	Posterior, thorax	Extends and rotates arm
Rectus abdominis	Anterior, abdomen	Flexes and rotates spine
Tibialis anterior	Anterior, tibia	Points foot toward head
Gastrocnemius	Posterior, tibia	Points foot away from head
Quadriceps (four separate muscles)	Anterior, femur	Extends lower leg
Biceps femoris	Posterior, femur	Flexes lower leg
Gluteus (three separate muscles)	Posterior, pelvis/buttocks	Extends and rotates thigh

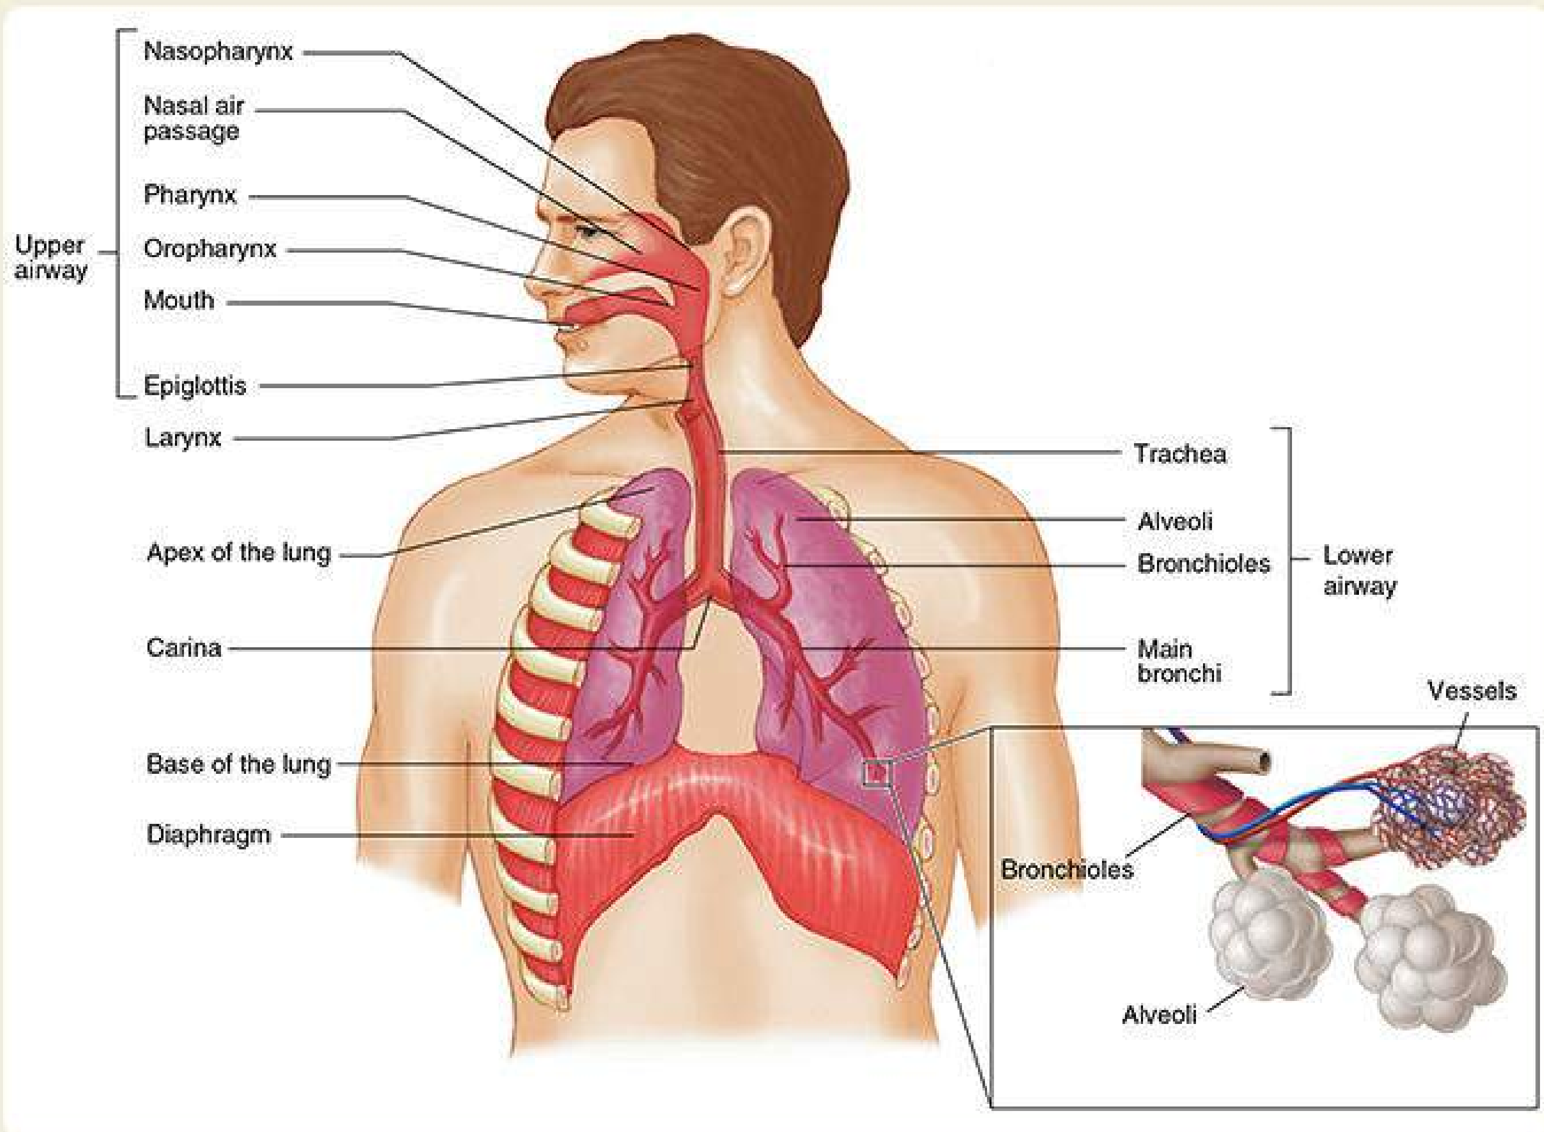

Figure 6-16 The respiratory system consists of all structures of the body that contribute to the process of breathing.

Two passageways are located at the bottom of the pharynx: the **trachea** (windpipe) and the esophagus, which is located immediately posterior to the trachea. The trachea is approximately 5 inches (13 cm) long and is a semirigid, enclosed air tube made up of rings of cartilage that are open in the back. The rings of cartilage keep the trachea from collapsing when air moves into and out of the lungs. Food and liquids enter the pharynx and pass into the esophagus, which carries them to the stomach (the digestive system is discussed later in the chapter). Air and other gases enter the trachea and go to the lungs.

Protecting the opening of the trachea is a thin, leaf-shaped flap called the **epiglottis**. This flap allows air to pass into the trachea but prevents food and liquid from entering the airway under normal circumstances. Air moves past the epiglottis into the larynx and the trachea.

The Lower Airway

The **Adam's apple**, or **thyroid cartilage**, which tends to be more visible in men, is in the anterior midline portion of the neck. The thyroid cartilage is actually the anterior part of the larynx. Tiny muscles open and close the vocal cords and control tension on them. Sounds are created as air is forced past the vocal cords, making them vibrate. The pitch of the sound changes as the cords open and close. You can feel the vibrations if you place your fingers lightly on the larynx as you speak or sing. The vibrations of air are shaped by the tongue and muscles of the mouth to form understandable sounds. Immediately below the thyroid cartilage is the palpable **cricoid cartilage**.

Between the thyroid and cricoid cartilage lies the **cricothyroid membrane**, which can be felt as a depression in the midline of the neck just inferior to the thyroid cartilage. Below the cricoid cartilage is the trachea. The trachea ends at the carina and divides into two smaller tubes. These tubes are the right and left mainstem bronchi, which enter the lungs. Each mainstem bronchus immediately branches within the lung into smaller and smaller airways.

Lungs

The two lungs are held in place by the trachea, the arteries and veins, and the pulmonary ligaments. Each lung is divided into lobes. The right lung has three lobes: the upper, middle, and lower lobes. The left lung has an upper lobe and a lower lobe. Each lobe is divided further into segments. The bronchioles end in about 700 million tiny, grapelike air sacs called **alveoli** Figure 6-17.

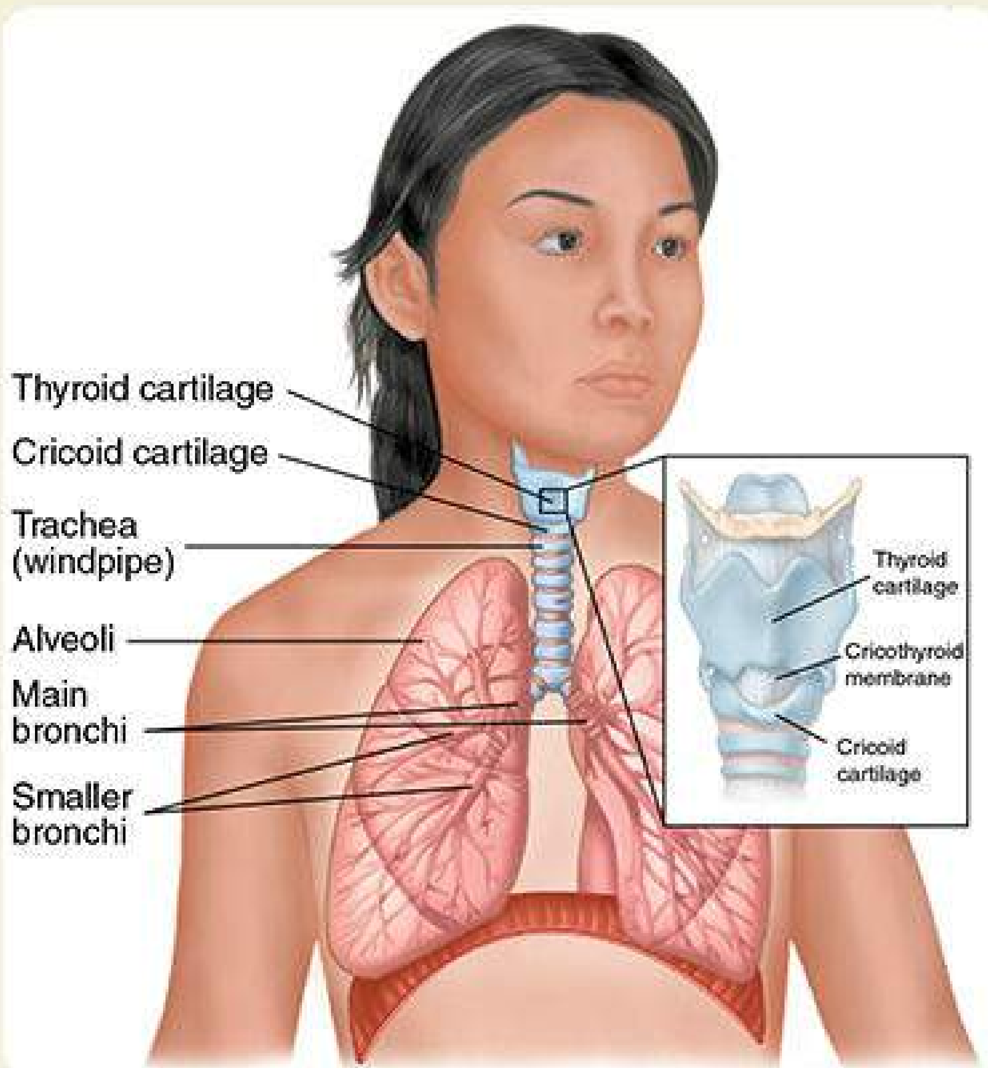

Figure 6-17 The lungs contain millions of air sacs (alveoli), which lie at the ends of air passages. Small blood vessels surround the alveoli, allowing for gas exchange.

YOU are the Provider PART 2

When you arrive at the scene, you find the patient lying on his side on the floor of his bedroom. His knees are drawn up to his abdomen, and he is in severe pain. As you assess the patient, your partner opens the jump kit and prepares to begin treatment.

Recording Time: 0 Minutes	
Appearance	Restless; diaphoretic; in severe pain
Level of consciousness	Conscious and alert
Airway	Open; clear of secretions and foreign bodies
Breathing	Increased rate; adequate depth
Circulation	Radial pulses, present and strong; skin, cool and clammy

The patient tells you that the pain is in the right upper side of his abdomen and that it began suddenly about 20 minutes ago.

2. On the sole basis of the patient's chief complaint, which organ or organs should you suspect is/are the cause of his condition?
3. What additional questions should you ask to gather more information about his chief complaint?

The primary purpose of all of the respiratory structures that have been discussed so far is to provide a pathway for air to reach the alveoli. The exchange of oxygen and carbon dioxide occurs within these alveoli. They do all the work and are referred to as the functional units of the respiratory system. The walls of the alveoli contain a network of tiny blood vessels (pulmonary capillaries) that carry the carbon dioxide from the body to the lungs and the oxygen from the lungs to the body.

The lungs cannot expand and contract themselves because they have no muscle. There is, however, a very definite mechanism in place to ensure that the lungs follow the motion of the chest wall and expand or contract with it. Covering each lung is a layer of smooth, glistening tissue called **pleura** Figure 6-18. Another layer of pleura lines the inside of the chest cavity. The two layers are called visceral pleura (covering the lungs) and parietal pleura (lining the chest wall). Between these two layers is a small amount of fluid that permits smooth gliding of the tissues. This is very similar in concept to how joints work.

Between the parietal pleura and the visceral pleura is the **pleural space**, called a *potential* space because under normal conditions, the space does not exist. These two layers are usually sealed tightly to one another by a thin film of fluid. When the chest wall expands, the lung is pulled with it and made to expand by the force exerted through these closely applied pleural surfaces. When blood or air leaks into the pleural space, however, the surfaces separate.

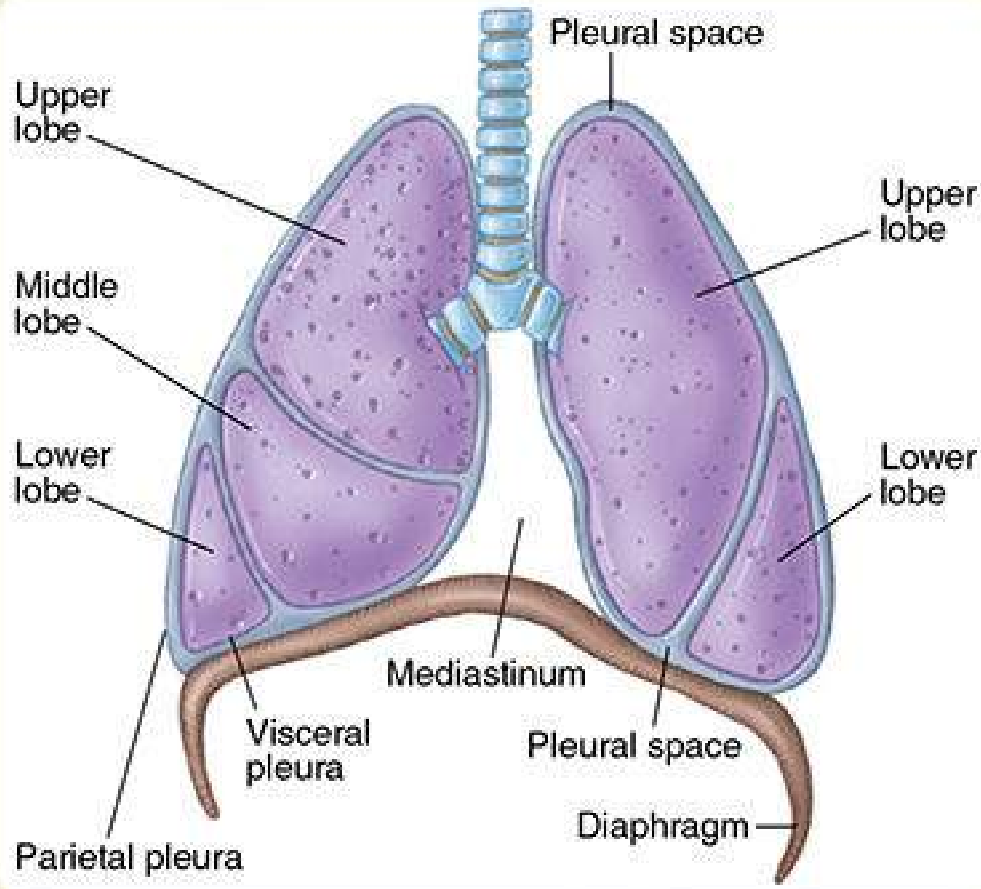

Figure 6-18 The pleura lining the chest wall and covering the lungs is an essential part of the breathing mechanism. The pleural space is not an actual space until blood or air leaks into it, causing the pleural surfaces to separate.

Muscles of Breathing

There are several muscles involved in making the lungs expand and contract. The primary muscle is the **diaphragm**. The diaphragm is unique because it has characteristics of voluntary (skeletal) and involuntary (smooth) muscles. It is a dome-shaped muscle that divides the thorax from the abdomen and is pierced by the great vessels and the esophagus **Figure 6-19**. It acts like a voluntary muscle when you take a deep breath, cough, or hold your breath. You control these variations in the way you breathe.

However, unlike other skeletal or voluntary muscles, the diaphragm performs an automatic function. Breathing continues during sleep and at all other times. Even though you can hold your breath or temporarily breathe faster or slower, you cannot continue these variations in breathing pattern indefinitely. When the concentration of carbon dioxide becomes too high, automatic regulation of breathing resumes. Therefore, although the diaphragm looks like voluntary skeletal muscle and is attached to the skeleton, it behaves, for the most part, like an involuntary muscle.

The other muscles involved in breathing are the neck (cervical) muscles, the intercostal muscles, the abdominal muscles, and the pectoral muscles. During inhalation, the diaphragm and intercostal muscles contract. When the diaphragm contracts, it moves down slightly, enlarging the thoracic cage from top to bottom. When the intercostal muscles contract, they move the ribs up and out. These actions combine to enlarge the chest cavity in all dimensions. As the chest cavity enlarges, pressure in the pleural space falls and air rushes into the lungs. This is referred to as negative pressure breathing because air is essentially sucked into the lungs. This part of the cycle is active, requiring the muscles to contract.

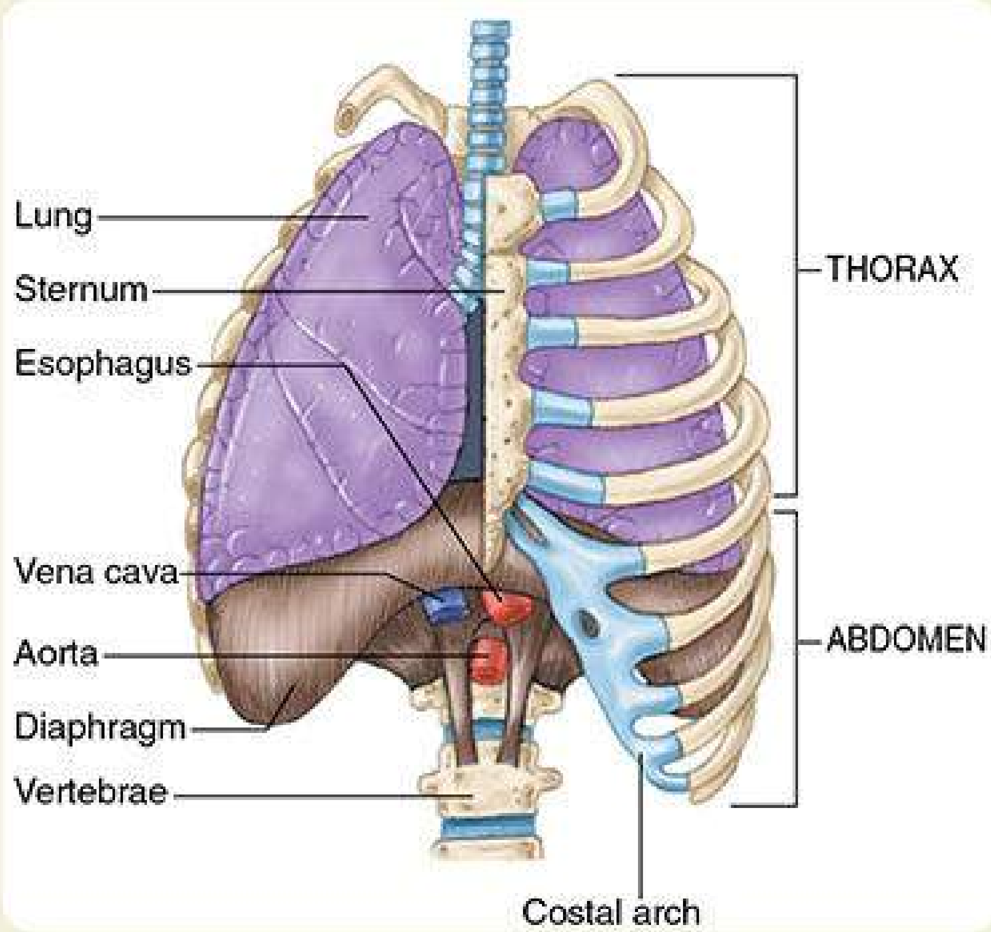

Figure 6-19 The dome-shaped diaphragm divides the thorax from the abdomen. It is pierced by the great vessels and the esophagus.

During exhalation, the diaphragm and the intercostal muscles relax. Unlike inhalation, exhalation does not normally require muscular effort. As these muscles relax, all dimensions of the thorax decrease, and the ribs and muscles assume a normal resting position. When the volume of the chest cavity decreases, air in the lungs is compressed into a smaller space. Pressure is increased, and air is pushed out through the trachea. This phase of the cycle is passive.

The process of breathing is typically easy and requires little muscular effort. But, now imagine breathing through a straw and suddenly the diameter of the straw decreases. The smaller the diameter of the straw, the more effort you will now have to exert to move air. As the resistance in the airway increases, you will begin to use accessory muscle groups, namely your abdominal and pectoral muscles, to assist the diaphragm in moving that air.

Words of Wisdom

When you assess a patient, make sure you assess both sides of the patient. It may seem like a waste of time to assess the left arm when the right arm is the one that is injured. However, you need to compare the sides to see whether there are differences. An abnormality on one arm may be "normal" if the same abnormality is found on the other arm. This idea of comparing sides applies to the respiratory system as well. You need to listen to both sides of the chest to evaluate the patient's lung sounds. Lung sounds can change on only one side of the chest, or they can change on both sides of the chest. Use all of the information you obtain from both sides of the body to help you make your patient care decisions.

The Respiratory System: Physiology

The function of the respiratory system is to provide the body with oxygen and eliminate carbon dioxide. The exchange of oxygen and carbon dioxide takes place in the lungs and in the tissues. It is a complicated process that occurs automatically unless the airways or the lungs become diseased or damaged. There are two separate, yet interdependent, overall functions of the respiratory system: ventilation and respiration.

Ventilation is the simple movement of air between the lungs and the environment. It requires chest rise and fall. You are providing artificial ventilation when you assist a patient who is not breathing with a bag-valve mask (BVM)—a large bag filled with air that, when squeezed, pushes air out one end. The typical device holds approximately 1,000 to 1,200 mL of air. BVMs are designed to rapidly reinflate and allow you to control the amount of air that is moved to achieve chest rise and fall in any given patient. Artificial ventilation is provided in the hope that your patient will resume respiration. **Respiration** is the process of gas exchange. Respiration provides the much-needed oxygen to cells and removes the waste product carbon dioxide. This exchange of gases also helps to control the pH of the blood.

Respiration

As blood travels through the body, it gives its oxygen and nutrients to various tissues and cells. Oxygen passes from the blood through the capillaries to tissue cells. In the reverse process, carbon dioxide and cell waste pass from tissue cells through capillaries to the blood **Figure 6-20**.

Each time you take a breath, the alveoli receive a supply of oxygen-rich air. Recall that the oxygen then passes into a network of pulmonary capillaries, which are located in the walls of the alveoli. The walls of the capillaries and the alveoli are extremely thin. Thus, air in the alveoli and blood in the capillaries are separated by two very thin layers of tissue.

Oxygen and carbon dioxide pass rapidly across these thin tissue layers by diffusion. **Diffusion** is a passive process in which molecules move from an area with a higher concentration of molecules (the air) to an area of lower concentration (the bloodstream). There are more oxygen molecules in the alveoli than in the blood. Therefore, the oxygen molecules move from the alveoli into the blood. Because there are more carbon dioxide molecules in the blood than in the inhaled air, carbon dioxide moves from the blood into the alveoli. This process is completely passive—nature does all the work.

The blood does not use all the inhaled oxygen as it passes through the body. Exhaled air contains 16% oxygen and 3% to 5% carbon dioxide; the rest is nitrogen **Figure 6-21**.

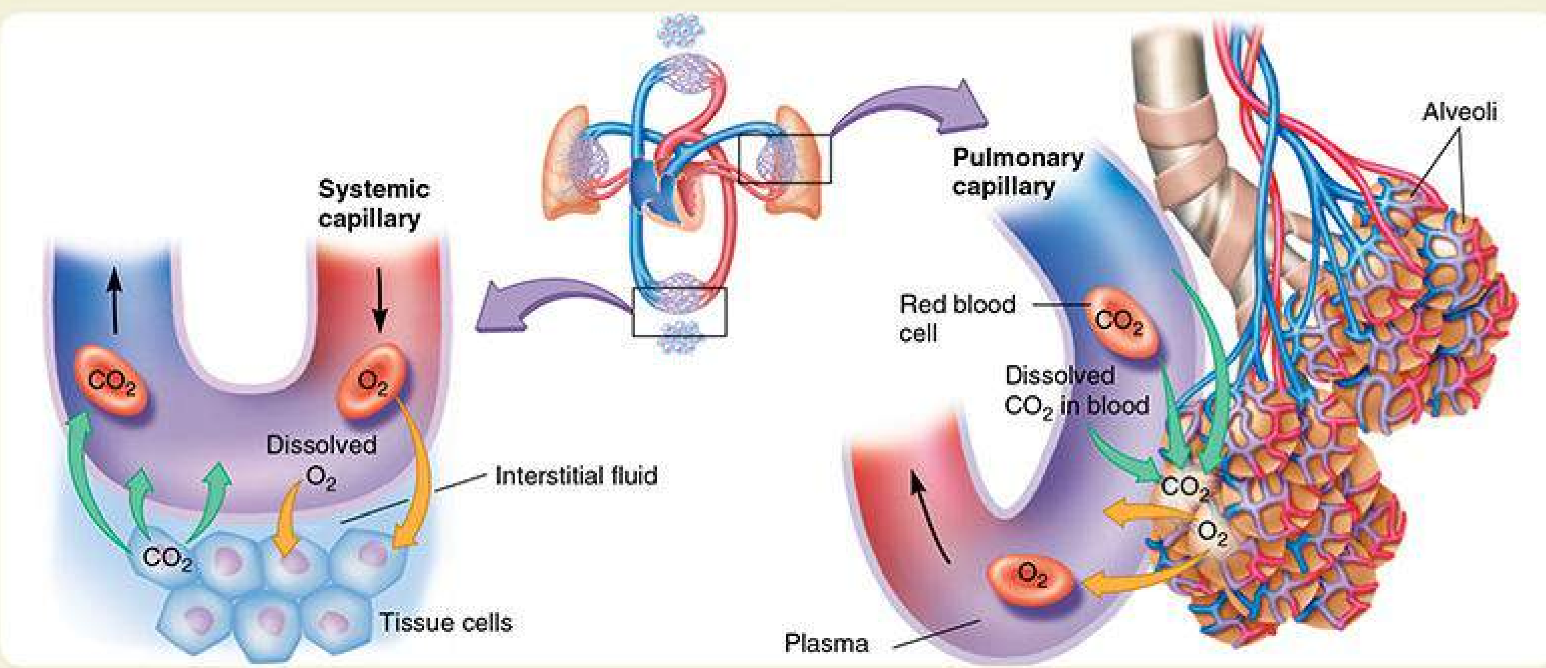

Figure 6-20 In the capillaries, oxygen (O_2) passes from the blood to the tissue cells, and carbon dioxide (CO_2) and waste pass from the tissue cells to the blood.

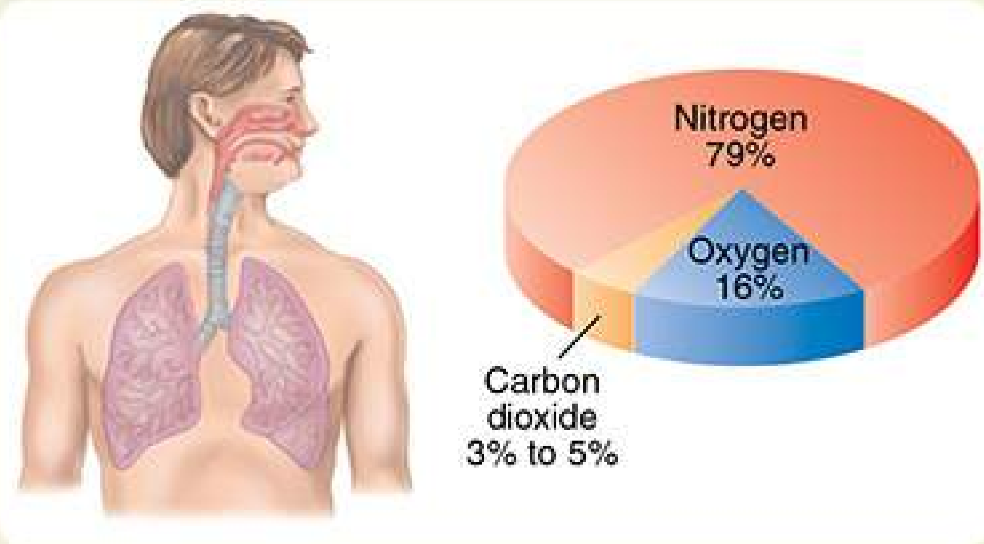

Figure 6-21 The components of exhaled air include oxygen, carbon dioxide, and nitrogen.

The Chemical Control of Breathing

The brain—or more specifically, the brain stem—controls breathing. The nerves in this area act as sensors for the level of carbon dioxide in the blood and subsequently the spinal fluid. The brain automatically controls breathing if the level of carbon dioxide or oxygen in the arterial blood is too high or too low. In fact, adjustments can be made in just one breath. For these reasons, you cannot hold your breath indefinitely or breathe rapidly and deeply indefinitely.

Breathing occurs as the result of a buildup of carbon dioxide, which causes the pH to decrease in the **cerebrospinal fluid (CSF)**. CSF is a colorless fluid in and around the brain and spinal cord that cushions these structures and filters out impurities and toxins. The cells are constantly working to eliminate carbon dioxide to regulate the acid–alkaline balance of the body. When the level of carbon dioxide becomes too high, a slight change occurs in the pH (the measure of acidity) of the CSF. The medulla oblongata (a portion of the brain stem), which is sensitive to pH changes, stimulates the phrenic nerve, sending a signal to the diaphragm to increase its rate of contraction. As the diaphragm becomes more active, the respiratory rate and tidal volume increase (discussed later in this chapter). As minute volume increases more carbon dioxide is exhaled. The primary reason you breathe is to lower your level of carbon dioxide, not to increase your level of oxygen.

The body also has a “backup system” to control respiration called the **hypoxic drive**. When the oxygen level falls, this system will also stimulate breathing. There are areas in the brain, the walls of the aorta, and the carotid arteries that act as oxygen sensors. These sensors are easily satisfied by minimal levels of oxygen in the arterial blood. Therefore, the backup system, the hypoxic drive, is much less sensitive and less powerful than the carbon dioxide sensors in the brain stem.

Special Populations

The anatomy of the respiratory system in children is proportionally smaller and less rigid than in an adult **Figure 6-22**. A child’s nose and mouth are much smaller than those of an adult. The larynx, cricoid cartilage, and trachea are smaller, softer, and more flexible as well. This makes the mechanics of breathing much more delicate. A child’s pharynx is also smaller and less deeply curved. The tongue takes up proportionally more space in a child’s mouth than in an adult’s mouth.

These anatomic differences are important for you to understand. For example, the smaller larynx of a child becomes obstructed more easily. The chest wall in children is softer. Therefore, children depend more heavily on the diaphragm for breathing. You will notice that a child’s abdomen moves in and out considerably with each breath, especially in an infant. Infants younger than 1 month do not know how to breathe through their mouth. Smaller children also have proportionally larger heads compared with the rest of their body. This will affect the way you treat a suspected spinal injury. Carefully consider these differences as you assess and treat an infant or a child.

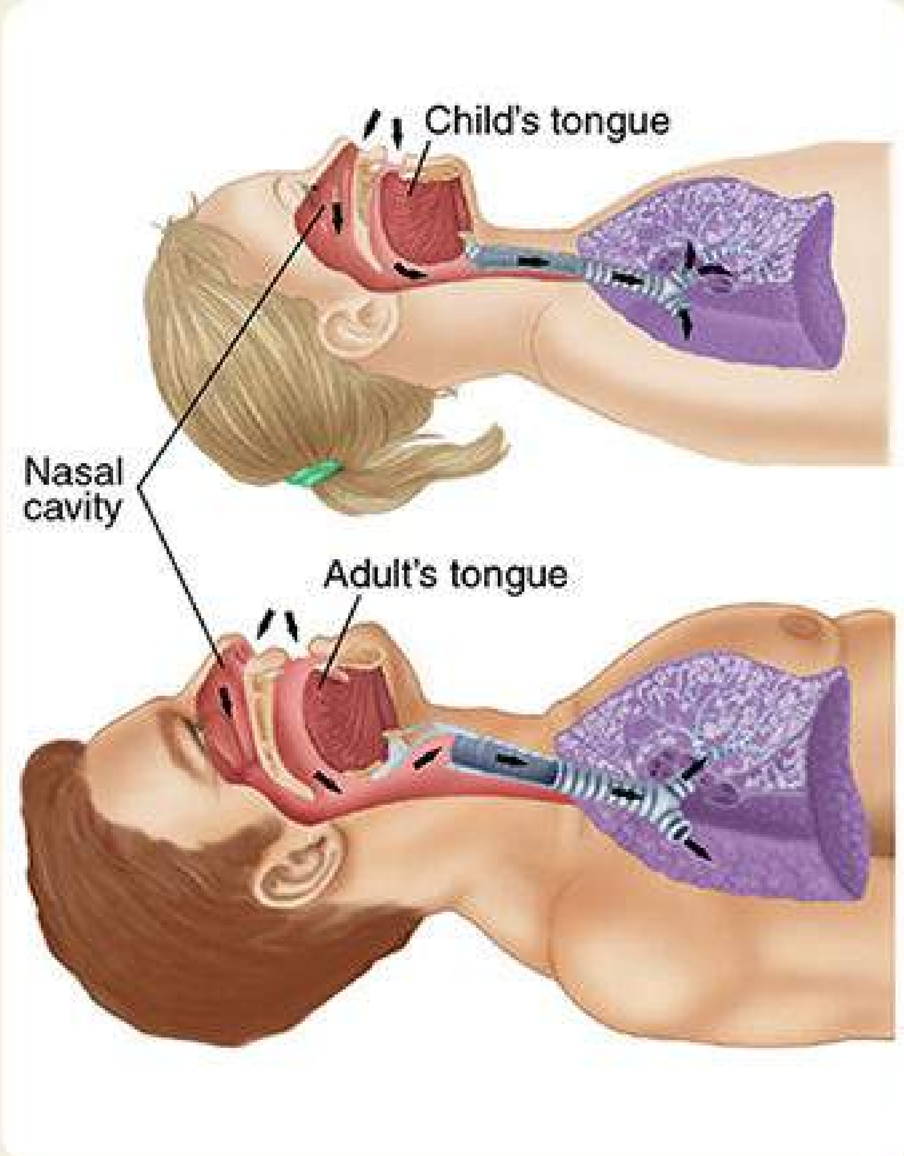

Figure 6-22 The respiratory system of a child is proportionally smaller and less rigid than that of an adult.

The Nervous System Control of Breathing

The exact way breathing occurs is complicated and also poorly understood by science. It is known that the medulla oblongata is primarily responsible for initiating the ventilation cycle and is primarily stimulated by high carbon dioxide levels. The function of the medulla is to keep you breathing without having to think about it. The medulla helps control the rhythm of breathing, initiates inspiration, sets the base pattern for respirations, and sends signals down the phrenic nerve to the diaphragm, triggering it to contract.

Special Populations

Normal breathing patterns in infants and children are essentially the same as those in adults. However, infants and children breathe faster than adults. An infant who is breathing normally will have respirations of 30 to 60 breaths/min. A child will have respirations of 12 to 40 breaths/min. Like adults, infants and children who are breathing normally will have smooth, regular inhalation and exhalation, equal breath sounds, and regular rise and fall movements on both sides of the chest.

Breathing problems in infants and children often appear the same as breathing problems in adults. Signs such as increased respirations, an irregular breathing pattern, unequal breath sounds, and unequal chest expansion indicate breathing problems in adults and children. Other signs that an infant or child is not breathing normally include the following:

- Muscle retractions, in which the muscles of the chest and neck are working extra hard in breathing
- Nasal flaring, in which the nostrils flare out as the child breathes
- Seesaw respirations in infants, in which the chest and abdominal muscles alternately contract to look like a seesaw

Exhalation becomes active when infants and children have trouble breathing. Normally, inhalation alone is the active, muscular part of breathing, as described earlier. However, with labored breathing, both inhalation and exhalation are hard work and involve the use of the accessory muscles. With labored breathing, exhalation is not passive. Instead, air is forced out of the lungs during exhalation, and the child will often begin to wheeze.

The pons, another area within the brain stem, has two areas, both of which help augment respirations during emotional or physical stress. The pons is involved in changing the depth of inspiration, expiration, or both. The medulla and the pons work together to help you get the right amount of air when you need it. The anatomy and physiology of the nervous system is discussed in more detail later in the chapter.

Ventilation

A substantial amount of air can be moved within the respiratory system. **Figure 6-23** shows the typical volumes. An adult man has a total lung capacity of 6,000 mL (equivalent to three 2-liter bottles of soda). An adult woman has about one-third less total capacity because the lung size is smaller.

Tidal volume is the amount of air that is moved into or out of the lungs during a single breath, generally 500 mL in an adult. **Inspiratory reserve volume** is the deepest breath you can take after a normal breath. Conversely, **expiratory reserve volume** is the maximum amount of air that you can forcibly breathe out after a normal breath. Gas remains in the lungs after exhalation simply to keep the lungs open. This is the **residual volume**. A loss of residual volume occurs when a person is hit in the chest and has the “wind knocked out” of him or her.

Dead space is the portion of the respiratory system that has no alveoli, and, therefore, little or no exchange of gas between air and blood occurs. The mouth, trachea, bronchi, and bronchioles are all considered dead space. When you ventilate a patient with any device, you create more dead space. Gas must first fill the device before it can be moved into the patient.

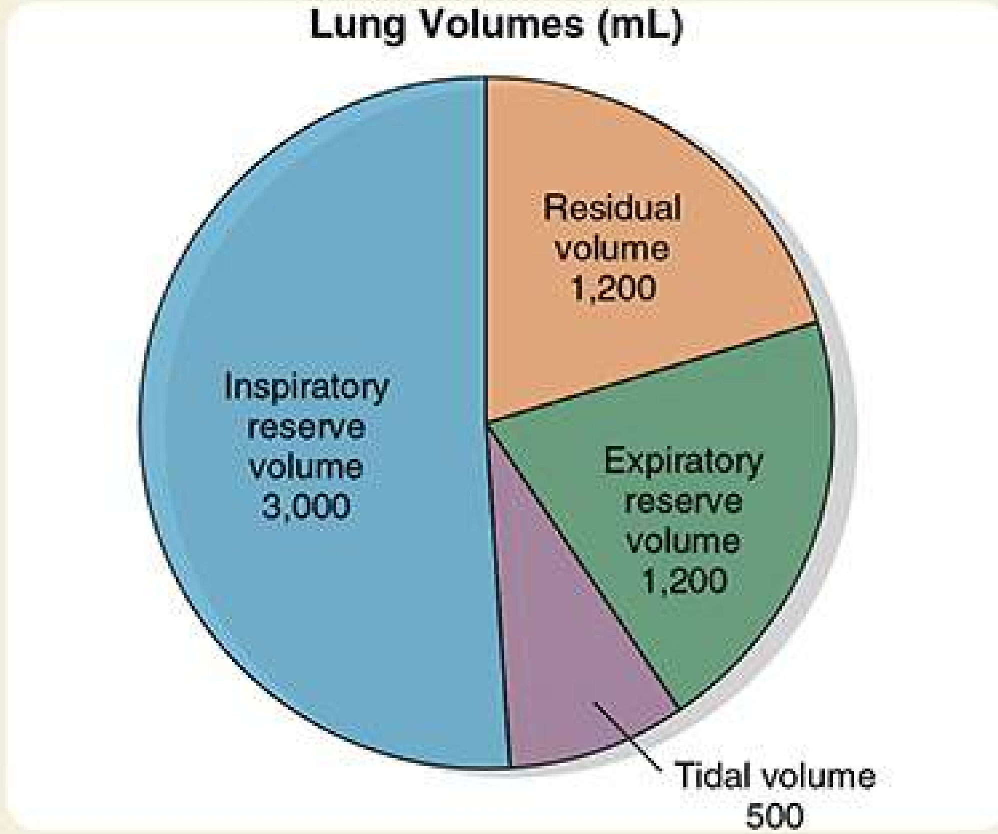

Figure 6-23 Lung volumes.

When you assess your patient, you need to accurately determine whether he or she is having trouble breathing. Often, EMTs will look at the patient's respiratory rate; this rate, however, provides only part of the information that is needed. The depth of each breath is critical information to know when assessing ventilation. **Minute volume** is another measure used to assess the amount of air that moves in and out of the lungs in 1 minute.

$$\text{Minute Volume} = \text{Respiratory Rate} \times \text{Tidal Volume}$$

This calculation helps you to determine if a patient is breathing adequately. While riding in the ambulance it will be difficult to determine the patient's exact tidal volume, but you will be able to estimate it. Consider the scenario of a patient who is breathing at a normal rate of 20 breaths/min. Yet, when you look at the patient's chest, it is barely moving. When you feel for air movement out of the mouth, you find very little movement. The patient is in trouble and needs your assistance now! Even though the patient's respiratory rate is normal, the amount of air being moved is inadequate. The minute volume is too low, and the patient needs ventilatory assistance. Always evaluate the amount of air being moved with each breath when assessing a patient's respirations.

Characteristics of Normal Breathing

You can think of a normal breathing pattern as a bellows system. Normal breathing should appear easy, not labored. As with a bellows that is used to move air to start a fire, breathing should be a smooth flow of air moving into and out of the lungs.

Normal breathing has the following characteristics:

- A normal rate and depth (tidal volume)
- A regular rhythm or pattern of inhalation and exhalation
- Clear, audible breath sounds on both sides of the chest
- Regular rise and fall movement on both sides of the chest
- Movement of the abdomen

Inadequate Breathing Patterns in Adults

An adult who is awake, alert, and speaking to you in full sentences usually has no immediate airway or breathing problems. However, keep supplemental oxygen on hand to assist with breathing should it become necessary. An adult who is not breathing well may appear to be working hard to breathe. This type of breathing pattern is called **labored breathing**. Labored breathing requires effort and may involve the accessory muscles of the chest, neck, and abdomen. The person may also be breathing much slower (fewer than 12 breaths/min) or much faster (more than 20 breaths/min) than normal. An adult at rest who is breathing normally will have respirations of 12 to 20 breaths/min Table 6-4.

Other signs that a person is not breathing normally include the following:

- Muscle retractions above the clavicles, between the ribs, and below the rib cage, especially in children
- Pale or cyanotic (blue) skin
- Cool, damp (clammy) skin
- Tripod position Figure 6-24 (a position in which the patient leans forward onto two arms)

Table 6-4 Normal Respiratory Rate Ranges

Adults	12 to 20 breaths/min
Children	12 to 40 breaths/min
Infants	30 to 60 breaths/min

Data Adapted From: Pediatric Advanced Life Support, 2012, the American Heart Association.

Figure 6-24 A patient in the tripod position will sit leaning forward on outstretched arms with the head and chin thrust slightly forward.

A patient in cardiac arrest may appear to be breathing. These occasional, gasping breaths are called **agonal gasps** and occur when the respiratory center in the brain continues to send signals to the breathing muscles. These gasps are not adequate because they are slow and generally shallow. In patients with agonal gasps, you will need to provide artificial ventilations and, most likely, chest compressions, both of which will be discussed in later chapters.

The Circulatory System: Anatomy

The **circulatory system** is a complex arrangement of connected tubes, including the arteries, arterioles, capillaries, venules, and veins **Figure 6-25**. Another name for this system is the cardiovascular (heart/ blood vessels) system. The circulatory system is entirely closed, with capillaries connecting arterioles and venules. There are two circuits in the body: the **systemic circulation** in the body and the **pulmonary circulation** in the lungs. The systemic circulation, the circuit in the body, carries oxygen-rich blood from the left ventricle through the body and back to the right atrium. In the systemic circulation, as blood passes through the tissues and organs, it gives up oxygen and nutrients and absorbs cellular wastes and carbon dioxide. The cellular wastes are eliminated in passages through the liver and kidneys. The pulmonary circulation, the circuit in the lungs, carries oxygen-poor blood from the right ventricle through the lungs and back to the left atrium. In the pulmonary circulation, as blood passes through the lungs, it is refreshed with oxygen and gives up carbon dioxide.

The Heart

The **heart** is a hollow muscular organ approximately the size of a clenched fist. It is made of a specialized muscle tissue called cardiac muscle or **myocardium** and actually works as two paired pumps; the left side is more muscular. A wall called the septum divides the heart down the middle into right and left sides. Each side of the heart is divided again into an upper chamber (**atrium**) and a lower chamber (**ventricle**). The left side of the heart, which pumps blood to the body, is a high-pressure pump; the right side supplies blood to the lungs and is a low-pressure pump.

The heart is an involuntary muscle. As such, it is under the control of the autonomic nervous system. However, it has its own electrical system and continues to function even without its central nervous system control. It is distinct from skeletal or smooth muscle in its requirement for a continuous supply of oxygen and nutrients.

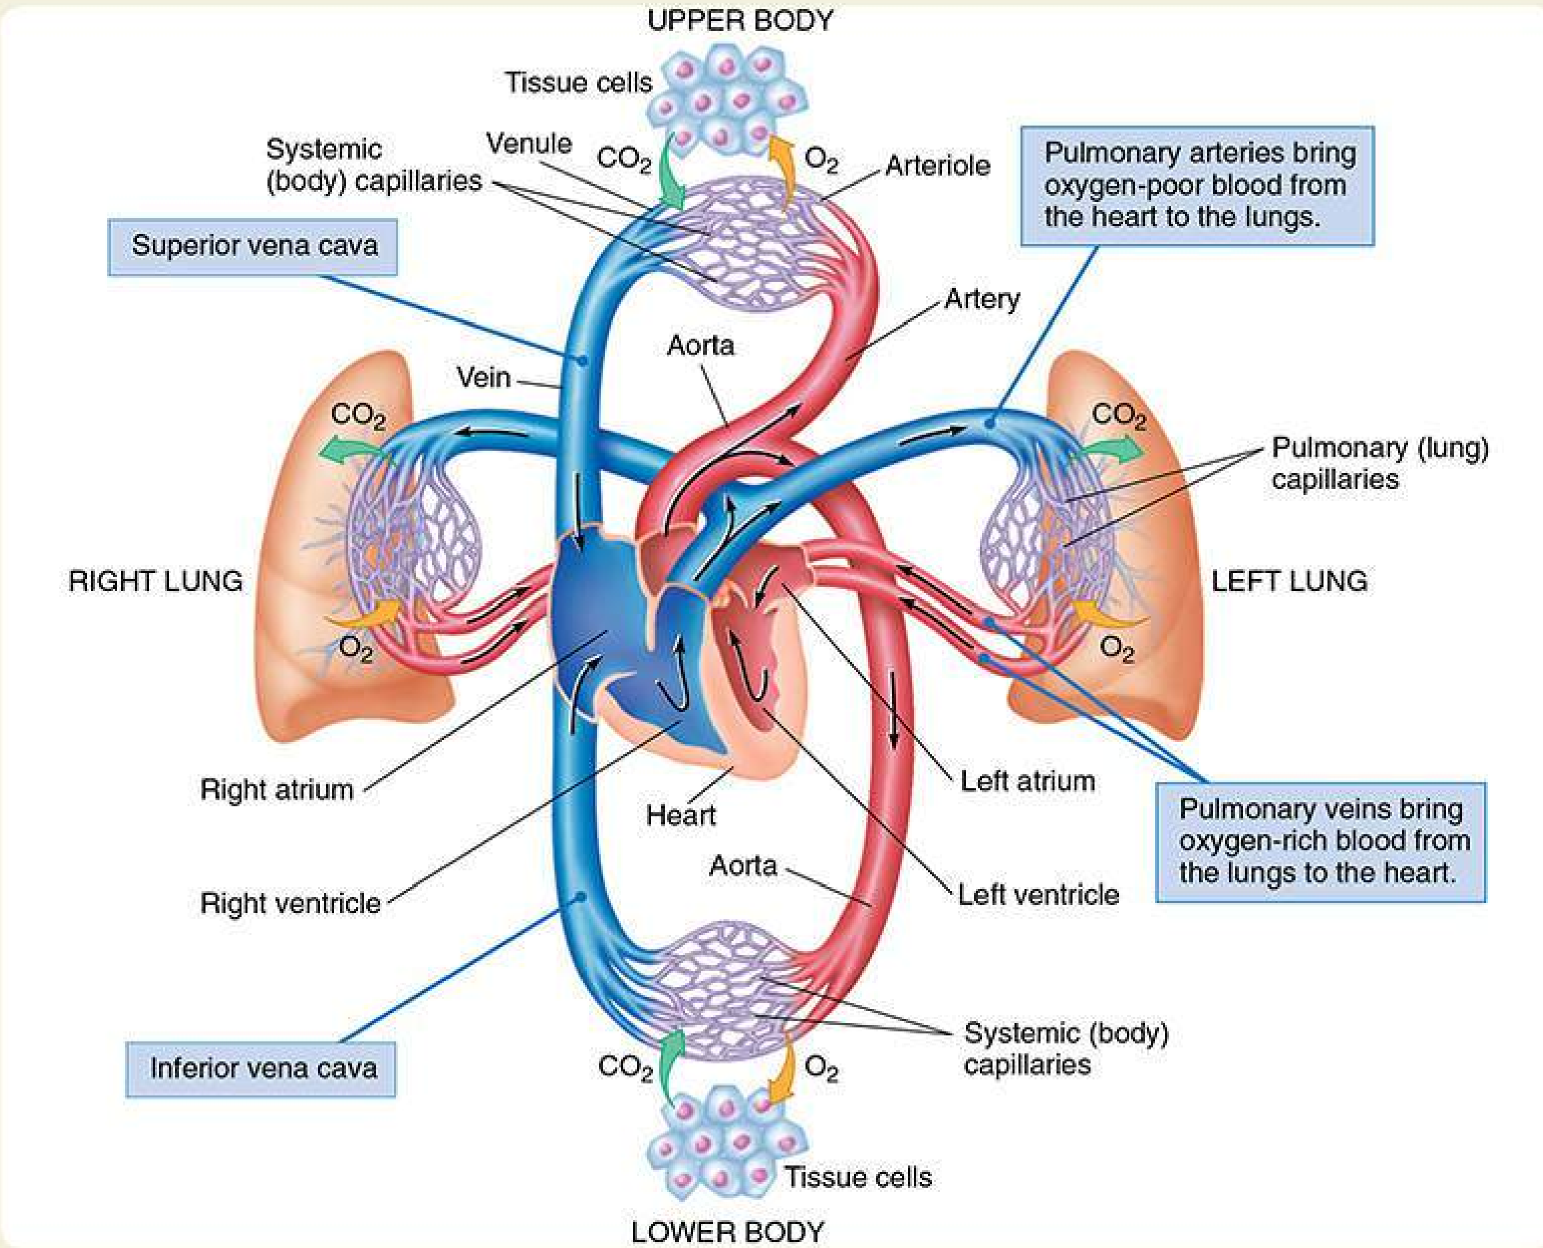

Figure 6-25 The circulatory system includes the heart, arteries, veins, and interconnecting capillaries. The capillaries are the smallest vessels and connect venules and arterioles. At the center of the system, and providing its driving force, is the heart. Blood circulates through the body under pressure generated by the two sides of the heart.

The heart must function continuously from birth to death and has developed special adaptations to meet the needs of this continuous function. It can tolerate a serious interruption of its own blood supply for only a very few seconds before the signs of a heart attack develop. Thus, its blood supply is rich and well distributed.

Circulation

The heart muscle's blood supply comes from the aorta. The aorta has two branches at its base that form the left and right coronary arteries. These arteries supply the heart muscle with oxygenated blood **Figure 6-26**.

The right side of the heart receives blood from the veins of the body **Figure 6-27A**. The blood enters from the superior and inferior venae cavae into the right atrium and then passes through the tricuspid valve to fill the right ventricle. After the right ventricle is filled, the tricuspid valve closes to prevent backflow after the right ventricular muscle contracts. Contraction of the right ventricle causes blood to flow through the pulmonic valve into the pulmonary artery and the pulmonary circulation.

The left side receives oxygenated blood from the lungs through the **pulmonary veins** into the left atrium, where the blood passes through the mitral valve into the left ventricle **Figure 6-27B**. Contraction of this most muscular of the pumping chambers pumps the blood through the aortic valve into the aorta and then to the arteries of the body.

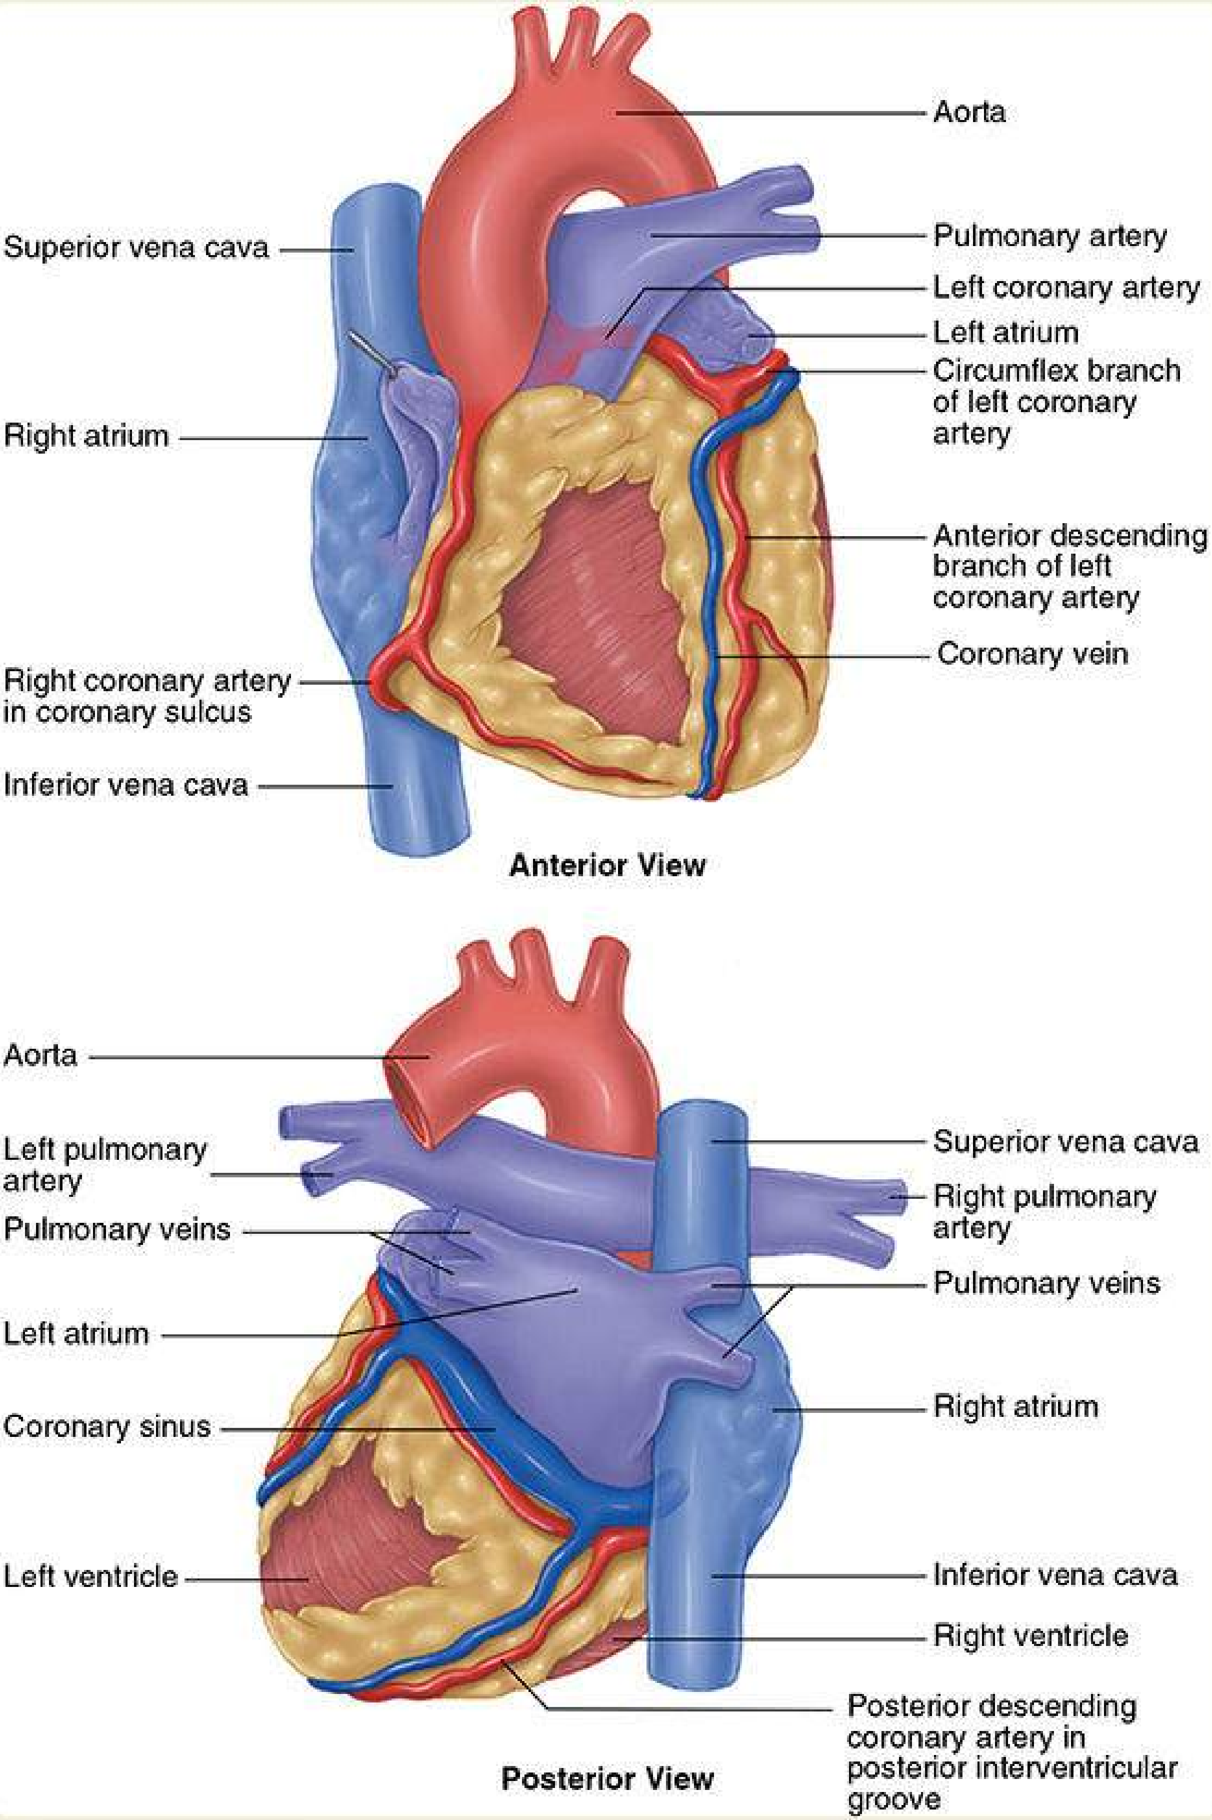

Figure 6-26 The two main coronary arteries supply the heart with blood.

The flow of blood through the four heart chambers is governed by one-way valves. The valves prevent the backflow of blood and keep it moving through the circulatory system in the proper direction. The **chordae tendineae** are thin bands of fibrous tissue that attach to the valves in the heart and prevent them from inverting. When a valve controlling the filling of a heart chamber is open, the other valve allowing it to empty is shut and vice versa. Normally, blood moves in only one direction through the entire system.

Normal Heartbeat

In the normal adult, the resting heartbeat may range from 60 to 100 beats/min. A very well-conditioned athlete may have a normal resting **heart rate (HR)** of 50 to 60 beats/min. During vigorous physical activity, the heart rate may rise to as fast as 180 beats/min. At each beat, 70 to 80 mL of blood is ejected from the adult heart. The amount of blood moved in one beat is called the **stroke volume (SV)**. In 1 minute, the entire blood volume of 5 to 6 L is circulated through all the vessels. The amount of blood moved in 1 minute is called the **cardiac output (CO)**. Cardiac output is equal to heart rate times stroke volume. Mathematically, cardiac output can be expressed as follows:

$$CO = HR \times SV$$

For example:

70 beats/min × 75 mL/beat = 5,250 mL/min or 5.25 L/min

Electrical Conduction System

A network of specialized tissue that is capable of conducting electrical current runs throughout the heart. The flow of electrical current through this network causes smooth, coordinated contractions of the heart. These contractions produce the pumping action of the heart. Each mechanical contraction of the heart is associated with two electrical processes. The first is depolarization, during which the electrical charges on the surface of the muscle cell change from positive to negative. The second is repolarization, during which the heart returns to its resting state and the positive charge is restored to the surface.

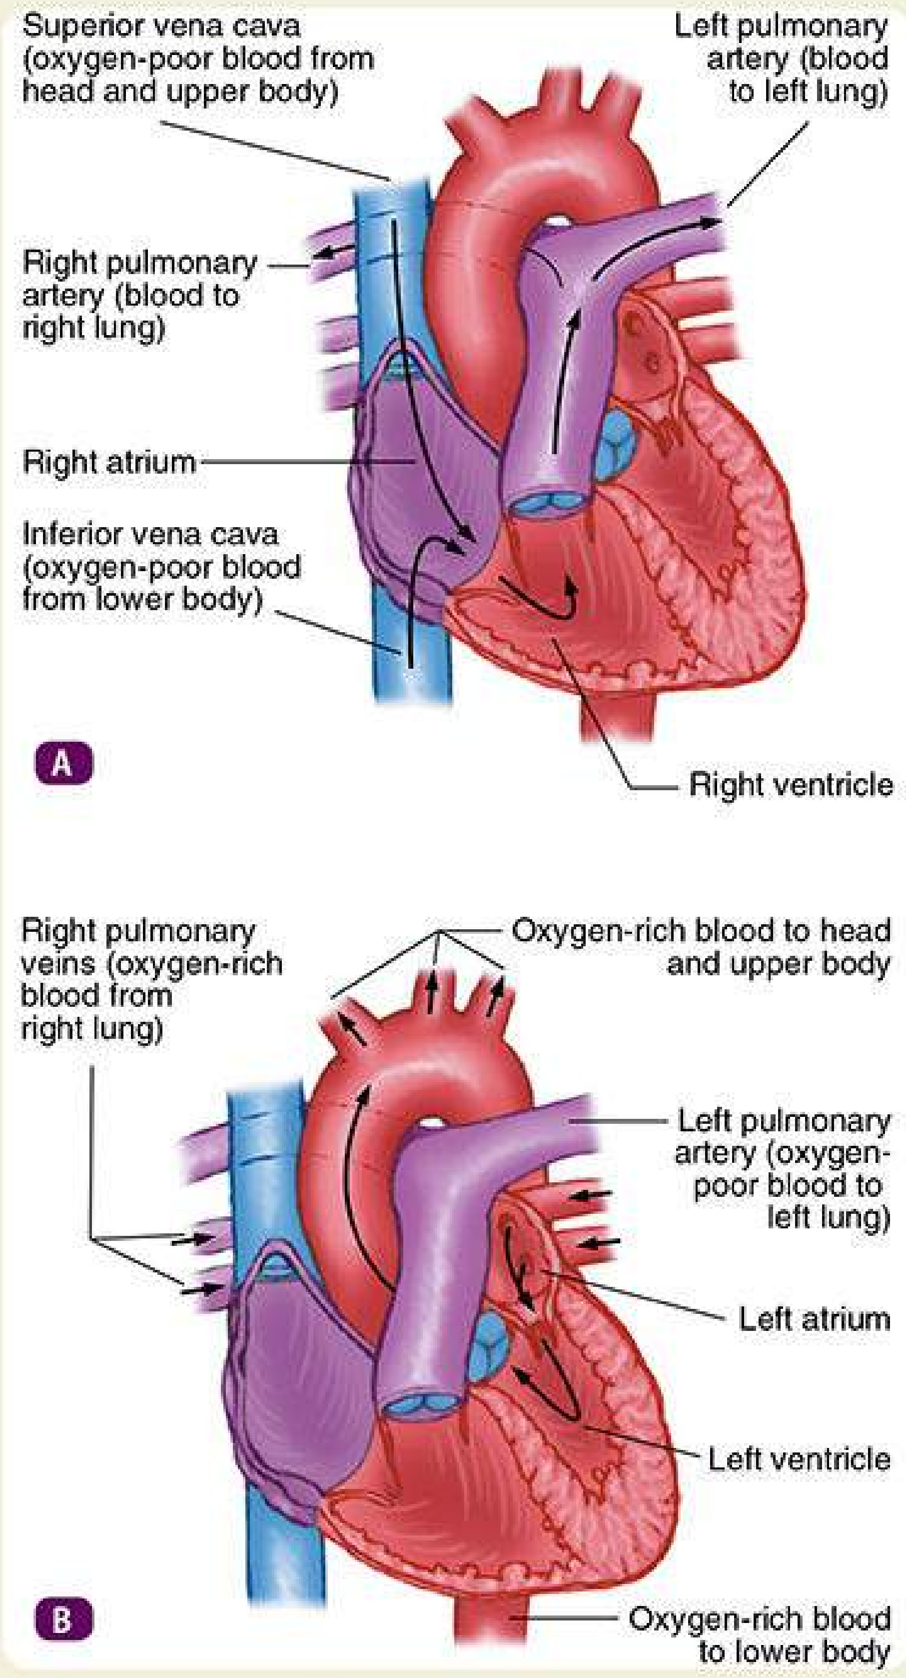

Figure 6-27 **A.** The right (slower pressure) side of the heart pumps blood from the body through the lungs. **B.** The left (higher-pressure) side of the heart pumps oxygen-rich blood to the rest of the body.

When the heart is working normally, the electrical impulse begins high in the atria at the sinoatrial node, then travels to the atrioventricular node and bundle of His, and moves through the Purkinje fibers to the ventricles. This movement produces a smooth flow of electricity through the heart, which depolarizes the muscle and produces a coordinated pumping contraction. Just as the walls of the heart can be injured when deprived of blood flow and oxygen, if areas of the heart's conduction system are deprived of blood flow and oxygen, serious abnormalities of the heart's rate, rhythm, and coordinated contraction can occur. Simply put, when the conduction system is injured, the heart will not beat properly. This may lead to dangerously low blood pressure which, if untreated, can result in the patient experiencing a loss of consciousness or cardiac arrest. Blood pressure is discussed later in the chapter.

Words of Wisdom

Many of the abnormal cardiac rhythms associated with cardiac arrest can be effectively treated with defibrillation. Therefore, any patient in cardiac arrest should have an automated external defibrillator (AED) applied as soon as possible.

Arteries

The arteries carry blood from the heart to all body tissues **Figure 6-28**. They branch into smaller arteries and then into arterioles. The arterioles, in turn, branch into the vast network of capillaries. The walls of an artery are made of fine, circular muscle tissue. Some arteries are made of fine circular muscle and elastic tissue.

Arteries contract to accommodate loss of blood volume and increase blood pressure. Blood is supplied to tissues as they need it. For example, the digestive system is supplied with more blood after you eat a meal. The leg muscles are more heavily supplied when jogging. Some tissues need a constant blood supply, especially the heart, kidneys, and brain. Other tissues, such as the muscles in the extremities, the skin, and intestines, can function with less blood when at rest. The ability to respond to the needs of the body owes itself to the way arteries are constructed. The middle layer of the artery is the **tunica media**, where the smooth muscles are found that can contract and dilate to change the diameter of the blood vessel.

The **aorta** is the main artery leaving the back left side of the heart; it carries freshly oxygenated blood to the body. This blood vessel is found just in front of the spine in the chest and abdominal cavities. The aorta has many branches that supply the body's vital organs. The coronary arteries supply the heart; the carotid arteries supply the head; the hepatic arteries supply the liver; the renal arteries supply the kidneys; and the mesenteric arteries supply the digestive system. The aorta divides at the level of the umbilicus into the two common iliac arteries that lead to the lower extremities. All of the aorta's branches ultimately become arterioles leading into the body's capillary network.

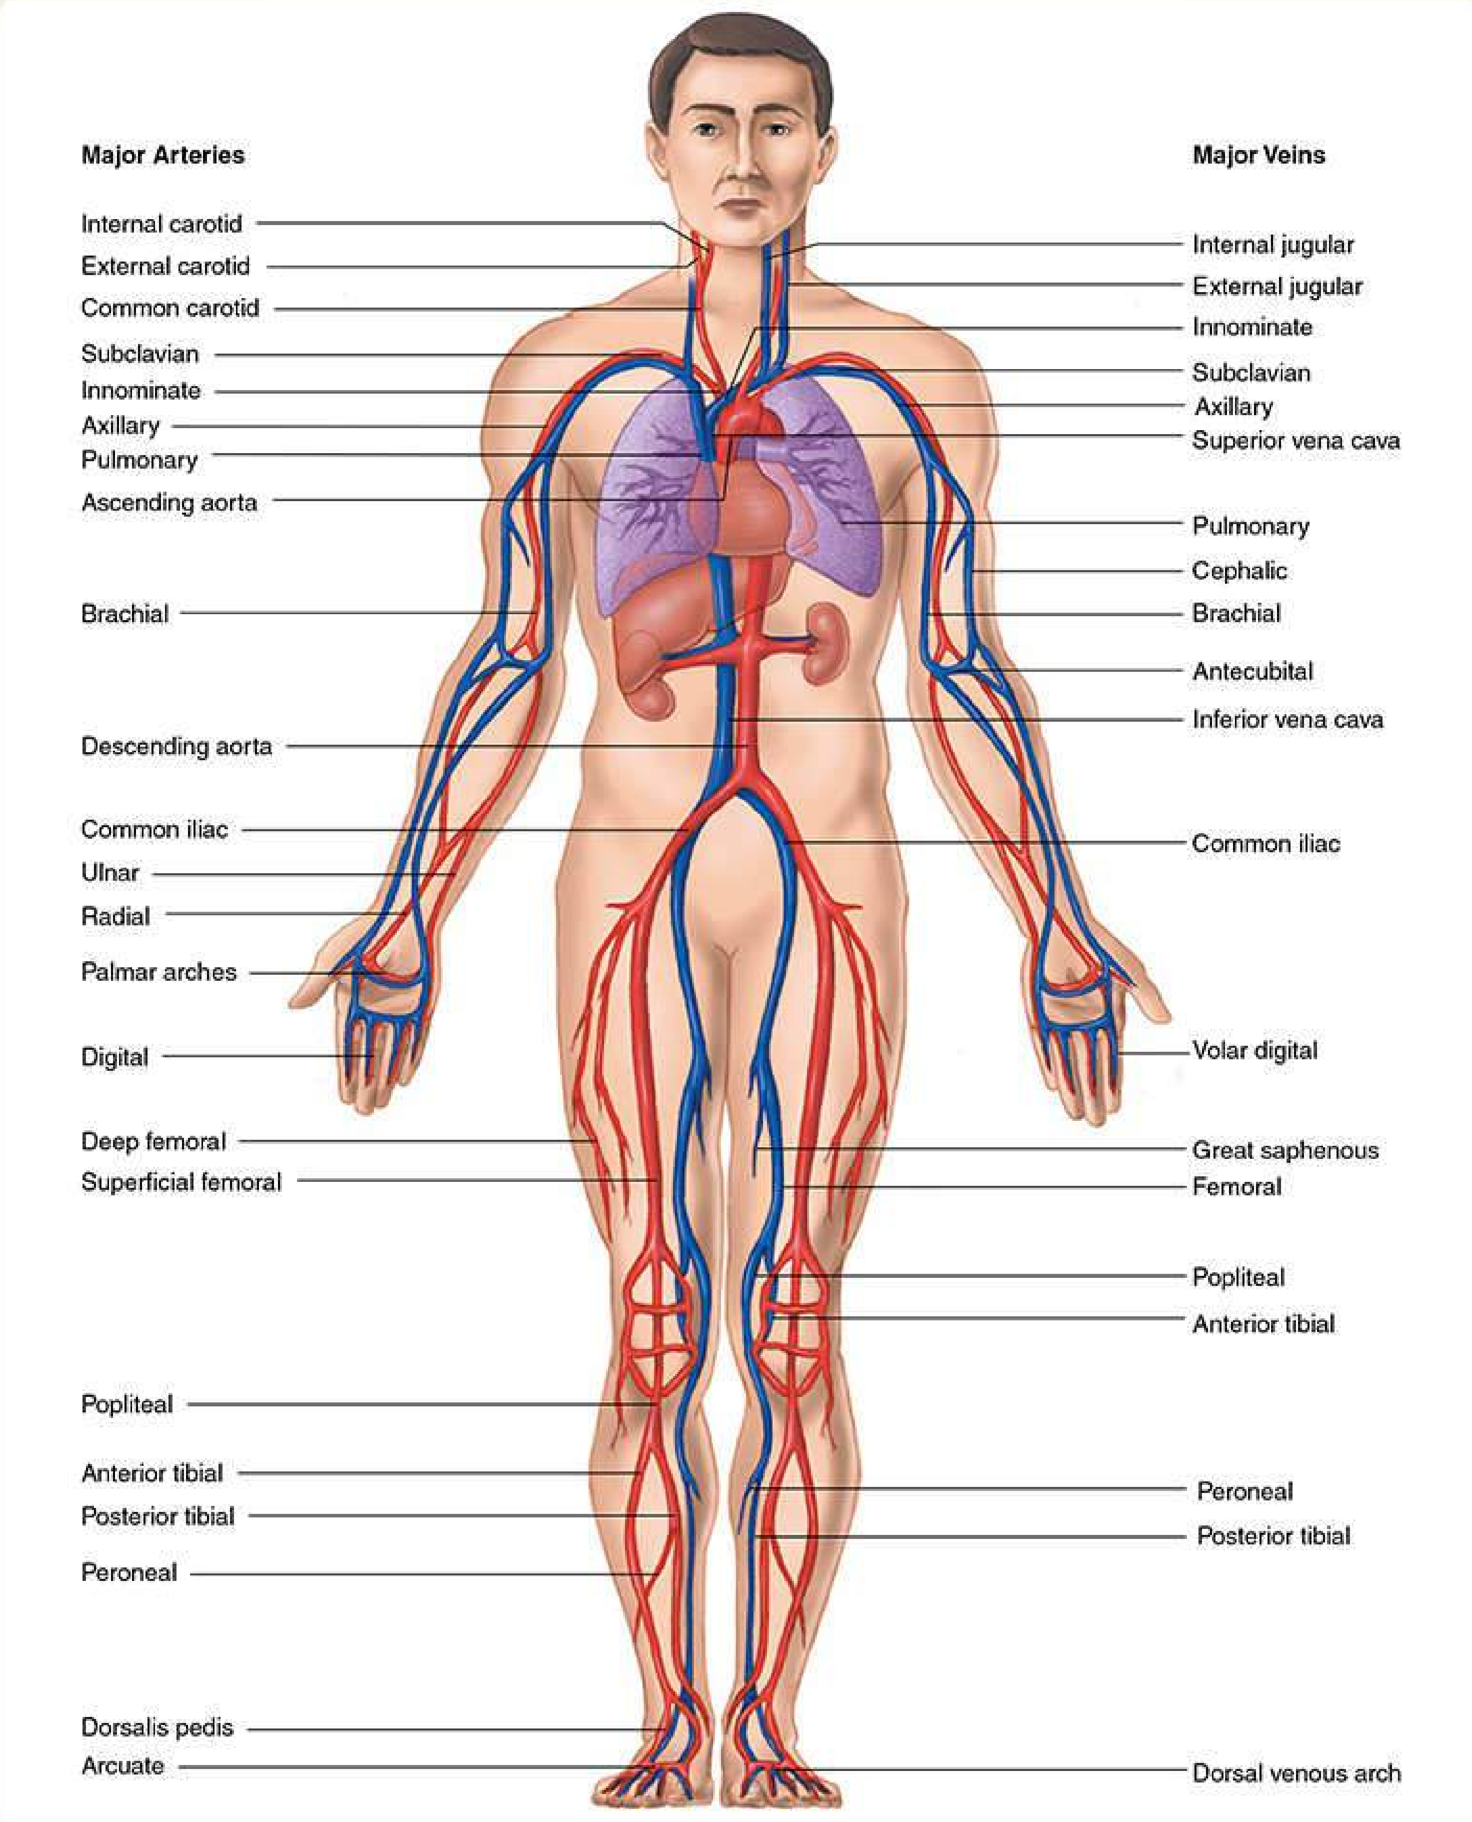

Figure 6-28 The main arteries supply blood to a vast network of smaller arteries and arterioles. Venules deliver oxygen-poor blood to the veins that return blood to the heart.

The **pulmonary artery** begins at the right side of the heart and carries oxygen-depleted blood to the lungs. It divides into finer and finer branches until it meets with the pulmonary capillary system located in the thin walls of the alveoli. These arteries are the only ones in the body that carry oxygen-depleted blood.

Arteries branch into smaller arteries and then into arterioles. **Arterioles** are the smallest branches of an artery leading to the vast network of capillaries.

The **pulse**, which is palpated most easily at the neck, wrist, or groin, is created by the forceful pumping of blood out of the left ventricle and into the major arteries. It is present throughout the entire arterial system. It can be felt most easily where the larger arteries near the skin can be pushed against a solid structure, like a bone or large muscle **Figure 6-29**. Pulses and their locations are listed in **Table 6-5**.

Capillaries

In the body, there are billions of cells and billions of capillaries. **Capillary vessels** are fragile divisions of the arterial system that allow contact between the blood and the cells of the tissues. Oxygen and other nutrients pass from blood cells and plasma in the capillaries to the individual tissue cells through the very thin wall of the capillary. Carbon dioxide and other metabolic waste products pass in a reverse direction from the tissue cells to the blood to be carried away. Blood in arteries is characteristically bright red, because its hemoglobin is rich in oxygen. Blood in the veins is dark blue-red, because it has passed through a capillary bed and given up its oxygen to the cells. Capillaries connect directly at one end with the flow-regulating arterioles and at the other with the venules.

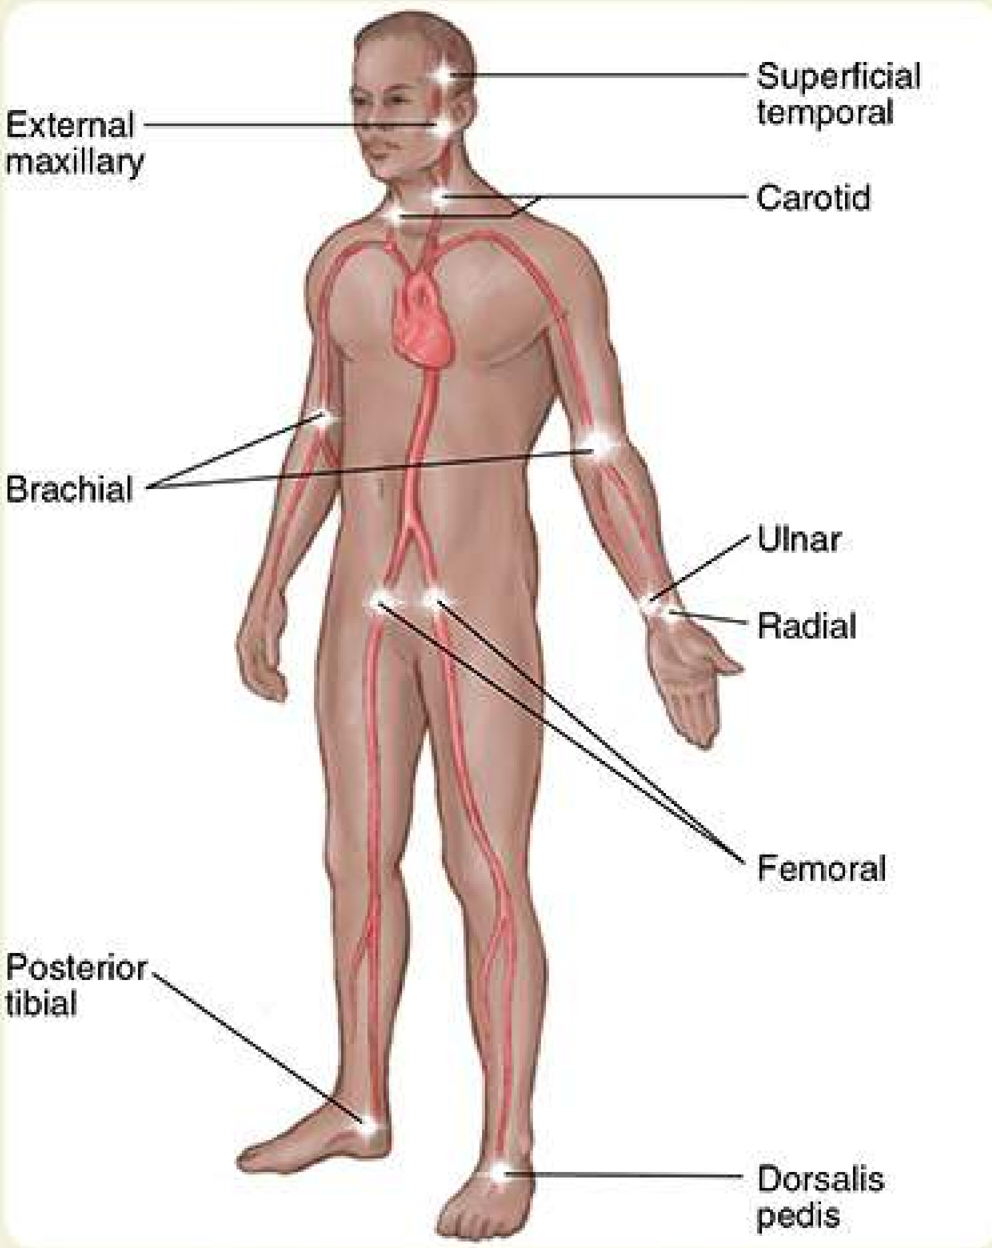

Figure 6-29 The central and peripheral pulses can be felt where the large arteries are near the skin.

Capillaries allow blood to move through them a single cell at a time. This slows the movement of blood. However, the design of this system can result in a backup of the blood cells. To solve this problem, the body has two systems in place to keep the blood cells moving. The first system consists of built-in bypasses at the capillary level. These are called arteriovenous shunts. This means that some of the blood cells will exit the arteriole only to be shunted to the venule without ever reaching the true capillary. These blood cells do not get to offload their oxygen. It may take several passes for any particular blood cell to actually reach the true capillaries where the work of delivering oxygen supplies and removing waste is done.

Table 6-5 Pulses

Central Versus Peripheral	Pulse Name	Location Where Felt
Central pulses	Carotid artery pulse	At the upper portion of the neck
	Femoral artery pulse	In the groin
Peripheral pulses	Radial artery pulse	At the wrist at the base of the thumb
	Brachial artery pulse	On the medial aspect of the arm, midway between the elbow and shoulder
	Posterior tibial artery pulse	Posterior to the medial malleolus
	Dorsalis pedis artery pulse	On the top of the foot

The other system built into the capillaries that helps control the flow of blood cells is made up of sphincters. Sphincters are small muscles in the arterioles that can be opened or closed. For example, when a patient is bleeding, chemical commands are sent to the sphincters to close. This prevents all blood cells from entering the capillaries. Blood is shunted off to another venule while still carrying oxygen. The benefit is that available blood is shunted into the major blood vessels, keeping them filled. The disadvantage is that waste is not being removed and nutrients are not being delivered to the cells.

This can go on temporarily, but eventually the tissues will be damaged if the cellular waste is not removed.

Veins

Once oxygen-depleted blood passes through the network of capillaries, it moves to the venules, which are the smallest branches of the veins. The blood returns to the heart via a network of larger and larger veins. Veins have much thinner walls than arteries and are generally larger in diameter. The veins become larger and larger and ultimately form two major vessels, called the superior and inferior venae cavae. These two veins lie just to the right of the spine and collect blood just before it enters the heart. Because pressure generated by the heart dissipates as blood passes through the capillaries, venous blood flow is assisted by gravity, skeletal muscle contraction, and intrathoracic pressure changes from breathing. One-way flow in the veins is governed by valves within the veins.

The **superior vena cava** carries blood returning from the head, neck, shoulders, and upper extremities. Blood from the abdomen, pelvis, and lower extremities passes through the **inferior vena cava**. The superior and inferior venae cavae join at the right atrium of the heart. The right ventricle receives blood from the right atrium and pumps it through the pulmonary arteries into the lungs. The venae cavae, aorta, and pulmonary arteries and veins are collectively known as the great vessels.

Recall that the body's ability to change blood flow is critical to survival. The body constricts blood vessels to change the size of the total blood volume container. A smaller container that has the same amount of liquid as the original container means a higher liquid pressure.

The state of the blood vessels—how dilated or constricted they are—is referred to as the **systemic vascular resistance (SVR)**. SVR is the resistance to blood flow within all of the blood vessels except the pulmonary vessels. The pathophysiology section of this chapter will discuss how various types of shock impact container size. In some types of shock, blood vessels dilate, the container becomes too large, and the patient's blood pressure falls dramatically **Table 6-6**.

Words of Wisdom

The terms *shock* and *hypoperfusion* are usually synonymous, at least when they are applied to multiple body systems. Localized hypoperfusion, however, such as from arterial occlusion (blockage), is not shock.

YOU are the Provider — PART 3

Your partner obtains and records the patient's vital signs and then gives him supplemental oxygen while you complete your assessment. The patient tells you he has a history of gallbladder problems. Based on your assessment and the patient's medical history, you suspect that the gallbladder is the origin of his pain.

Recording Time: 2 Minutes	
Respirations	24 breaths/min; adequate depth
Pulse	110 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	142/82 mm Hg
Oxygen saturation (Spo_2)	98% (on oxygen)

4. What additional symptoms would you expect the patient to experience based on the function of the gallbladder?

Table 6-6 Effects of Blood Vessel Diameter on Blood

State	Effects
Constricted blood vessel	Decreased size of container Increased pressure within container
Normal diameter	Balance of size and pressure
Dilated blood vessel	Increased size of container Decreased pressure within container

The Spleen

The spleen is a solid organ located under the rib cage in the left upper part of the abdomen. The spleen is actually part of the lymphatic system, but because it processes blood, it will be discussed here. At any one time there is about 450 mL of blood in the spleen. In the event of sudden blood loss, the body is able to squeeze the spleen and move this blood reservoir into the general circulation. Filtering is the basic duty of the spleen. Virtually all of the blood in the body passes though the spleen where it is filtered. Worn out blood cells, foreign substances, and bacteria are removed from the blood, and hemoglobin is recycled. Another function of this organ is to assist in the immune response.

The spleen is particularly susceptible to injury from blunt trauma because it is made of delicate tissue and because it is located directly under the flexible lower ribs, with very little soft tissue to cushion it. Therefore, it is one of the most frequently injured abdominal organs in patients with blunt trauma. Because the spleen is highly vascular, injury can lead to severe internal bleeding.

Blood Composition

Blood is a complex, thick, red fluid composed of plasma, red blood cells (erythrocytes), white blood cells (leukocytes), platelets, and protein molecules. The work of the circulatory system is to accomplish movement of blood, or perfusion.

Plasma is a sticky, yellow fluid that carries the blood cells and nutrients. This is the liquid portion of the blood. The primary components are water and proteins. All of the other components together make up 1% of the plasma:

- **Water:** Constitutes 92% of plasma
- **Proteins:** Constitute 7% of the plasma. The majority of this protein is albumin, which has a role in controlling the movement of water into and out of the circulation. Also includes clotting factors, enzymes, and some hormones
- **Oxygen:** Very little oxygen is dissolved in the plasma; almost all oxygen is bound to hemoglobin (found in red blood cells)
- **Carbon dioxide:** Transported as bicarbonate in the plasma
- **Nitrogen:** The air that you breathe is mostly nitrogen; therefore, this gas is dissolved within the plasma
- **Nutrients:** Fuel for the cells
- **Cellular wastes:** Lactic acid, carbon dioxide, etc

- **Others:** Hormones, other cellular products

Red blood cells (erythrocytes) contain hemoglobin, which gives blood its red color. Hemoglobin is responsible for carrying oxygen. The majority of carbon dioxide is carried by conversion to carbonic acid, which dissolves in the plasma. A small amount of carbon dioxide is carried by hemoglobin. **White blood cells** (leukocytes) play a role in the body's immune defense mechanisms against infection. **Platelets** are tiny, disc-shaped elements that are much smaller than the cells. They are essential in the initial formation of a blood clot, the mechanism that stops bleeding.

The Circulatory System: Physiology

Blood pressure (BP) is the pressure the blood exerts against the walls of the arteries as it passes through them. When the cardiac muscle of the left ventricle contracts, it pumps blood from the ventricle into the aorta. This muscular contraction phase is called **systole**. When the muscle of the ventricle relaxes, the ventricle fills with blood. This phase is called **diastole**. The pulsed, forceful ejection of blood from the left ventricle of the heart into the aorta is transmitted through the arteries as a pulsatile pressure wave. This pressure wave keeps the blood moving through the body. The high and low points of the wave can be measured with a **sphygmomanometer** (blood pressure cuff) and are expressed numerically in millimeters of mercury (mm Hg). The high point is called the systolic blood pressure (measured as the heart muscle is contracting). The low point is called the diastolic blood pressure (measured when the heart muscle is in its relaxation phase). There are several pressures within the circulatory system that are essential to understanding how this system works. Table 6-7 shows the various pressures from within the circulatory system and their meaning.

The average adult has approximately 6 L of blood in the vascular system. Children have less, 2 to 3 L, depending on their age and size. Infants have only about 300 mL. The loss of an amount of blood that may be insignificant for an adult could be fatal for an infant.

Normal Circulation in Adults

In all healthy people, the circulatory system is automatically adjusted and readjusted constantly so 100% of the capacity of the arteries, veins, and capillaries holds 100% of the blood at that moment. All of the vessels are never fully dilated or constricted. The size of arteries and veins is controlled by the nervous system, according to the amount of blood that is available and many other factors, to keep blood pressure normal at all times. Under the condition of normal pressure, with a system that can hold just 100% of the blood available, all parts of the system will have adequate blood supply all the time.

Perfusion is the circulation of blood in an organ or tissue in adequate amounts to meet the cells' current needs. Blood enters an organ or tissue through the arteries and leaves it through the veins Figure 6-30. Loss of normal blood pressure is an indication that blood is no longer circulating efficiently to every organ in the body. (However, a "good blood pressure" does not indicate that it is reaching all parts of the body.) There are many reasons for loss of blood pressure. The result in each case is the same: organs, tissues, and cells are no longer adequately perfused or supplied with oxygen and food, and wastes can accumulate. Under these conditions, cells, tissues, and whole organs may die. The state of inadequate circulation, when it involves the entire body, is called **shock**, or hypoperfusion.

Table 6-7 Cardiovascular Pressures

Name	Description	Clinical Significance
Systolic blood pressure	Pressure within the arteries when the heart is contracting; left ventricular force	Indicates heart pumping effectiveness Indicates blood available to the heart
Diastolic blood pressure	Pressure within the arteries when the heart is at rest	Indicates adequate cardiac relaxation and pressure in the arteries between heart beats Indicates amount of blood within blood vessels
Pulse pressure	Difference between systolic blood pressure and diastolic blood pressure	Relationship between systolic and diastolic pressures; provides information about the body's response to stress
Preload	Amount of blood returning to the heart	Too little preload, and blood pressure falls Too high preload, and the heart cannot move blood effectively
Afterload	Pressure to be overcome when left ventricle contracts (pressure within the aorta)	Diastolic pressure is the same as afterload
Cardiac output (CO)	Amount of blood moved in 1 minute	$CO = SV \times HR$
Stroke volume (SV)	Amount of blood moved in one beat of the heart (left ventricle)	Weak left ventricle moves less blood per beat than a strong left ventricle
Systemic vascular resistance (SVR)	Resistance to blood flow within all of the blood vessels (except the pulmonary vessels)	The higher the SVR, the smaller the container; therefore, the higher the pressure of blood within the vessel

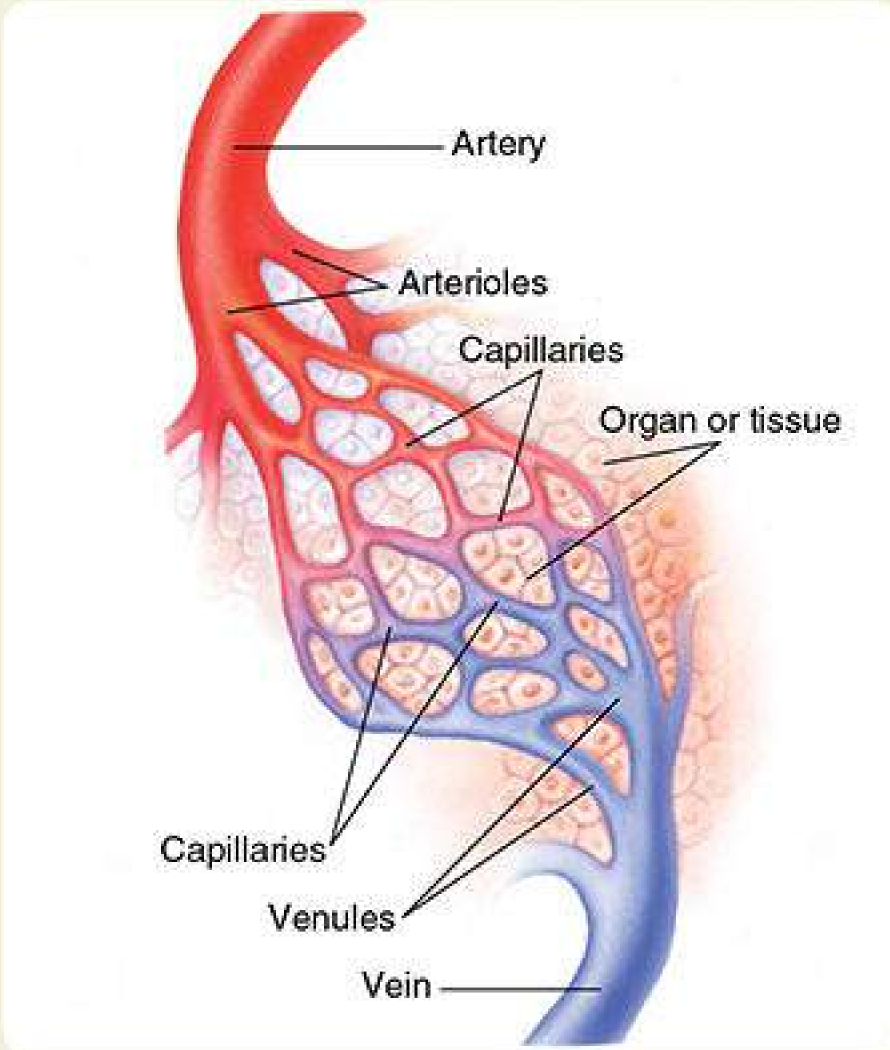

Figure 6-30 Blood enters an organ or tissue through the arteries and leaves through the veins. This process, called perfusion, provides adequate blood flow to the tissue to meet the cells' needs.

▶ Inadequate Circulation in Adults

When a patient has a small amount of blood loss, the arteries, veins, and heart automatically adjust to the smaller new volume. The adjustment occurs in an effort to maintain adequate pressure throughout the circulatory system and maintain circulation for every organ. The adjustment occurs very rapidly after the loss, usually within minutes. Specifically, the vessels constrict to provide a smaller bed for the reduced volume of blood to fill, and the heart pumps more rapidly to circulate the remaining blood more efficiently. As the blood pressure falls, the pulse increases in an attempt to keep the cardiac output constant at 5 to 6 L per minute. If the loss of blood is too great, the adjustment fails, and the patient goes into shock. This can be expressed by the following formula, in which MAP is mean arterial pressure, HR is heart rate, SV is stroke volume, and SVR is systemic vascular resistance:

$$MAP = (HR \times SV) \times SVR$$

Since heart rate (HR) times stroke volume (SV) equals cardiac output (CO), this can also be written as:

$$MAP = CO \times SVR$$

Figure 6-31 illustrates this formula.

The Function of Blood

Most blood is unevenly distributed throughout the body. Approximately 30% of blood is found within the heart, arteries, and capillaries. Seventy percent of blood is found within the veins and venules. This may seem confusing, but if you remember that the heart and arteries are high-pressure systems and veins are low-pressure systems, it becomes clearer. As blood pressure falls, blood flow slows down and there is more blood in the veins. The blood flows away from the left ventricle and moves back to the right atria.

Consider the movement of blood and its ultimate function of perfusion. You know that capillaries are the smallest portions of the circulatory system where materials are able to exit and enter the bloodstream. Nutrients move from the capillaries into the **interstitial space** (space between the cells) and into the cells. Wastes move from the cells through the interstitial space and into the capillaries.

Inside the capillary, two main forces are at work: hydrostatic pressure and oncotic pressure. **Hydrostatic pressure** occurs as fluid pushes against the vessel walls to force fluid out of the capillary. **Oncotic pressure** is the opposing force and occurs because proteins in the blood plasma cause water to be pulled into the capillary by diffusion.

The movement of fluid into and out of the capillaries occurs as follows. Blood flows into the arterial side of the capillary. Water is forced out because the pressure is high. At the same time, water is trying to enter the capillary. Pressure on the arterial side is higher, so the hydrostatic pressure is also higher, and water, carrying nutrients, leaves the capillary and enters the interstitial space. The hydrostatic pressure is greatly diminished, however, by the time the fluid reaches the venous side because the effort of pushing the fluid out of the capillary decreased its force. This decrease in pressure is beneficial because oncotic pressure is still pushing fluid into the capillary and the pressure is higher. Water, with all of the wastes from the cells, enters the venous side of the capillary. These wastes are then carried away **Figure 6-32**.

Another function of blood is the ability to clot. Coagulation, or clotting, occurs as the result of a very complex chemical process that creates small fibers near the injured blood vessel, trapping red blood cells. This chemical process involves platelets and clotting factors that are in the bloodstream. **Table 6-8** outlines the major functions of the blood.

Blood under pressure will gush or spurt intermittently from an artery. When blood comes from a vein, it flows in a steady stream. From capillaries, blood will ooze at many tiny individual points. Clotting normally takes from 6 to 10 minutes.

Nervous System Control of the Cardiovascular System

The nervous system, discussed next, has direct effects on the cardiovascular system. The sympathetic nervous system sends commands to the adrenal glands where two hormones, **epinephrine** (also known as adrenaline) and **norepinephrine** (also known as noradrenaline), are secreted to stimulate the heart and blood vessels. The release of epinephrine and norepinephrine affects receptors within the heart and blood vessels and improves the ability to cope with stress, known as the fight-or-flight reaction. Two types of receptors within the heart and blood vessels will be discussed next so you can understand how the nervous system controls the circulatory system.

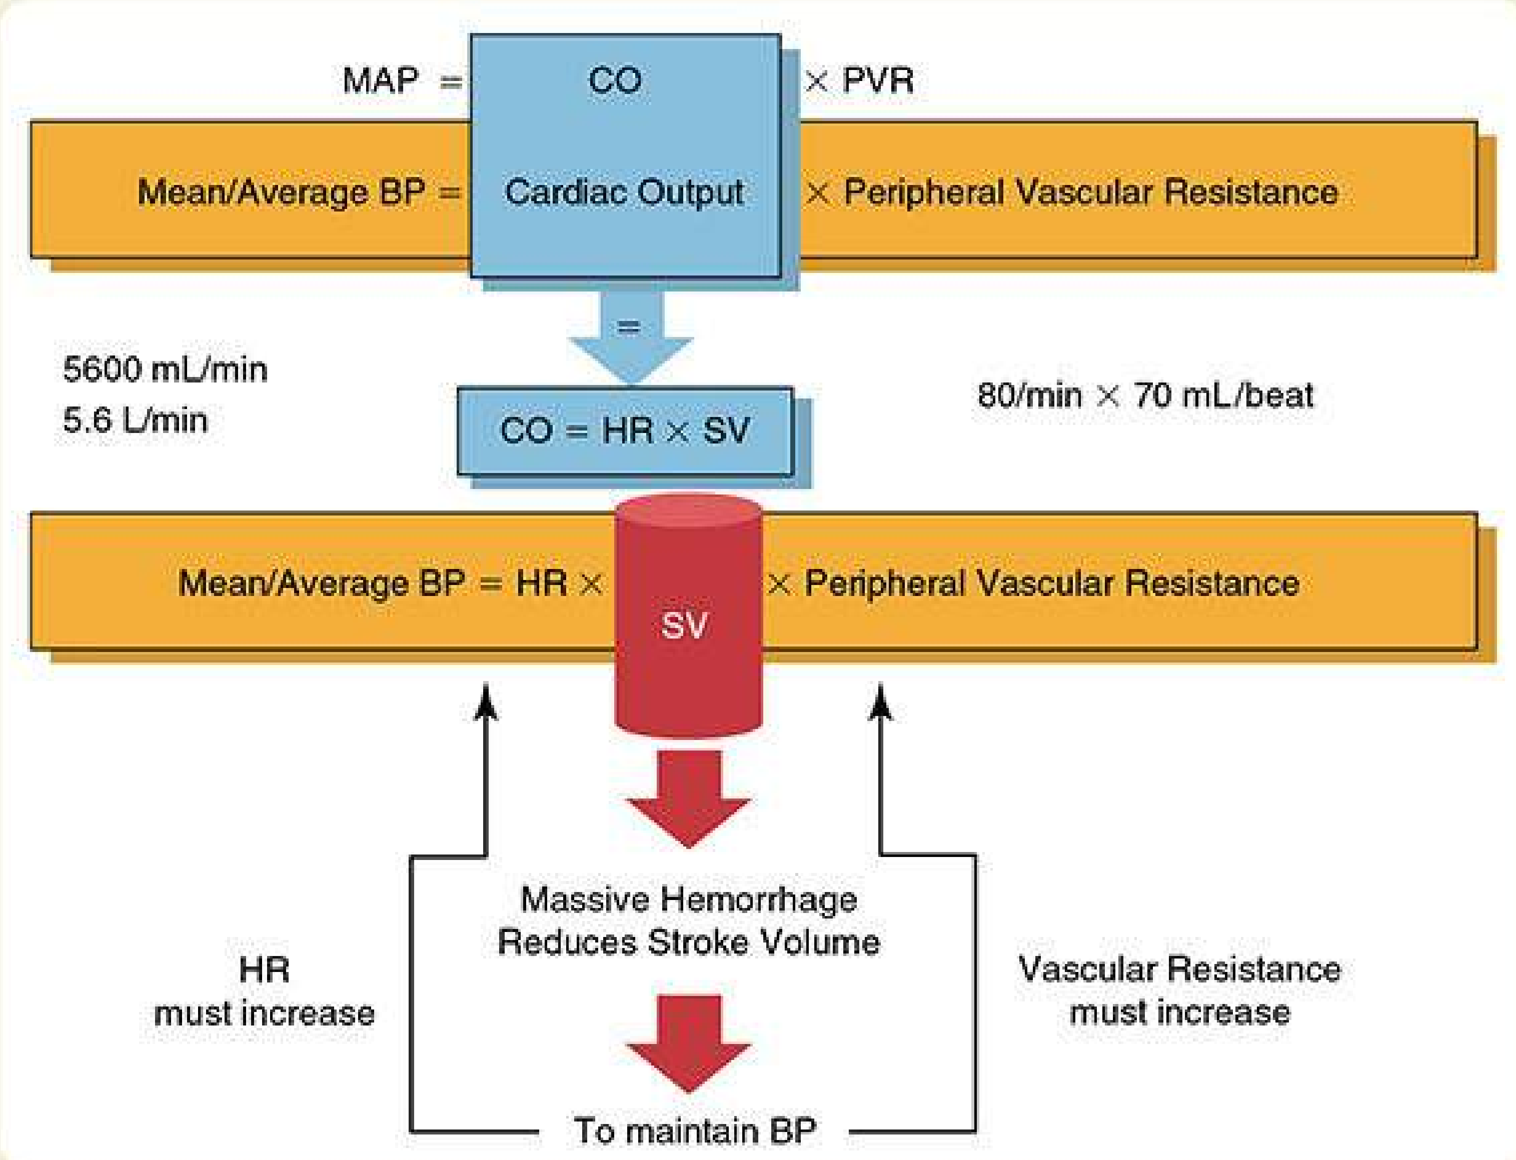

Figure 6-31 Significant blood loss results in reduced stroke volume. To compensate, the body increases heart rate and systemic vascular resistance to maintain mean arterial pressure.

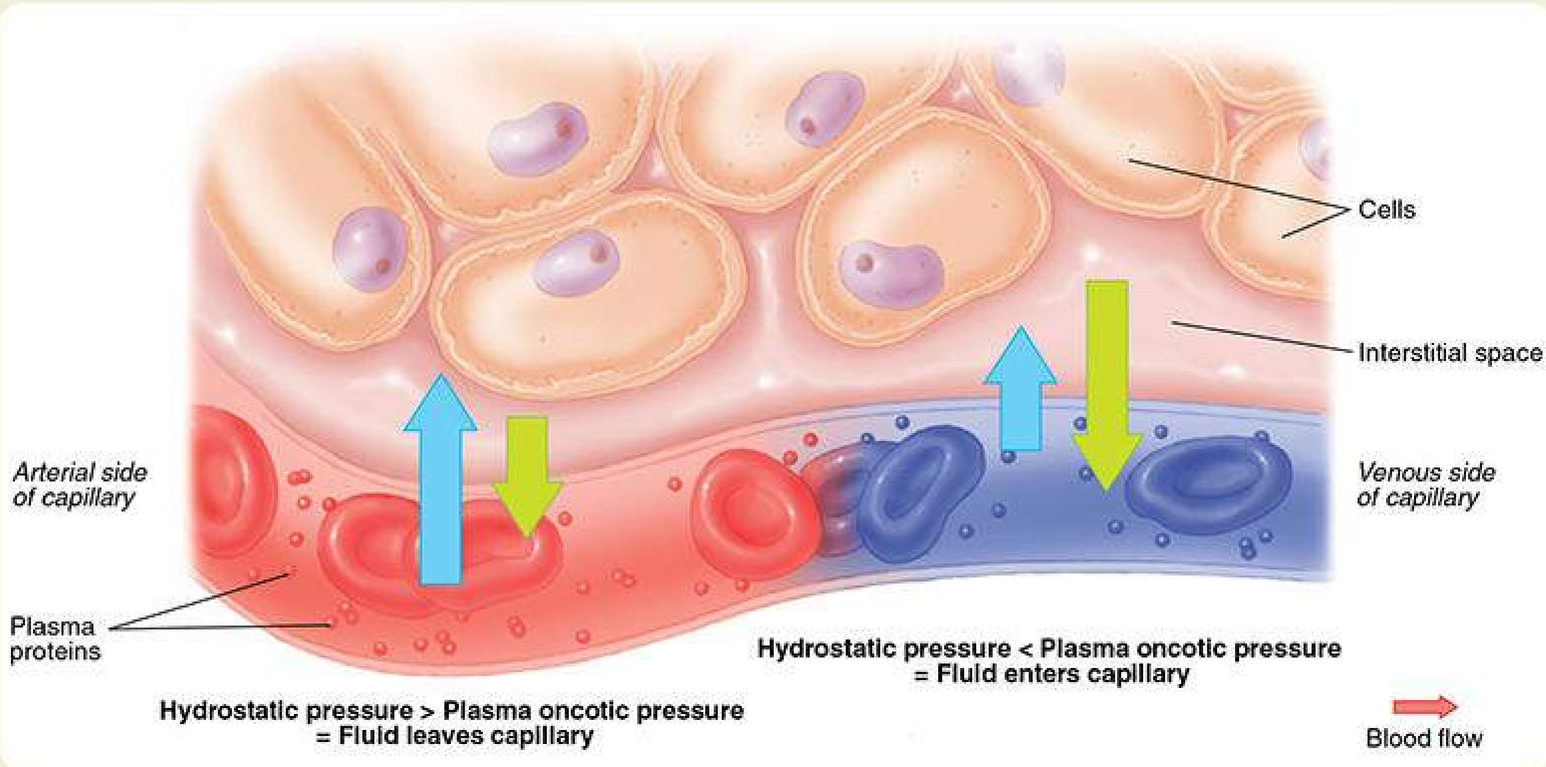

Figure 6-32 Fluid movement from capillaries to interstitial space and back.

The heart and blood vessels have **alpha-adrenergic receptors** and **beta-adrenergic receptors** within them. **Adrenergic** simply means related to the adrenal gland, where epinephrine and norepinephrine are made. The alpha-adrenergic receptors are found in the blood vessels. When stimulated, the blood vessels constrict, thereby increasing blood pressure. The beta-adrenergic receptors are found in the heart and lungs. When beta-1 receptors are stimulated, they cause the heart to increase its rate and also squeeze harder with each contraction. This increases cardiac output. When beta-2 receptors are stimulated, the bronchi in the lungs dilate. This allows more air to be inhaled and exhaled; therefore, more oxygen is available to the cells of the body. Together, the alpha- and beta-adrenergic receptors prepare the body for fight or flight.

Table 6-8 Functions of the Blood and the Components of Blood in Use

Function	Component of the Blood in Use
Fights infection	White blood cells
Transports oxygen	Red blood cells (hemoglobin)
Transports carbon dioxide	Plasma
Controls (buffer) pH	Chemicals within the plasma
Transports wastes and nutrients	Plasma (water)
Clotting (coagulation)	Platelets and clotting factors in the plasma

Table 6-9 Nervous System Effects on the Cardiovascular System

Portion of Nervous System	Receptor	Stimulation Area	Effect When Stimulated
Sympathetic nervous system	Alpha-1	Blood vessels	Constricted blood vessels; skin becomes pale, cool, clammy
	Beta-1	Heart	Increased heart rate
			Increased force of heart contraction
	Beta-2	Lungs	Bronchodilation
Parasympathetic nervous system	Muscarinic	Heart	Decreased heart rate
			Decreased force of contraction

The parasympathetic nervous system also has effects on the cardiovascular system. When stimulated, this system causes the heart to slow and beat more weakly. Although the sympathetic and parasympathetic divisions function in opposition to each other, this opposition is considered complementary rather than antagonistic. The net effect is a dynamic body able to respond quickly for fight or flight Table 6-9.

The brain needs to know how the body is performing so that adjustments in the pressure exerted by circulating blood can be made. How is the brain alerted to what is happening at the feet, the liver, or the heart? Signals are sent through the nervous system from special pressure sensors (baroreceptors) spread throughout the body, which allow the brain to receive information about blood pressure. Remember, the main function of the cardiovascular system is to perfuse blood throughout the body. The main locations for these pressure receptors are found in the arch of the aorta and the carotid arteries. By measuring the pressure in these two locations, the body can ensure that the most vulnerable and most important cells get oxygen.

With this information, the brain is able to act to maintain perfusion. To see the system in action, you may want to try this test. Kneel down to the floor. Now, as fast as you can, jump up. Did you pass out? Most likely you did not pass out because these systems with their pressure sensors are designed to maintain perfusion.

When you jumped up quickly, gravity was relocating the blood out of your brain. The baroreceptors detected the decrease in blood pressure at the carotid arteries. A signal was sent to the brain. The brain understood the implication of low blood pressure and immediately turned on the sympathetic nervous system. The blood vessels contracted, and the heart rate increased. The heart pumped harder. Your blood pressure returned to normal and may even have gone slightly high. Again, the baroreceptors detected this change. Signals were sent to the brain. The sympathetic nervous system was turned off. The parasympathetic nervous system was turned on. The heart rate slowed, and the force of the heart's contractions weakened. All of this happened in a fraction of a second. That is how responsive the cardiovascular system can be.

The Nervous System: Anatomy and Physiology

The **nervous system** is perhaps the most complex organ system within the human body. It is composed of two major structures, the brain and the spinal cord, and thousands of nerves that allow every part of the body to communicate. This system is responsible for fundamental functions such as controlling breathing, heart rate, and blood pressure. However, what makes the nervous system so special is that it allows the performance of higher level activity. Reading a good book, enjoying music, having a discussion with a friend, and even watching television require the brain to engage memory, understanding, and thought. Here is where the true complexity of the nervous system can be seen.

The nervous system is divided into two main portions: the **central nervous system (CNS)** (the brain and spinal cord) and the **peripheral nervous system (PNS)** (the nerves outside of the brain and spinal cord that link the CNS to various organs of the body). The **somatic nervous system** regulates activities over which there is voluntary control, such as walking, talking, and writing. The **autonomic nervous system** controls the many body functions that occur without voluntary control, including digestion, dilation and constriction of blood vessels, sweating, and all other involuntary actions that are necessary for basic body functions. Thus, the nervous system as a whole can be divided anatomically into the central and peripheral nervous systems and functionally into somatic (voluntary) and autonomic (involuntary) components Figure 6-33.

The Central Nervous System

Brain

The **brain** is the controlling organ of the body. It is the center of consciousness. It is responsible for all of your voluntary body activities, your perception of your surroundings, and the control of your reactions to the environment. In addition, the brain enables you to experience all the unique thoughts and feelings that make you an individual. The brain is subdivided into several areas, all of which have specific functions. Three major subdivisions of the brain are the cerebrum, the cerebellum, and the brain stem Figure 6-34.

The **cerebrum**, which is the largest part of the brain and is sometimes called the gray matter, makes up about three-fourths of the volume of the brain and is composed of four lobes: frontal, parietal, temporal, and occipital. The cerebrum on one side of the brain controls activities on the opposite side of the body. Each lobe of the cerebrum is responsible for a specific function. For example, one group of brain cells in the frontal lobe is responsible for the activity of all the voluntary muscles of the body. Brain cells in this area generate impulses that are sent along nerve fibers that extend from each cell into the spinal cord. An area in the parietal lobe has cells that receive sensory impulses from the peripheral nerves of the body. Other parts of the cerebrum are responsible for other body functions. For example, the occipital region, in the back of the cerebrum, receives visual impulses from the eyes; other areas control hearing, balance, and speech. Still other parts of the cerebrum are responsible for emotions and other characteristics of an individual's personality.

The **cerebellum**, which is located underneath the great mass of cerebral tissue, is sometimes called the little brain. The major function of this area is to coordinate the various activities of the body, particularly body movements. Without the cerebellum, very specialized muscular activities such as writing would be impossible.

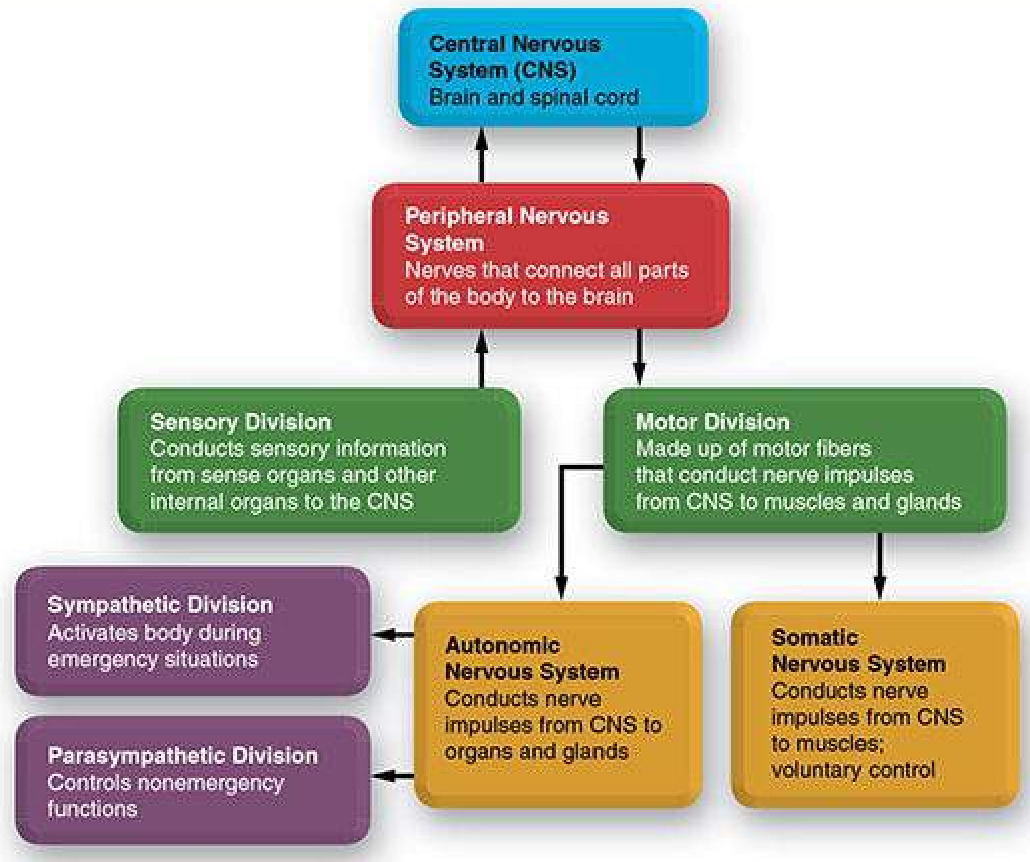

Figure 6-33 The basic configuration of the nervous system.

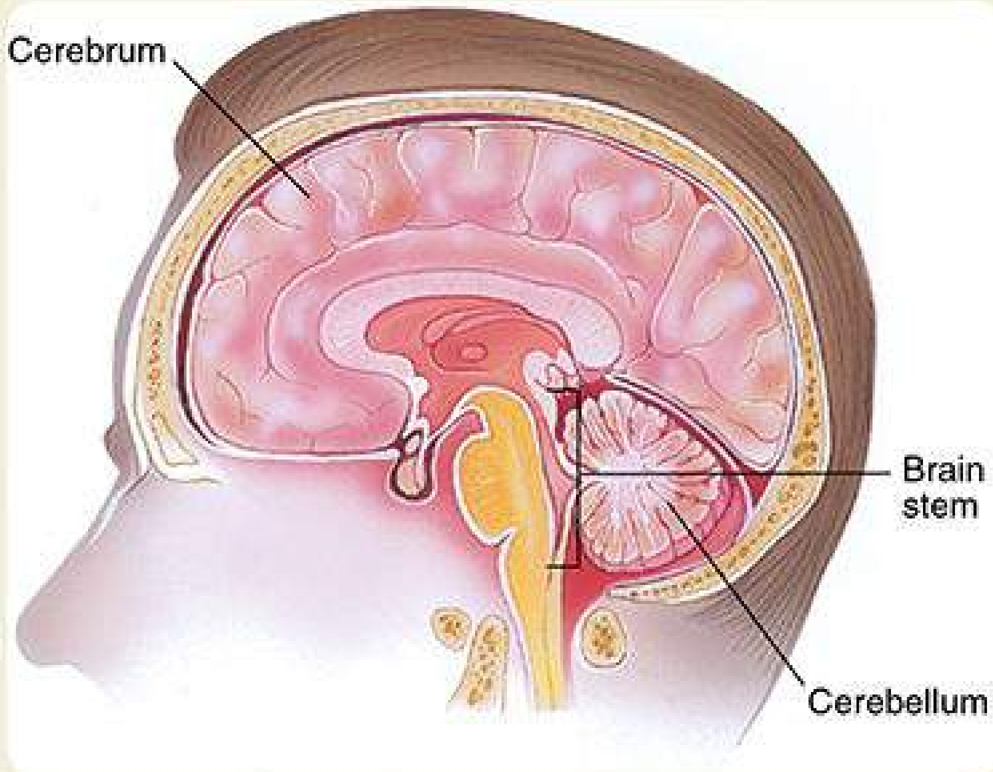

Figure 6-34 The brain lies well protected within the skull. Its major subdivisions are the cerebrum, the cerebellum, and the brain stem.

The **brain stem** is so called because the brain appears to be sitting on this portion of the CNS as a plant sits on its stem. The brain stem is the most primitive part of the CNS. It lies deep within the cranium and is the best-protected part of the CNS. The brain stem is the controlling center for virtually all body functions that are absolutely necessary for life. Cells in this part of the brain control cardiac, respiratory, and other basic body functions such as the regulation of consciousness. As you are reading this book, your **reticular activating system** in the midbrain is keeping you awake. The brain stem comprises three areas: the **midbrain**, the **pons**, and the **medulla oblongata**.

The brain has many other anatomic areas, all of which have specific and important functions. The brain receives a vast amount of information from the environment, sorts it all out, and directs the body to respond appropriately. Many of the responses involve voluntary muscle action; others are automatic and involuntary. Table 6-10 summarizes the major portions of the nervous system and their functions.

Cerebrospinal Fluid. Recall that CSF filters out impurities and toxins; it also absorbs shocks. When forces are applied to the head, CSF allows the brain to shift in the skull without tearing. If a trauma patient has CSF leaking from the ears or nose, this is considered a significant finding, indicating a skull fracture.

Table 6-10 Structures of the Nervous System and General Functions

System	Major Structure	Subdivision	General Function
Central nervous system	Brain	Occipital lobe Parietal lobe Temporal lobe	Vision and storage of visual memories Sense of touch and texture; storage of those memories Hearing, smell, and language; storage of sound and odor memories
		Frontal lobe	Voluntary muscle control and storage of those memories
		Prefrontal area	Judgment and predicting consequences of actions, abstract intellectual functions
		Limbic system	Basic emotions, basic reflexes (chewing, swallowing, etc)
		Diencephalon (thalamus)	Relay center; filters important signals from routine signals
		Diencephalon (hypothalamus)	Emotions, temperature control, interface with endocrine system (hormone control)
	Brain stem	Midbrain	Level of consciousness, reticular activating system, muscle tone, and posture
		Pons	Respiratory patterning and depth
		Medulla oblongata	Heart rate, blood pressure, respiratory rate
	Spinal cord		Reflexes, relays information to and from body
Peripheral nervous system	Cranial nerves		Brain stem to head and neck; special peripheral nerves that connect directly to body parts
	Peripheral nerves		Brain to spinal cord to body part; receive stimulus from body, send commands to body

Circulation in the Head. The brain requires a constant flow of oxygenated blood to support brain function. Blood is supplied to the head through the carotid arteries, which can be palpated on either side of the neck. Deoxygenated blood drains from the head via the internal and external jugular veins.

Spinal Cord

The spinal cord is an extension of the brain stem Figure 6-35. Like the brain, the spinal cord contains nerve cell bodies, but the major portion of the spinal cord is made up of nerve fibers that extend from the cells of the brain. These nerve fibers transmit information to and from the brain. All fibers join together just below the brain stem to form the spinal cord. At the level of the neck, the nerves cross; this is why issues on the left side of the brain relate to the right side of the body, and vice versa. The spinal cord exits through the foramen magnum. It is encased within the spinal canal down to the level of the second lumbar vertebra. The spinal canal is created by an opening through the vertebrae, stacked one on another. Each vertebra surrounds the cord, and together the vertebrae form the bony spinal canal.

The primary function of the spinal cord is to transmit messages between the brain and the body. These messages are passed along the nerve fibers as electrical impulses, just as messages are passed along a telephone cable. The nerve fibers are arranged in specific bundles within the spinal cord to carry the messages from one specific area of the body to the brain and back.

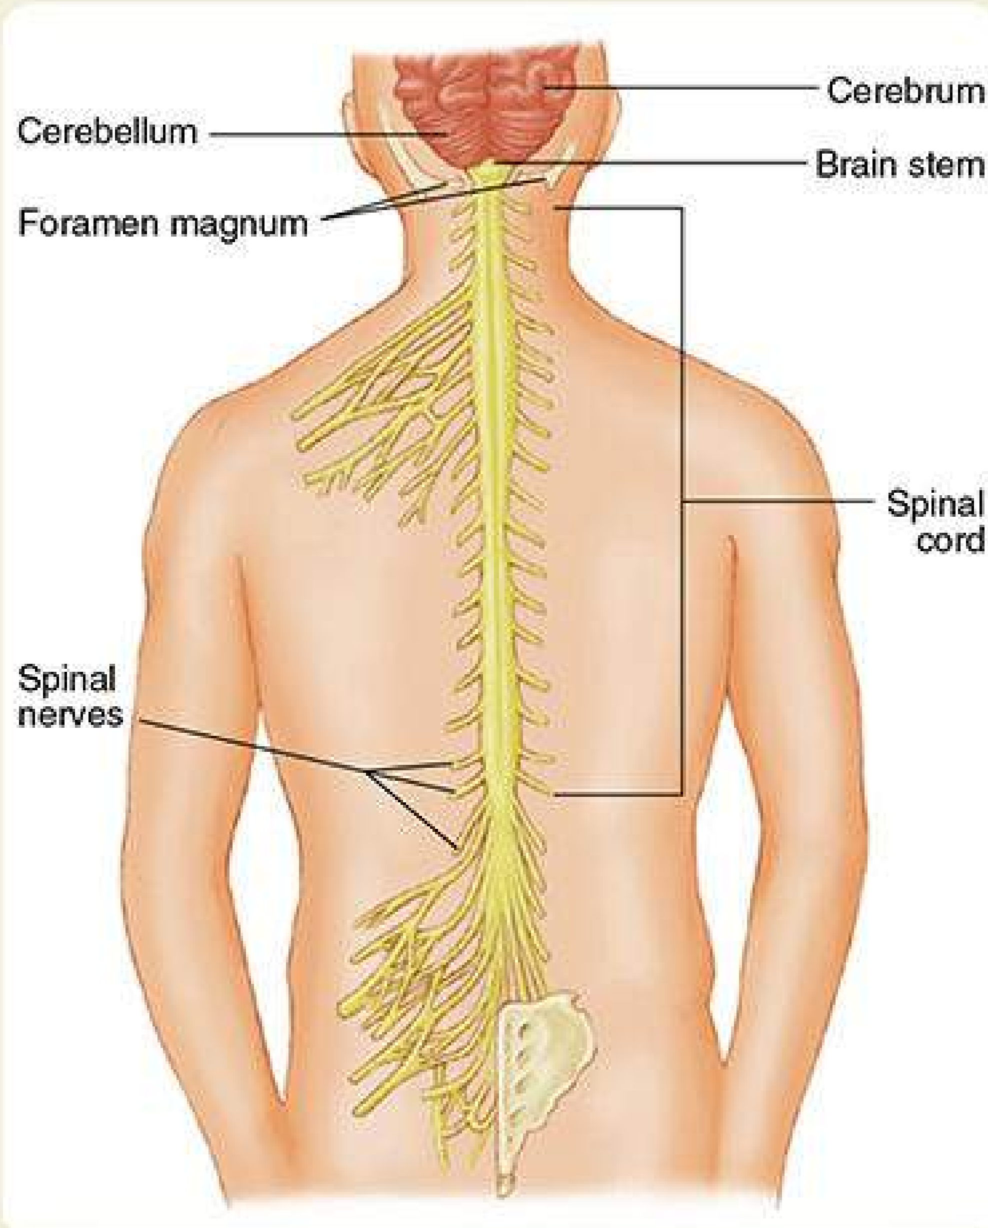

Figure 6-35 The spinal cord is a continuation of the brain stem. It exits the skull at the foramen magnum and extends down to the level of the second lumbar vertebra.

▶ The Peripheral Nervous System

Recall that the PNS is divided into the somatic nervous system and the autonomic nervous system. The autonomic nervous system, in turn, is split into two areas. The sympathetic nervous system is responsible for the fight-or-flight response, enabling you to fight if you find yourself in a dangerous situation or to run away. This fight-or-flight reaction generally increases the activity within your body so that your muscles are able to perform more effectively. An increased heart and respiratory rate, pupil dilation, and increased use of glucose all provide you with the resources to defend yourself or flee the scene.

The **parasympathetic nervous system**, the other half of the autonomic nervous system, generally slows down the body. When you are eating, your blood supply needs to move to your stomach and intestines so the food you eat can be processed. The parasympathetic nervous system slows your body's heart rate and respirations and allows your food to be properly digested.

There are two types of nerves within the peripheral nervous system: sensory nerves and motor nerves.

YOU are the Provider — PART 4

You prepare the patient for transport. He remains conscious and alert, but is still experiencing severe pain. Shortly after loading him into the ambulance and departing the scene, you perform a reassessment.

Recording Time: 12 Minutes	
Level of consciousness	Conscious and alert
Respirations	24 breaths/min; adequate depth
Pulse	112 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	138/88 mm Hg
Spo_2	97% (on oxygen)

You allow the patient to assume a position of comfort, which seems to help with his pain. With an estimated time of arrival at the hospital of 10 minutes, you call in your radio report.

5. How does knowledge of anatomy, physiology, and medical terminology facilitate communication with other health care professionals?

Sensory Nerves

Sensory nerves of the body are complex. There are many types of sensory cells in the nervous system. Sensory cells are located in the eyes, ears, skin, muscles, joints, lungs, and other organs of the body. When a sensory cell is stimulated, it transmits its own special message to the brain. There are special sensory nerves to detect heat, cold, position, motion, pressure, pain, balance, light, taste, and smell, as well as other sensations. Specialized nerve endings are adapted for each cell so it perceives only one type of sensation and transmits only that message.

The sensory impulses constantly provide information to the brain about what the different parts of the body are doing in relation to your surroundings. Thus, the brain is continuously made aware of its surroundings. For example, the cranial nerves supply sensations directly to the brain. Visual sensations (what you see) reach the brain directly by way of the optic nerve (the second cranial nerve) in each eye. The nerve endings for the optic nerve lie in the retina of the eye. The nerve endings are stimulated by light, and the impulses are carried along the nerve that passes through a hole in the back of the eye socket and carries impulses to the occipital portion of the brain.

When sensory *nerve* endings in the extremities are stimulated, the impulses are transmitted along a peripheral nerve to the spinal cord. The cell body of the peripheral nerve lies in the spinal cord. The impulse is then transmitted from that cell body to another nerve ending in the spinal cord and from there up the spinal cord to the sensory area in the parietal lobe of the brain, where the sensory information can be interpreted and acted on by the brain.

As another example, an irritating stimulus to the sensory nerve, such as heat, transmits from the sensory nerve along the connecting nerve directly to the motor nerve and stimulates it. The muscle responds promptly, withdrawing the limb from the irritating stimulus even before this information can be transmitted to the brain. Technically, you do not "feel" the heat of the fire before you move your hand away. The withdrawal reflex is in place to limit damage to the body.

Motor Nerves

Each muscle in the body has its own motor nerve. Whereas sensory nerves carry information *to* the brain, **motor nerves** carry information *from* the brain to the muscles of the body. The cell body for each motor nerve lies in the spinal cord, and a fiber from the cell body extends as part of the peripheral nerve to its specific muscle. Electrical impulses that are produced by the cell body in the spinal cord are transmitted along the motor nerve to the muscle and cause it to contract. The cell body in the spinal cord is stimulated by an impulse produced in the motor strip of the cerebral cortex. This impulse is transmitted along the spinal cord to the cell body of the motor nerve.

The Integumentary System (Skin): Anatomy

The skin is divided into two parts: the superficial epidermis, which is composed of several layers of cells, and the deeper dermis, which contains the specialized skin structures. Below the skin lies the **subcutaneous tissue** layer **Figure 6-36**. The cells of the epidermis are sealed to form a watertight protective covering for the body.

The **epidermis** is the most superficial layer of the skin and varies in thickness in different areas of the body. On the soles of the feet, the back, and the **scalp**, it is quite thick, but in some areas of the body, the epidermis is only two or three cell layers thick. The epidermis is actually composed of several layers of cells. These layers can be separated into two regions. At the base of the epidermis is the **germinal layer**, which continuously produces new cells that gradually rise to the surface. On the way to the surface, these cells die and enter the **stratum corneal layer**. This is the dead layer of skin. Whereas the germinal layer has a blood supply, the stratum corneal layer does not. The journey from the germinal layer to the surface takes about 4 weeks. The outermost cells of the epidermis are constantly rubbed away and replaced by new cells produced by the germinal layer. The germinal layer also contains cells that produce pigment granules. These granules help to produce skin color.

Below the germinal layer is the **dermis**. Within the dermis lie many of the special structures of the skin: sweat glands, sebaceous (oil) glands, hair follicles, blood vessels, and specialized nerve endings.

Sweat glands produce sweat for cooling the body. The sweat is discharged onto the surface of the skin through small pores, or ducts, that pass through the epidermis. The sebaceous glands produce sebum, the oily material that seals the surface epidermal cells. The **sebaceous glands** lie next to hair follicles and secrete sebum along the hair follicle to the skin surface. In addition to providing waterproofing for the skin, sebum keeps the skin soft so it does not crack.

Hair follicles are the small organs that produce hair. The hair grows from the follicle along a shaft until it reaches the epidermal surface. A sebaceous gland is located along the hair shaft. Connected to the hair is a small muscle. The muscle pulls the hair into an erect position when you are cold or frightened. Hair goes through stages of growth and rest. Each hair follicle on the scalp grows for about 3 years and then rests for about 1 to 2 years.

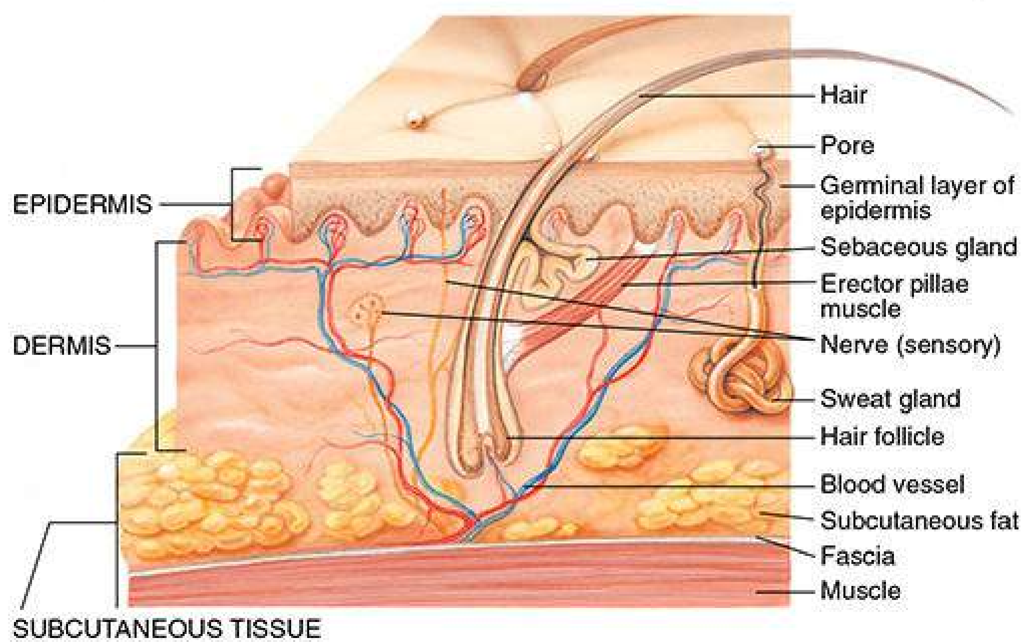

Figure 6-36 The skin has two distinct layers: the epidermis and the dermis. Below the skin is a layer of subcutaneous tissue.

Blood vessels provide nutrients and oxygen to the skin. The blood vessels lie in the dermis. Small branches extend up to the germinal layer. A complex array of nerve endings also lies in the dermis. These specialized nerve endings are sensitive to environmental stimuli; they respond to these stimuli and send impulses along the nerves to the brain.

Beneath the skin, immediately under the dermis and attached to it, lies the subcutaneous tissue. The subcutaneous tissue is composed largely of fat. The fat serves as an insulator for the body and as a reservoir to store energy. The amount of subcutaneous tissue varies greatly from individual to individual. Beneath the subcutaneous tissue lie the muscles and the skeleton. The subcutaneous layer helps to anchor the skin to the structures below. As you age, the loss of the subcutaneous layer causes the skin to have limited support, forming wrinkles in the skin.

The skin covers the entire external surface of the body. The various orifices (openings to the body)—including the mouth, nose, anus, and vagina—are not covered by skin. Orifices are lined with mucous membranes. **Mucous membranes** are quite similar to skin in that they provide a protective barrier against bacterial invasion. Mucous membranes differ from skin in that they secrete **mucus**, a watery substance that lubricates the openings. Thus, mucous membranes are moist, whereas the skin is dry. A mucous membrane lines the entire gastrointestinal tract from the mouth to the anus.

The Integumentary System (Skin): Physiology

The skin, the largest single organ in the body, serves three major functions: to protect the body in the environment, to regulate the temperature of the body, and to transmit information from the environment to the brain.

The protective functions of the skin are numerous. Water makes up a large portion of the body. This water contains a delicate balance of chemical substances in solution. The skin is watertight and serves to keep this balanced internal solution intact. The skin also protects the body from the invasion of infectious organisms: bacteria, viruses, and fungi. These organisms are everywhere and are routinely found lying on the skin surface. However, they never penetrate the skin unless it is broken by injury; thus, the skin provides a constant protection against outside invaders.

The major organ for regulation of body temperature is the skin. Blood vessels in the skin constrict when the body is in a cold environment and dilate when the body is in a warm environment. In a cold environment, constriction of the blood vessels shunts the blood away from the skin to decrease the amount of heat radiated from the body surface. When the outside environment is hot, the vessels in the skin dilate, the skin becomes flushed or red, and heat radiates from the body surface.

Also, in a hot environment, sweat is secreted to the skin surface from the sweat glands. Evaporation of the sweat requires energy. This energy, as body heat, is taken from the body during the evaporation process, which causes the body temperature to fall. Sweating alone will not reduce body temperature; evaporation of the sweat must also occur.

Information from the environment is carried to the brain through a rich supply of sensory nerves that originate in the skin. Nerve endings that lie in the skin are adapted to perceive and transmit information about heat, cold, external pressure, pain, and the position of the body in space. The skin thus recognizes any changes in the environment. The skin also reacts to pressure, pain, and pleasurable stimuli.

The Digestive System: Anatomy

The digestive system, also called the gastrointestinal system, is composed of the gastrointestinal tract (stomach and intestines), mouth, salivary glands, pharynx, esophagus, liver, gallbladder, pancreas, rectum, and anus. The function of this system is **digestion**: the processing of food that nourishes the individual cells of the body. The organs of this system are found within the abdomen.

The Abdomen

The **abdomen** is the second major body cavity; it contains the major organs of digestion and excretion. The diaphragm separates the thorax from the abdominal cavity. Anteriorly and posteriorly, thick muscular abdominal walls create the boundaries of this space. Inferiorly, the abdomen is separated from the pelvis by an imaginary plane that extends from the pubic symphysis through the sacrum Figure 6-37. Some organs lie in the abdomen and the pelvis, depending on the posture of the patient.

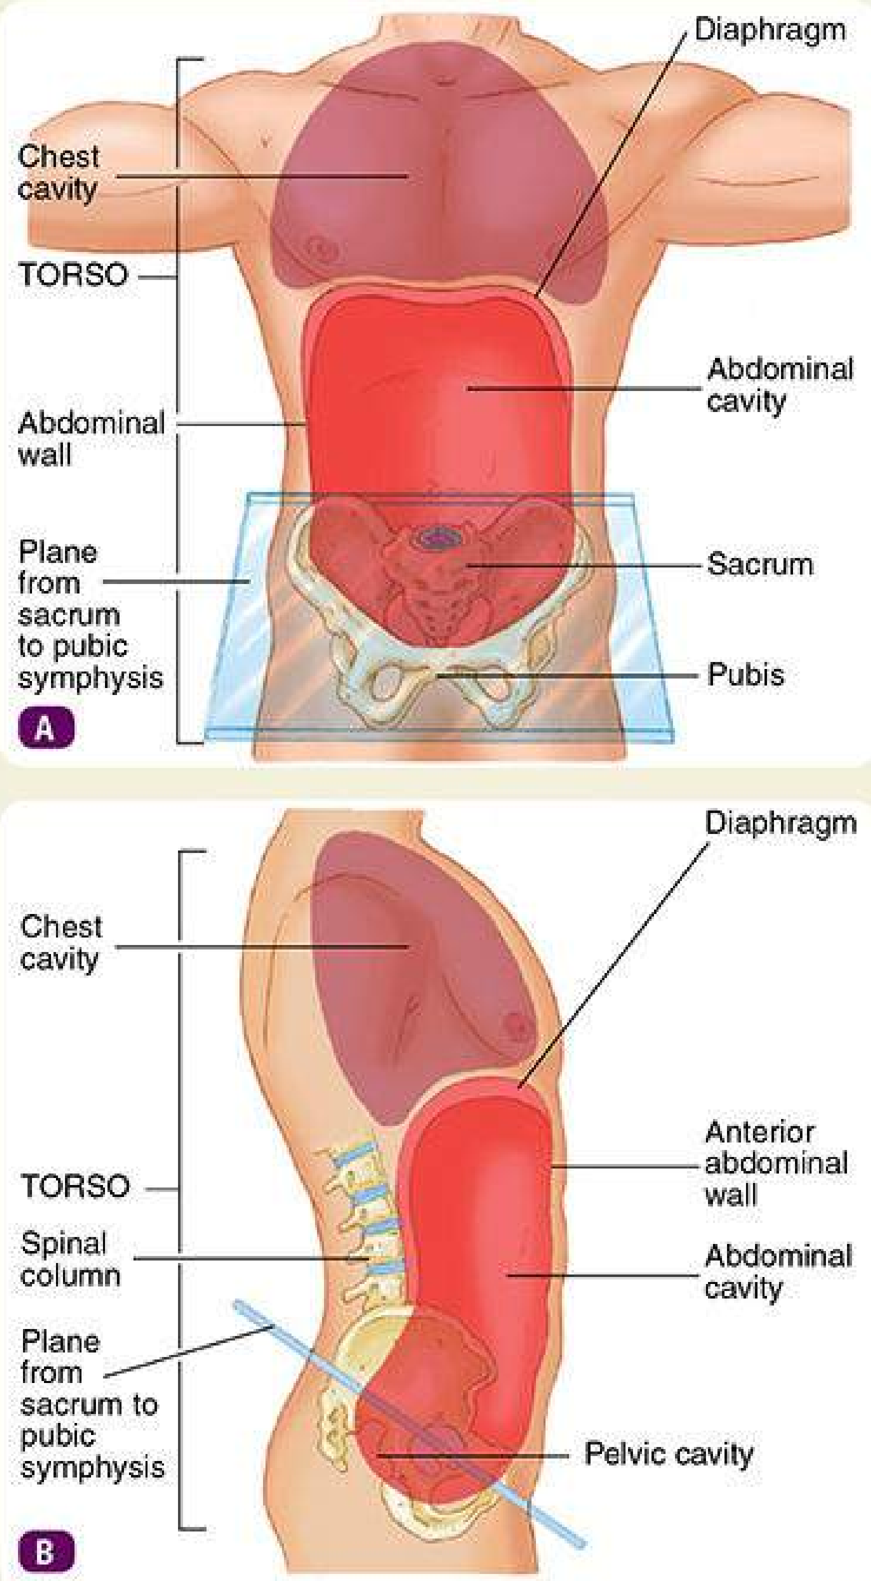

Figure 6-37 The boundaries of the abdomen are the anterior and posterior abdominal cavity walls, the diaphragm, and an imaginary plane from the pubic symphysis to the sacrum. The region below the plane is called the pelvic cavity. **A.** Anterior view. **B.** Lateral view.

The simplest and most common method of describing the portions of the abdomen is by quadrants, the four equal areas formed by two imaginary lines that intersect at right angles at the umbilicus. On the anterior abdominal wall, the quadrants thus formed are the right upper, right lower, left upper, and left lower **Figure 6-38**. “Right quadrant” and “left quadrant” refer to the patient’s right and left. Pain or injury in a given quadrant usually arises from or involves the organs that lie in that quadrant. This simple means of designation will allow you to identify injured or diseased organs that require emergency attention.

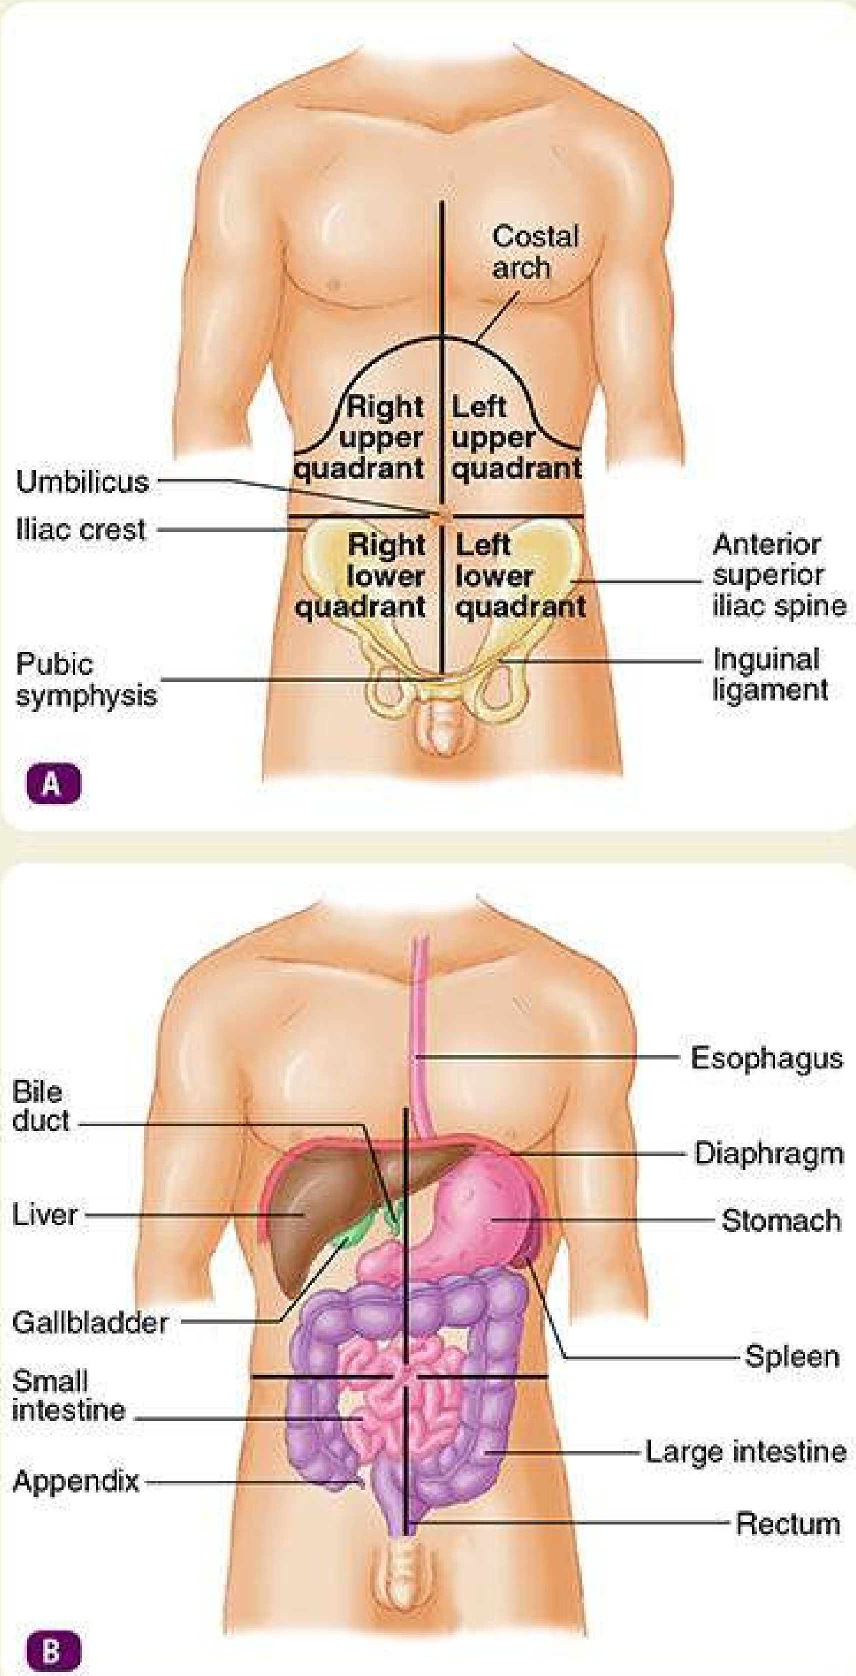

Figure 6-38 **A.** In the abdomen, quadrants are the easiest system for identifying areas. Major bony landmarks are also shown. **B.** Several of the organs in the abdomen lie in more than one quadrant.

Organs and Vascular Structures

In the right upper quadrant (RUQ), the major organs are the liver, the gallbladder, and a portion of the colon. Most of the liver lies in this quadrant, almost entirely under the protection of the 8th to 12th ribs. The liver fills the entire anteroposterior depth of the abdomen in this quadrant. Therefore, injuries in this area are frequently associated with injuries of the liver.

In the left upper quadrant (LUQ), the major organs are the stomach, the spleen, and a portion of the colon. The spleen is almost entirely under the protection of the left rib cage, whereas the stomach may sag well down into the left lower quadrant when full. The spleen lies in the lateral and posterior portion of this quadrant, under the diaphragm and immediately in front of the 9th to 11th ribs. The spleen is frequently injured, especially when these ribs are fractured.

The right lower quadrant (RLQ) contains two portions of the large intestine: the **cecum**, the first portion into which the small intestine (ileum) opens, and the ascending colon. The **appendix** is a small, tubular structure that is attached to the lower border of the cecum. In the left lower quadrant (LLQ) lie the descending and the sigmoid portions of the colon.

Several organs lie in more than one quadrant. The small intestine, for instance, occupies the central part of the abdomen around the umbilicus, and parts of it lie in all four quadrants. The pancreas lies just behind the abdominal cavity on the posterior abdominal wall in both upper quadrants. The large intestine also traverses the abdomen, beginning in the RLQ and ending in the LLQ as it passes through all four quadrants. The urinary bladder lies just behind the pubic symphysis in the middle of the abdomen and, therefore, lies in both lower quadrants and also in the pelvis.

The kidneys and pancreas are called **retroperitoneal** organs because they lie behind the abdominal cavity **Figure 6-39**. They are above the level of the umbilicus, extending from the 11th rib to the 3rd lumbar vertebra on each side. The kidneys are approximately 5 inches (13 cm) long and lie just anterior to the costovertebral angle.

Mouth

The mouth consists of the lips, cheeks, gums, teeth, and tongue. A mucous membrane lines the mouth. The roof of the mouth is formed by the hard and soft palates. The hard palate is a bony plate lying anteriorly; the soft palate is a fold of mucous membrane and muscle that extends posteriorly from the hard palate into the throat. The soft palate is designed to hold food that is being chewed within the mouth and to help initiate swallowing.

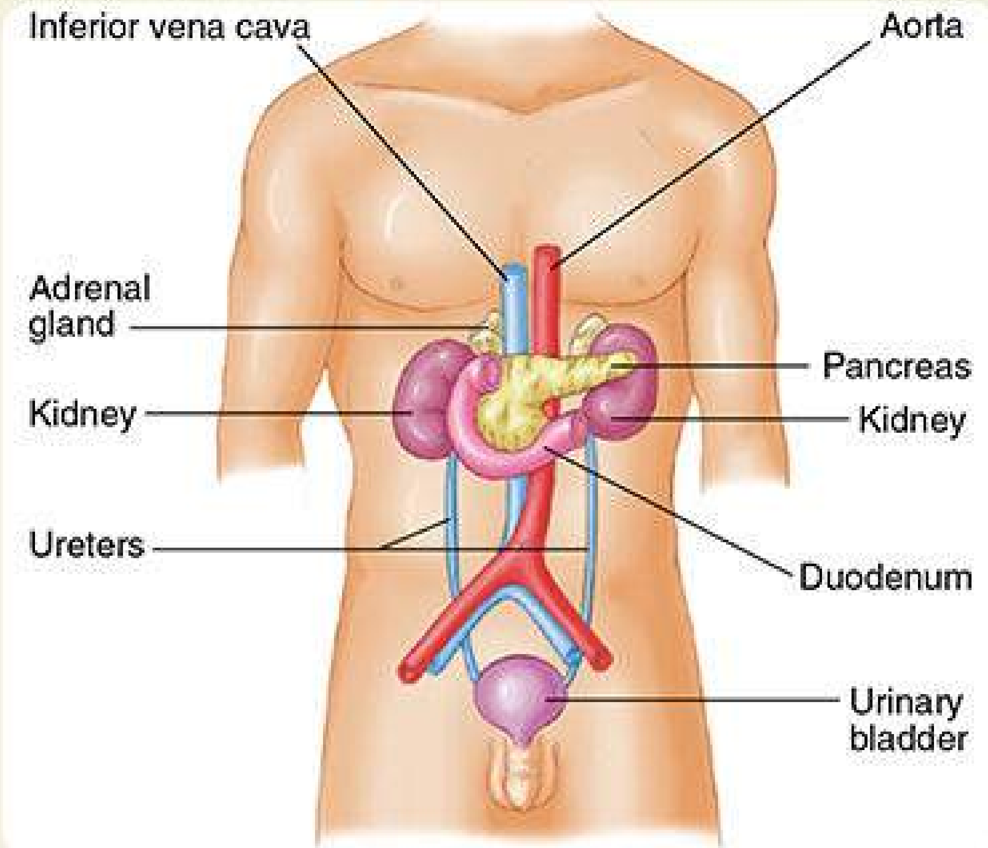

Figure 6-39 The major organs of the retroperitoneal space lie behind the abdominal cavity, above the level of the umbilicus, and extend from the 11th rib to the 3rd lumbar vertebra. The bladder, inferior vena cava, and aorta also lie in this space.

Salivary Glands

There are two sets of salivary glands, one set on each side of the mouth under the tongue, and the other set in front of each ear. They produce nearly 1.5 L of saliva daily. Saliva is approximately 98% water. The remaining 2% is composed of mucus, salts, and organic compounds. Saliva serves as a binder for the chewed food that is being swallowed and as a lubricant within the mouth. Saliva also contains certain digestive enzymes.

▶ Oropharynx

The oropharynx is a tubular structure that extends vertically from the back of the mouth to the esophagus and trachea. An automatic movement of the pharynx during swallowing lifts the larynx to permit the epiglottis to close over it so that liquids and solids are moved into the esophagus and away from the trachea.

▶ Esophagus

The esophagus is a collapsible tube about 10 inches (25 cm) long that extends from the end of the pharynx to the stomach and lies just anterior to the spinal column in the chest. Contractions of the muscle in the wall of the esophagus propel food through it to the stomach. Liquids pass with very little assistance.

Stomach

The stomach is a hollow organ located in the left upper quadrant of the abdominal cavity, largely protected by the lower left ribs. Muscular contractions in the wall of the stomach and gastric juice, which contains a lot of mucus, convert ingested food to a thoroughly mixed semisolid mass, called **chyme**. The stomach produces approximately 1.5 L of gastric juice daily for this process. The primary function of the stomach is to receive food in large quantities intermittently, store it, and provide for its movement into the small bowel in regular, small amounts. In 1 to 3 hours, the semisolid food mass derived from one meal is propelled by muscular contraction into the duodenum, the first part of the small intestine.

Pancreas

The **pancreas**, a flat, solid organ, lies below and behind the liver and stomach and behind the peritoneum. It is firmly fixed in position, deep within the abdomen, and is not easily damaged. It contains two kinds of glands, and the two portions of the pancreas are intertwined. One portion is exocrine, and it secretes nearly 2 L of pancreatic juice daily. This juice contains many enzymes that aid in the digestion of fat, starch, and protein. Pancreatic juice flows directly into the duodenum through the pancreatic ducts. The other portion of the gland—the islets of Langerhans—is endocrine. These are where insulin and glucagon (hormones) are produced. Insulin and glucagon regulate the amount of glucose in the blood.

Liver

The **liver** is a large, solid organ that takes up most of the area immediately beneath the diaphragm in the right upper quadrant and also extends into the left upper quadrant. It is the largest solid organ in the abdomen and has several functions. Poisonous substances produced by digestion are brought to the liver and rendered harmless. Factors that are necessary for blood clotting and for the production of normal plasma are formed here. Between 0.5 and 1 L of bile is made by the liver daily to assist in the normal digestion of fat. The liver is the primary organ for the storage of sugar or starch for immediate use by the body for energy. It also produces many of the factors that aid in the proper regulation of immune responses. Anatomically, the liver is a large mass of blood vessels and cells, packed tightly together. It is fragile and, because of its size, relatively easily injured. Blood flow in the liver is high, because all of the blood that is pumped to the gastrointestinal tract passes into the liver, through the portal vein, before it returns to the heart. In addition, the liver has a generous arterial blood supply of its own. Ordinarily, approximately 25% of the cardiac output of blood (1.5 L) passes through the liver each minute.

Bile Ducts

The liver is connected to the intestine by the **bile ducts**. The **gallbladder** is a small pouch extending from the bile ducts that serves as a reservoir and concentrating organ for bile produced in the liver. Together, the bile ducts and the gallbladder form the biliary system. The gallbladder discharges stored and concentrated bile into the duodenum through the common bile duct. The presence of food in the duodenum triggers a contraction of the gallbladder to empty it. The gallbladder usually contains about 60 to 90 mL of bile.

Small Intestine

The **small intestine** is the major hollow organ of the abdomen. The cells lining the small intestine produce enzymes and mucus to aid in digestion. Enzymes from the pancreas and the small intestine carry out the final processes of digestion. More than 90% of the products of digestion (amino acids, fatty acids, and simple sugars), together with water, ingested vitamins, and minerals, are absorbed across the wall of the lower end of the small intestine into veins to be transported to the liver. The small intestine is composed of the duodenum, the jejunum, and the ileum. The duodenum, which is about 12 inches (30 cm) long, is the part of the small intestine that receives food from the stomach. Here, food is mixed with secretions from the pancreas and liver for further digestion. Bile, produced by the liver and stored in the gallbladder, is emptied as needed into the duodenum. Bile is green-black, but through changes during digestion, it gives feces its typical brown color. Its major function is in the digestion of fat. The jejunum and ileum together measure more than 20 feet (6 m) on average to make up the rest of the small intestine.

Large Intestine

The **large intestine**, another major hollow organ, consists of the cecum, the colon, and the rectum. About 5 feet (1.5 m) long, it encircles the outer border of the abdomen around the small bowel. The major function of the colon, the portion of the large intestine that extends from the cecum to the rectum, is to absorb the final 5% to 10% of digested food and water from the intestine to form solid stool, which is stored in the rectum and passed out of the body through the anus.

Appendix

Recall that the appendix is a tube that opens into the cecum (the first part of the large intestine) in the right lower quadrant of the abdomen. It is 3 to 4 inches (8 to 10 cm) long and may easily become obstructed and, as a result, inflamed and infected. Appendicitis, which is the term for this inflammation, is one of the major causes of severe abdominal distress.

Rectum

The lowermost end of the colon is the **rectum**. It is a large, hollow organ that is adapted to store quantities of feces until it is expelled. At its terminal end is the anus, a 2-inch (5-cm) canal lined with skin. The rectum and anus are supplied with a complex series of circular muscles called sphincters that control, voluntarily and automatically, the escape of liquids, gases, and solids from the digestive tract. Table 6-11 provides a summary of the organs and functions of the digestive system.

Table 6-11 Digestive Organs and Functions

Organ/ Structure	Function
Mouth	Mechanically breaks down food; begins chemical breakdown with saliva
Esophagus	Moves food from the mouth to the stomach; muscular and vascular structure
Stomach	Performs mechanical and chemical breakdown of food: food in, chyme out
Small intestine: duodenum, jejunum, and ileum	Major site for chemical breakdown of food; major absorption of water, fats, proteins, carbohydrates, and vitamins
Large intestine	Water absorption; formation of feces; bacterial digestion of food
Anus/ rectum	Last portion of large intestine; sphincter to control release of feces
Liver	Production of bile; assists with carbohydrate, protein, and fat metabolism of nutrients within the bloodstream; manufactures proteins for immune regulation and clotting; detoxification of blood; elimination of waste
Pancreas	Exocrine: enzymes for protein, carbohydrate, and fat breakdown within the duodenum Endocrine: insulin and glucagon
Gallbladder	Storage of bile

The Digestive System: Physiology

Digestion of food, from the moment it is taken into the mouth until essential compounds are extracted and delivered by the circulatory system to nourish all of the cells in the body, is a complicated chemical process. In succession, different secretions, primarily **enzymes**, are added to the food by the salivary glands, the stomach, the liver, the pancreas, and the small intestine to convert the food into basic sugars, fatty acids, and amino acids. These basic products of digestion are carried across the wall of the intestine and transported through the portal vein to the liver. In the liver, the products are processed further and stored or transported to the heart through veins draining the liver. The heart then pumps the blood with these nutrients throughout the arteries to the capillaries, where the nutrients pass through the capillary walls to nourish the body's individual cells.

In normal routine activity, without any food or fluid ingestion at all, between 8 and 10 L of fluid is secreted daily into the gastrointestinal tract. This fluid comes from the salivary glands, stomach, liver, pancreas, and small intestine. In a healthy adult, about 7% of the body weight is delivered as fluid daily to the gastrointestinal tract. If significant vomiting or diarrhea occurs for more than 2 or 3 days, the person will experience a substantial loss of body composition and become severely ill.

The Lymphatic System: Anatomy and Physiology

The lymphatic system is composed of the spleen, lymph nodes, lymph, lymph vessels, thymus gland, and other components and supports the circulatory system and the immune system. Unlike the circulatory system, the lymphatic system has no pump and relies on muscle contractions and movements of the body for lymph to flow.

Lymph is a thin, straw-colored fluid that carries oxygen, nutrients, and hormones to the cells and waste products of metabolism away from the cells and back into the capillaries so that they may be excreted. Lymph vessels closely parallel the veins, forming a network throughout the body that serves as an auxiliary to the circulatory system. **Lymph nodes** are located in various places along the lymph vessels in the body. These tiny, oval-shaped structures filter lymph.

Together with the circulatory system, the lymphatic system helps to rid the body of toxins and other harmful materials.

The Endocrine System: Anatomy and Physiology

The brain controls the body through the nervous system, using electrical impulses, and the endocrine system, using hormones. The **endocrine system** is a complex message and control system that integrates many body functions. Endocrine glands release their hormones directly into the bloodstream **Figure 6-40**. Epinephrine, norepinephrine, and insulin are examples of hormones. Each endocrine gland produces one or more hormones. Each hormone has a specific effect on some organ, tissue, or process **Table 6-12**. The brain controls the release of hormones by the endocrine glands. **Hormones** can have a stimulating or an inhibiting effect on the body's organs and systems. For example, when you are frightened, your brain stimulates the adrenal gland through a hormone to release epinephrine and norepinephrine. This increases your blood pressure and heart rate. The resulting increase in blood pressure and heart rate decreases the amount of hormone released by the adrenal gland. The brain then reduces the amount of stimulation to the **adrenal glands**. Thus, a new steady state is achieved at heightened levels of alertness. This cycle is known as a feedback loop, and it helps keep the body's systems and functions in balance **Figure 6-41**.

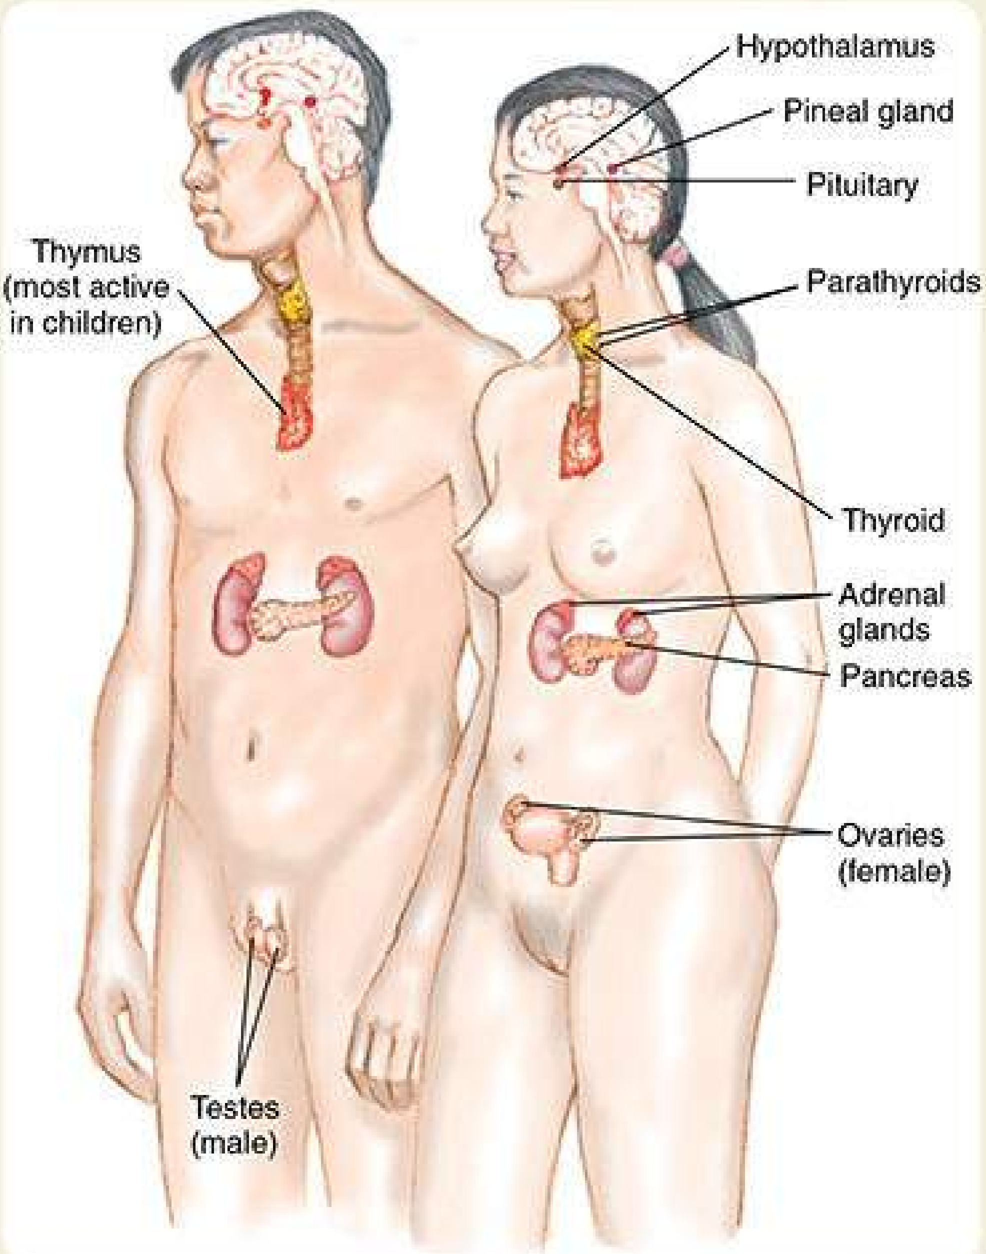

Figure 6-40 The endocrine system controls the production and release of hormones in the body.

Table 6-12 Endocrine Glands

Gland	Location	Function	Hormones Produced
Adrenal	Above the kidneys	Stress response, fight-or-flight reaction	Epinephrine, norepinephrine, cortisol, and others
Ovaries	Female pelvis (two glands)	Regulate sexual function, characteristics, and reproduction	Estrogen and others
Pancreas	Retroperitoneal space	Regulates glucose metabolism and other functions	Insulin, glucagon, and others
Parathyroid	Neck (behind and beside the thyroid) (three to five glands)	Regulates serum calcium	Parathyroid hormone
Pituitary	Base of skull	Regulates all other endocrine glands	Multiple, controls other endocrine glands
Testes	Male scrotum (two glands)	Regulate sexual function, characteristics, and reproduction	Testosterone and others
Thyroid	Neck (over the larynx)	Regulates metabolism	Thyroxine and others

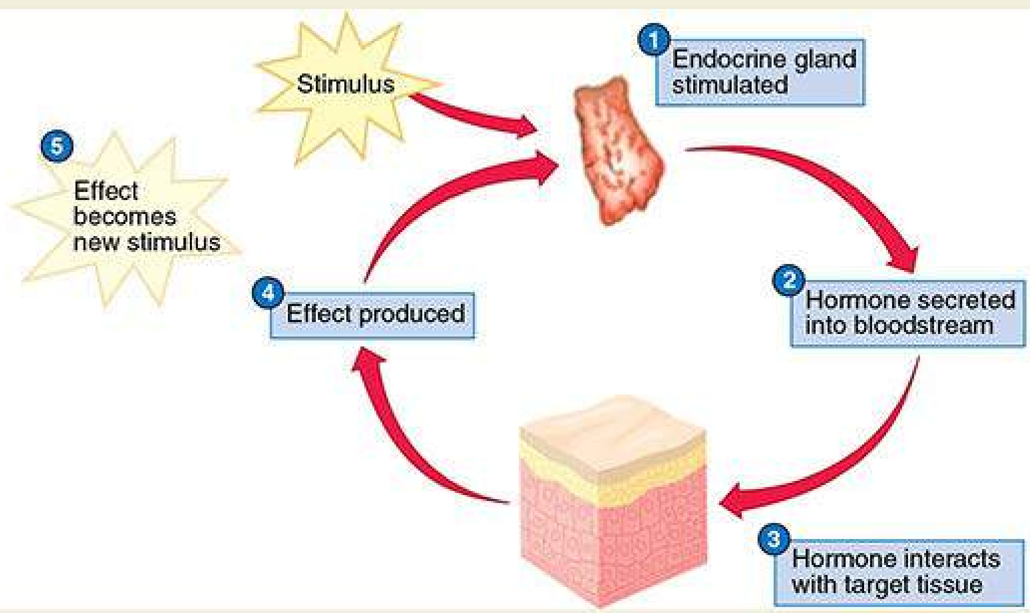

Figure 6-41 The endocrine system is tightly controlled with primary and secondary feedback loops to keep body systems in balance.

Excesses or deficiencies in hormone levels cause various diseases. With endocrine diseases, specific body functions are increased, decreased, or absent. Diabetes mellitus is a common condition. Because production of the hormone insulin is deficient, the body is unable to use glucose normally. Glucose is the primary fuel of the body. Insulin is responsible for rapidly moving glucose into cells; without insulin, glucose moves slowly. This creates a series of complications as the body struggles to find a more readily available fuel for its cells. People with diabetes begin to burn fats and proteins to create the glucose that cells are craving. Interestingly, the end result is higher and higher blood glucose levels as glucose accumulates, unable to be moved efficiently into the cells. Chapter 19, *Endocrine and Hematologic Emergencies*, discusses how high blood glucose levels affect the body.

The Urinary System: Anatomy and Physiology

The **urinary system** controls the discharge of certain waste materials filtered from the blood by the kidneys. In the urinary system, the kidneys are solid organs; the ureters, bladder, and urethra are hollow organs **Figure 6-42**. The main functions of the urinary system are: (1) to control fluid balance in the body, (2) to filter and eliminate wastes, and (3) to control pH balance.

The body has two **kidneys** that lie on the posterior muscular wall of the abdomen behind the peritoneum in the retroperitoneal space. These organs rid the blood of toxic waste products and control its balance of water and salt. Blood flow in the kidneys is high. Nearly 20% of the output of blood from the heart passes through the kidneys each minute. Large vessels attach the kidneys directly to the aorta and the inferior vena cava. Waste products and water are constantly filtered from the blood to form urine. The kidneys continuously concentrate this filtered urine by reabsorbing the water as it passes through a system of specialized tubes within them. The tubes finally unite to form the **renal pelvis**, a cone-shaped area that collects urine from the kidneys and funnels it through the ureter into the bladder. Normally, each kidney drains its urine into one ureter through which the urine passes to the bladder.

A **ureter** passes from the renal pelvis of each kidney along the surface of the posterior abdominal wall behind the peritoneum to drain into the urinary bladder. The ureters are small (0.2 inches [0.5 cm] in diameter), hollow, muscular tubes. **Peristalsis**, a wavelike contraction of smooth muscle, occurs in these tubes to move the urine to the bladder.

The **urinary bladder** is located immediately behind the pubic symphysis in the pelvic cavity and is composed of smooth muscle with a specialized lining membrane. The two ureters enter posteriorly at its base on either side. The bladder empties to the outside of the body through the **urethra**. In the man, the urethra passes from the anterior base of the bladder through the penis. In the woman, the urethra opens in front of the vagina. A healthy adult forms 1.5 to 2 L of urine every day. This waste is extracted and concentrated from the 1,500 L of blood that circulates through the kidneys daily.

YOU are the Provider — PART 5

Shortly before arriving at the hospital, you reassess the patient. He remains conscious and alert and tells you that his pain is less severe than before. After transferring patient care to the attending physician, you later learn that the patient had an inflamed gallbladder, which was surgically removed.

Recording Time: 20 Minutes	
Level of consciousness	Conscious and alert
Respirations	20 breaths/min; adequate depth
Pulse	90 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	132/80 mm Hg
Spo_2	99% (on oxygen)

6. Should your documentation of an EMS call differ from your verbal communication with other health care professionals? Why or why not?

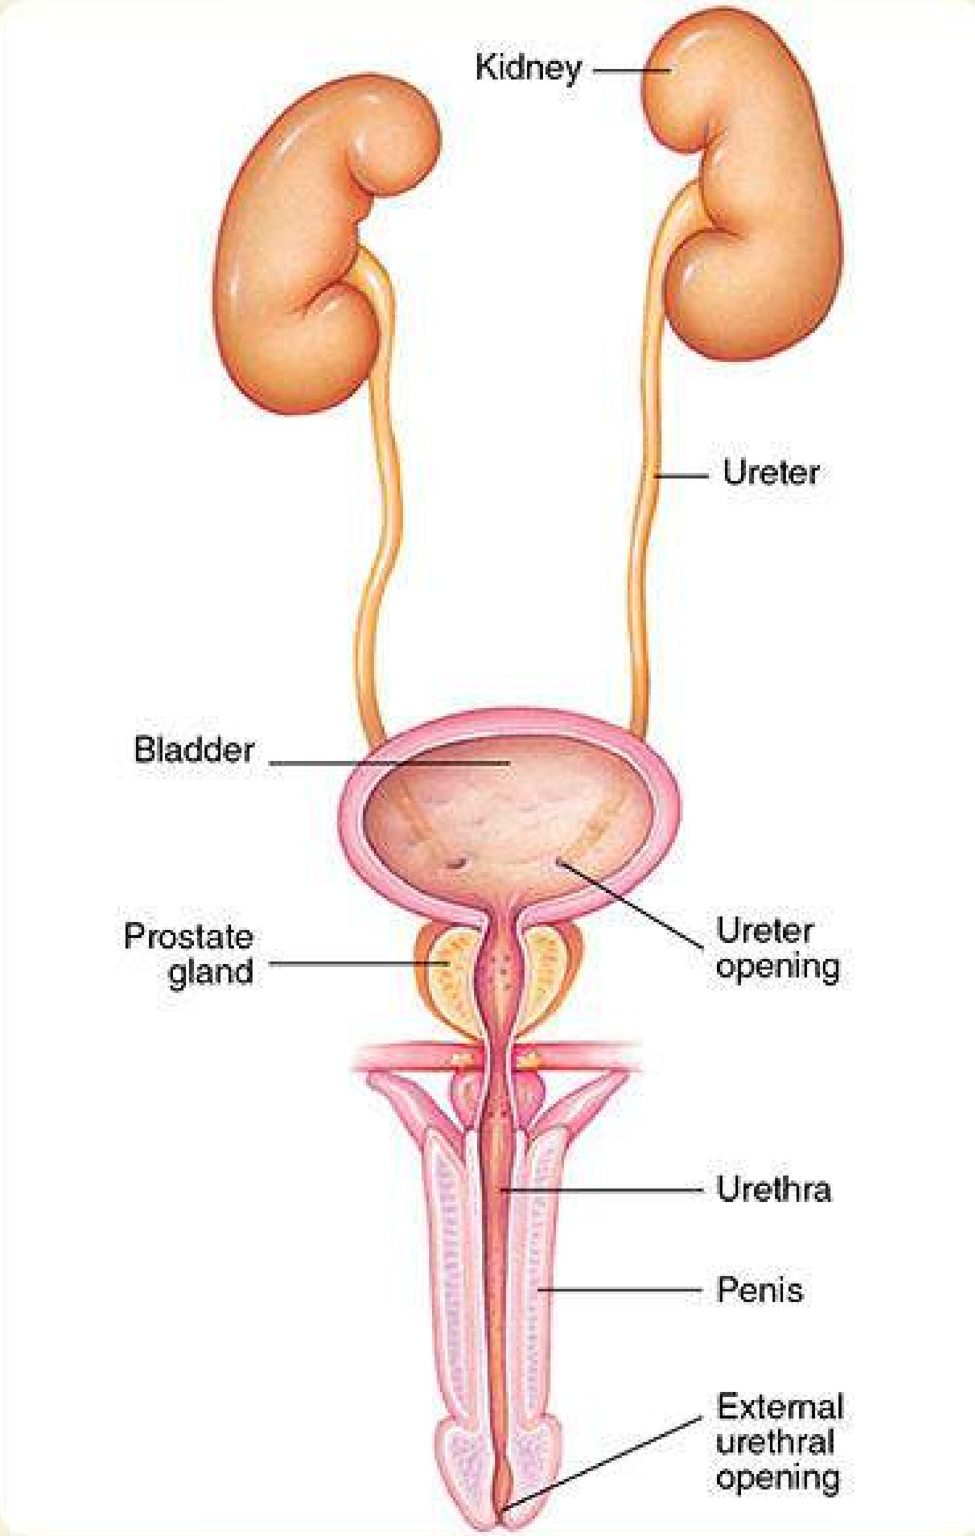

Figure 6-42 The urinary system lies in the retroperitoneal (behind the peritoneum) space behind the organs of the digestive system. The urinary system in men and women includes the kidneys, ureters, bladder, and urethra. This diagram shows the male urinary system.

The Genital System: Anatomy and Physiology

The **genital system** controls the reproductive processes by which life is created. The male genitalia, except for the **prostate gland** and the **seminal vesicles**, lie outside the pelvic cavity. The female genitalia, with the exception of the clitoris and labia, are contained entirely within the pelvis. The male and female reproductive organs have certain similarities and, of course, basic differences. They produce sperm and egg cells and reproductive hormones and play a significant role in sexual intercourse and reproduction.

The Male Reproductive System and Organs

The male reproductive system consists of the testicles, epididymis, vasa deferentia, prostate gland, seminal vesicles, and penis **Figure 6-43**. Each **testicle** contains specialized cells and ducts; some of these produce male hormones, and others develop sperm. The hormones are absorbed directly into the bloodstream from the testicles. The sperm are immature and are moved from the testicles to the epididymis so they can develop. During ejaculation, the sperm are carried through **vasa deferentia** (or vas deferens) to the urethra. Finally, the sperm are deposited by the penis.

The function of the reproductive system is to reproduce. Sperm are able to join with an egg to begin the process of life. In addition to reproduction, this system is also responsible for the production of sex hormones. Many of the physical characteristics of men, such as increased muscle mass, body hair, and deep voice, are attributed to the powerful effects of the hormones released by the testes. Finally, the penis, though part of the reproductive system, is also part of the urinary system. Any damage or infection to the penis can cause problems within the urinary bladder and/or the kidneys.

The Female Reproductive System and Organs

The female reproductive organs include the ovaries, fallopian tubes, uterus, cervix, and vagina **Figure 6-44**. The **ovaries**, like the testicles, produce sex hormones and specialized cells for reproduction. The female sex hormones are absorbed directly into the bloodstream. A specialized ovum, or egg cell, matures and is released regularly during the adult woman's reproductive years. The ovaries release a mature egg approximately every 28 days. This egg travels through the fallopian tubes where fertilization normally occurs. The fallopian tubes exit into the uterus.

The **fallopian tubes** connect with the uterus and carry the ovum into the cavity of this organ. The uterus is pear-shaped and hollow, with muscular walls. The narrow opening from the uterus to the vagina is the cervix. The **vagina** (birth canal) is a muscular, distensible tube that connects the uterus with the vulva (the external female genitalia). The vagina receives the penis during sexual intercourse, when **semen** is deposited in it. The sperm in the semen may pass into the uterus and fertilize an egg, causing pregnancy. Should the pregnancy come to completion at about 40 weeks, the neonate will pass through the vagina and be born. The vagina also channels the menstrual flow from the uterus out of the body.

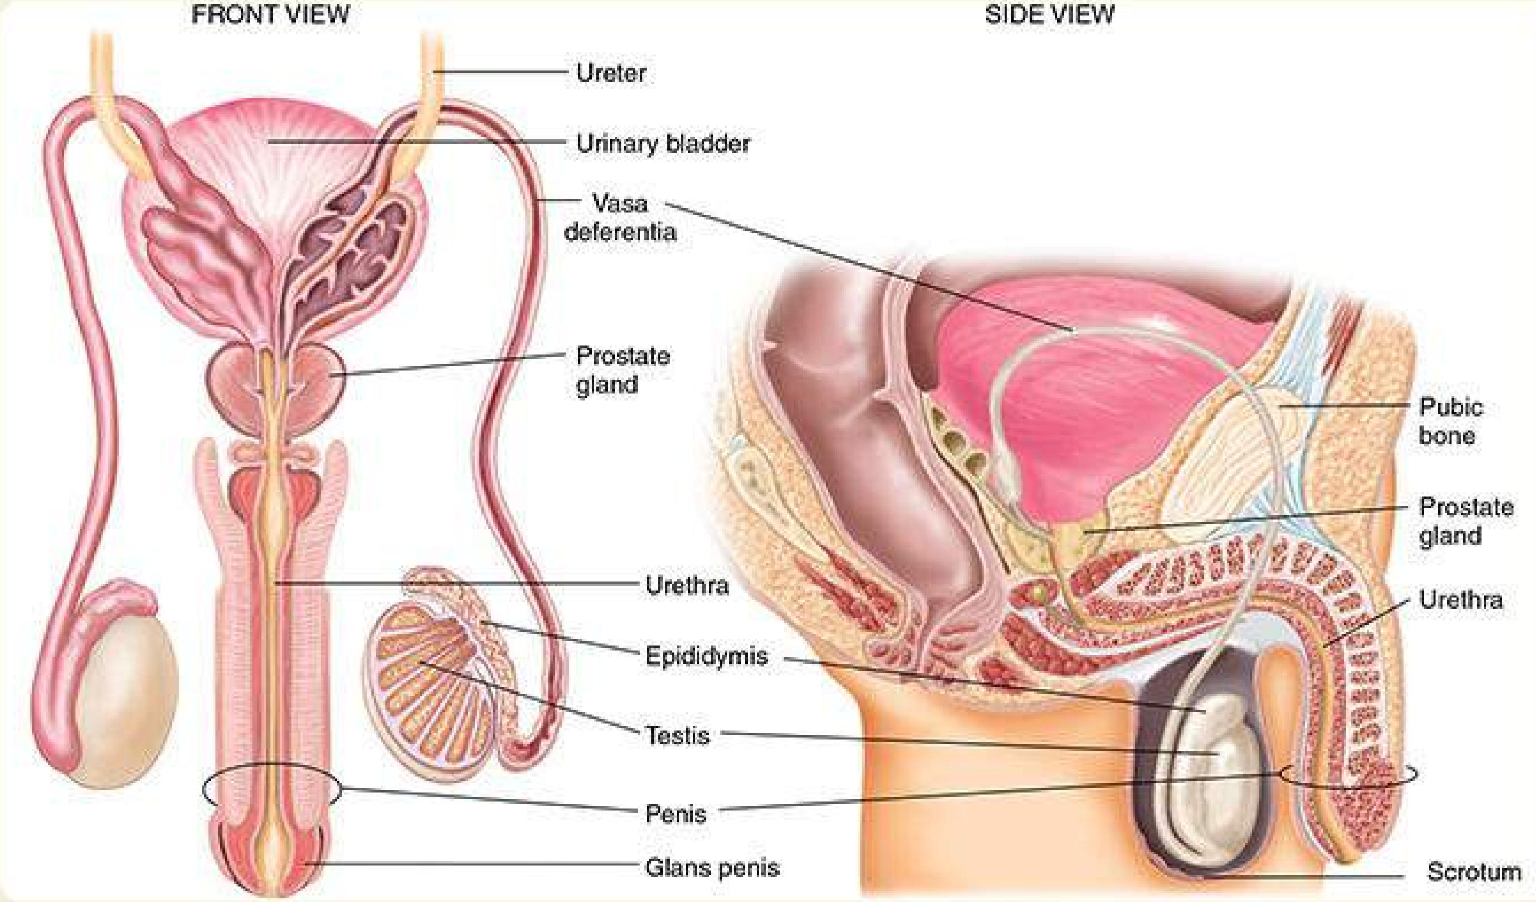

Figure 6-43 The male reproductive system consists of the testicles, epididymis, vasa deferentia, prostate gland, seminal vesicles, and penis.

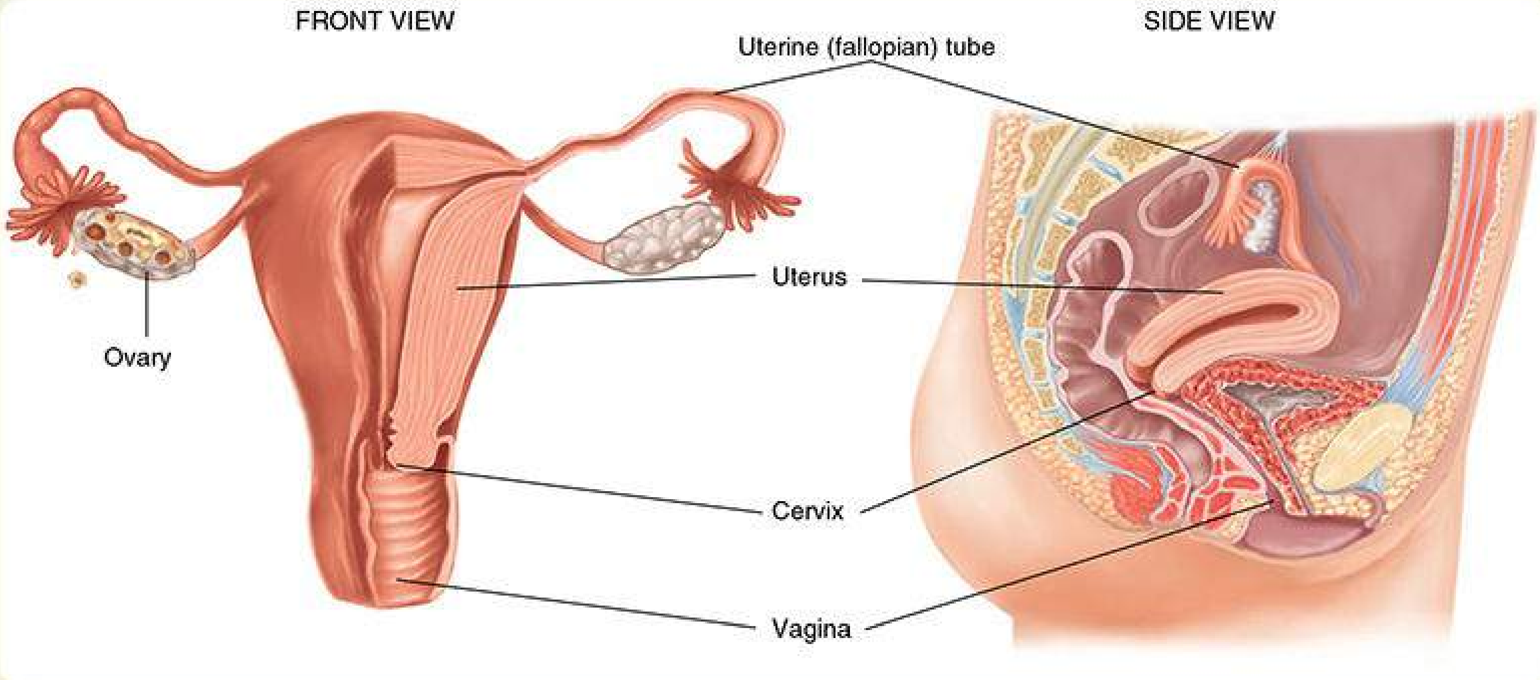

Figure 6-44 The female reproductive system consists of the ovaries, fallopian tubes, uterus, cervix, and vagina.

The functions of the female reproductive system are similar to those of the male reproductive system: reproduction and hormone balance. Urination occurs through the urethra, which in women is not interconnected to the reproductive tract. In men, the urethra is interconnected.

Life Support Chain

You have learned that all functions of the human body depend on a continuous, adequate supply of oxygen to the cells. Cells are the foundation of the human body. Billions of cells compose the human body. Some cells make hair, other cells are involved in storing memory, and others help to move your eyes as you read this page. Cells with a common job grow close to each other and form tissues. Groups of tissues that perform similar or interrelated jobs form organs. A series of organs with similar jobs make up the body systems discussed in this chapter.

The body's cells, tissues, and organs, regardless of their function, all require oxygen, nutrients, and the removal of wastes to perform their job. Oxygen is brought to the cells through the respiratory and circulatory systems. Nutrients are made available to the body after you eat. The digestive system takes the food you eat and breaks it down into, among other things, glucose. The circulatory system is the carrier of these supplies and wastes through the process of perfusion. If interference occurs in this delivery system, cells will become damaged or die.

Cells use oxygen to take available nutrients and turn them into chemical energy through the biochemical process of **metabolism (cellular respiration)**. **Adenosine triphosphate (ATP)** is involved in energy metabolism and is used to store energy. Cells prefer to operate using oxygen because it provides the cells with 15 times as much ATP as when they operate without oxygen. The process that uses oxygen is called aerobic (meaning with air) metabolism. When you perform an activity over a long period of time, such as running a marathon, your body is using anaerobic metabolism. The waste products of **aerobic metabolism** are carbon dioxide and water. Some cells have become so specialized that they are unable to survive without constant supplies of oxygen; for example, the brain and heart. Without oxygen, brain cells will begin to die within 4 to 6 minutes.

Most cells in the body are able to continue to function, even without oxygen. This anaerobic (without air) state allows cells to operate despite a lack of available oxygen. When illness or injury occurs, the body needs to shift available resources to areas in need while ensuring that critical areas, such as the brain and heart, have an uninterrupted supply of resources. Any time that available oxygen is limited to portions of the body, cells will switch to **anaerobic metabolism**. When you perform a short-term, high-intensity activity such as lifting weights, your body is using anaerobic metabolism. In this state, very limited amounts of energy are able to be released so the body must quickly correct the oxygen deficiency or risk cellular death. The most well-known by-product of anaerobic metabolism is lactic acid, which is the material that causes muscle burning during anaerobic exercise. **Lactic acid** is converted back to a useful energy source once oxygen is available. Anaerobic metabolism can be supported in most cells for only 1 to 3 minutes.

Words of Wisdom

Remember

- When cells function with oxygen, they use aerobic metabolism.
  - They generate large amounts of ATP (cellular energy) and produce wastes of carbon dioxide and water.
- When cells function without oxygen, they use anaerobic metabolism.
  - They generate small amounts of ATP (cellular energy) and produce waste of lactic acid.

All of this movement of material—oxygen, waste, nutrients—how does it happen? The main force moving these elements is diffusion. Recall that when you breathe, oxygen moves from an area of higher concentration to one of lower concentration.

Cells are surrounded by fluid that allows for easy movement of nutrients and wastes. A physical property of this fluid that is a critical factor to cell survival is pH, which is the measure of acidity or alkalinity in a solution. Solutions that are high in pH (>7.0) are considered alkaline. A common example is soap. Solutions that are low in pH (<7.0) are considered acidic. Sulfuric acid in automotive batteries is one example. A solution that is neither acidic nor alkaline is considered neutral (pH 7.0). The body's cells want to exist in a near-neutral environment.

Your body spends a large amount of energy working to maintain a normal pH (normal human pH is 7.35 to 7.45). The waste products of cells are often acidic, such as carbon dioxide. Carbon dioxide is transported by combining with water to create carbonic acid, which is more soluble in the plasma. The plasma also contains sodium bicarbonate, which is alkaline and helps to buffer or neutralize the acidic waste products of cells.

The blood and lungs interact continuously to help to maintain the pH level in the body by controlling the level of carbon dioxide, and therefore the level of carbonic acid, in the blood. If the blood becomes acidic, the respiratory centers in the brain stem will increase breathing to blow off more carbon dioxide. If too much carbon dioxide is blown off, then the body can become too alkaline, which is what happens during hyperventilation.

Pathophysiology

Pathophysiology is the study of how normal physiologic processes are affected by disease. Many diseases can occur in patients and will result in calls to EMS. Some examples are diabetes (a disease of the pancreas), pneumonia (a disease of the lungs), and stroke (resulting from disease of the brain). Pathophysiologic changes that occur with specific diseases and trauma are discussed in the chapters of Section 6, *Medical* and Section 7, *Trauma*.

Respiratory compromise and shock are two common emergencies that you will likely encounter in your work as an EMT. This section provides an overview of respiratory compromise, shock, and alteration of cell metabolism as background for how the body responds to disease or injury.

Respiratory Compromise

Respiratory compromise is the inability of the body to move gas effectively, which can result in a decreased level of oxygen in the body (hypoxia), an elevated level of carbon dioxide in the body (hypercarbia), or both. Recall the two concepts of breathing: ventilation and respiration. Ventilation is the movement of air between the lungs and environment, while respiration is the process of gas exchange. Respiratory compromise results when one of these functions is impaired.

Factors That Impair Ventilation

The ability to move gas back and forth can be impaired in a variety of ways. A blocked airway is one example. If a person chokes on what he or she is eating, this will partially or completely block the movement of air through the trachea. The airway can also be blocked by foreign bodies (eg, toys, or broken teeth), swelling in the airway, trauma to the mouth or neck, and swallowing blood or vomitus. The most common airway obstruction is blockage by the tongue. When a person is unconscious, the tongue relaxes and sags posteriorly in the mouth. The patient cannot "swallow his tongue," but the relaxed tongue blocks the opening to the trachea. Fortunately, the airway can be easily opened with manual techniques that will be discussed in later chapters.

Impairment of the muscles of breathing will impair the movement of gas. Neuromuscular diseases, such as cerebral palsy, can interfere with the ability of the brain to send signals to the diaphragm. Trauma can injure the phrenic nerve (the nerve that signals the diaphragm to contract and initiate inspiration) or damage the brain stem. If a patient's level of consciousness is too low, ventilatory problems can occur. This means that any condition that results in a loss of consciousness can have a direct effect on ventilation. For example, a soccer player who is unconscious after being struck in the head during a match may have impaired ventilation.

Ventilation can also be impaired when the airway is obstructed physiologically; for example, during an asthma attack. Early in an asthma attack, hyperventilation results in a decrease in the amount of carbon dioxide in the blood. As the patient fatigues, the level of carbon dioxide increases. Contraction of muscles surrounding the lower airways prevents effective ventilation.

Ventilation can also be impaired by numerous other factors including drug overdose (which depresses the central nervous system), trauma to the chest wall, and allergic reactions. These are discussed in their respective chapters in greater detail.

Factors That Impair Respiration

Impairment of respiration (movement of gas at the cellular level) can also cause respiratory compromise.

A change in the atmosphere can interfere with a person's ability to breathe. The air you breathe is 21% oxygen, and the air you exhale is 16% oxygen. This means there is only a 5% margin of safety for oxygen concentration in the air you breathe. In certain situations—for example, in a fire—oxygen is displaced by another gas. When there is insufficient oxygen in the air, insufficient oxygen is inhaled. That means there is less oxygen in the alveoli to diffuse into the blood that passes by the lungs. If the cells of the body do not have enough oxygen delivered to them, they will not be able to function normally.

Respiration can also be impaired at high altitudes. At high altitudes, gas pressures change. The low atmospheric pressure of oxygen at high altitudes can impair oxygen movement into the blood.

Words of Wisdom

There are two ways to express the amount of oxygen in the air: as a straight percentage or as a fraction of the inspired oxygen (FIO_2). FIO_2 is expressed as the decimal equivalent of the percentage of oxygen being delivered. Therefore, since oxygen makes up 21% of ambient room air, the FIO_2 of ambient room air is 0.21. The oxygen from a nonrebreathing mask at 15 L/min is approximately 90%, therefore the FIO_2 of the air from a nonrebreathing mask at 15 L/min is approximately 0.9.

Another way respiration can become compromised occurs when movement of the gas across the cell membrane is impaired. If the patient has fluid in the alveoli, this fluid may prevent or hinder gas exchange. In pneumonia, mucus and pus form a barrier, preventing gas from accessing the alveoli. If the interstitial space (space between the cells in the lungs) is filled with fluid, this edema increases the distance from the capillary to the air in the alveoli. Because of the increased distance, it will take longer for the gas to move from inside the alveoli to inside the capillary. If one of the blood vessels bringing blood to the lungs is clogged, this will also affect the amount of gas that diffuses into and out of the blood.

Ventilation/Perfusion Mismatch

One way to understand respiratory compromise is the ventilation/perfusion ratio. This measurement, also called the **$\dot{V}/\dot{Q}$ ratio**, describes how much gas is being moved effectively (ventilation) through the lungs and how much blood is flowing around the alveoli where gas exchange (perfusion) occurs. A mismatch occurs when one of those two variables is abnormal.

For example, in a patient with pulmonary embolism, a blood clot breaks off from a large vein and creates a sudden clog in one of the branches of the pulmonary arteries, preventing blood flow to the alveoli in the lung. Part of the circulating blood does not receive air, and, therefore, gas is not exchanged. Therefore, the "Q" portion of the $\dot{V}/\dot{Q}$ ratio is abnormal.

Another example is pulmonary edema, in which gas is unable to move effectively through the alveoli into the lung. Due to fluid (edema) buildup in the lungs, blood passing through the lung does not get air exchange because there is no ventilation occurring in that portion of the lung. Therefore the "V" portion of the $\dot{V}/\dot{Q}$ ratio is impacted.

When either the "V" or the "Q" is impacted, respiratory compromise can occur.

Effects of Respiratory Compromise on the Body

Regardless of the cause of impaired ventilation or respiration, the overall effect of respiratory compromise is the same.

- Oxygen levels throughout the body fall and carbon dioxide levels rise.
- The brain detects an increase in carbon dioxide levels.

- The body increases its respiratory rate in an attempt to return the carbon dioxide levels to normal.
- If increased respiration does not occur or is not effective in returning the carbon dioxide levels to normal, the blood will become more acidic.
- Similarly, blood oxygen levels will begin to fall. This will cause the brain to issue further commands to breathe.

Decreased oxygen levels will force cells to move from aerobic metabolism to anaerobic metabolism. Remember, the heart and brain cells cannot survive without a constant supply of oxygen and will die in minutes. Anaerobic metabolism generates a fraction of the needed energy, and cellular functions will be impaired. Recall that a by-product of anaerobic metabolism is lactic acid. If too much of this acid is created, the pH of the blood will drop further. If the pH becomes too low, cells will die.

If respiratory compromise is mild and gradual, the body can adapt. Anaerobic metabolism that is severe or lasts more than 1 to 3 minutes can overwhelm the body's ability to adapt; if left untreated, it can exhaust the body's energy supplies and the patient may die Table 6-13.

Shock

Recall that shock (hypoperfusion) is a condition in which organs and tissue receive an inadequate flow of blood and oxygen, or perfusion. It can occur due to inadequacy of the central circulation (insufficient blood volume, or a heart that does not pump effectively) or of the peripheral circulation (inability of the body to control the size of the blood vessels).

Oxygen delivery is directly related to the concentration of blood cells within the blood (hemoglobin concentration), the amount of oxygen being carried by the blood (oxygen saturation), and the pumping ability of the heart (cardiac output). Impairment in any one of these three areas will lead to impaired oxygen delivery and shock.

Table 6-13 Summary of Respiratory Compromise

Category	Problem	Effect
Ventilation	Damage to the regulatory centers of the brain Inability to exhale effectively Inability to inhale effectively Injury to chest Obstruction of the airway Overdose/toxic exposure Loss of consciousness Weakened respiratory muscles	Erratic breathing pattern and rate Carbon dioxide builds up in blood Oxygen levels in the blood decrease Breathing depth decreases Decreased or absent movement of air Decreased level of consciousness leading to decreased breathing rate and depth Breathing depth decreases Breathing depth decreases
Respiration	Fluid within the alveoli (pulmonary edema) Mucus or infectious wastes Impaired blood flow to the lungs (pulmonary embolism)	Prevents gas from entering the alveoli Prevent gas from entering the alveoli Affects blood flow to lung tissue where gas exchange occurs
Oxygenation	Decreased oxygen in the air breathed Increased carbon dioxide in the air breathed Toxins in the air breathed	Affects diffusion of gas Affects diffusion of gas Affect ability of oxygen to be carried effectively in blood

Impaired oxygen delivery causes cellular hypoxia (decreased amount of oxygen delivered to the cells), which in turn leads to anaerobic metabolism, lactic acid production, and organ dysfunction.

Shock is categorized into several types depending on the cause. These types are defined in Table 6-14 and discussed in more detail in Chapter 12, *Shock*.

Effects of Shock on the Body

The effects of inadequate perfusion on the body are similar to those of respiratory compromise. The level of oxygen supplied to the tissues falls. This causes the cells to engage in anaerobic metabolism, which results in increased lactic acid production.

A severe metabolic acidosis ensues, leading to increased levels of carbon dioxide within the blood. Patients who can compensate increase their breathing rate and depth, thereby increasing their minute volume.

Baroreceptors detect the decreased blood pressure and initiate the release of epinephrine and norepinephrine. The heart rate will increase, the heart will beat more forcefully, and the blood vessels will constrict. The body's goal is to maintain blood pressure to the areas of the body that are unable to survive without oxygen: the brain and the heart.

Another compensatory mechanism, particularly with hypovolemic shock, is the movement of fluid outside of the cells and outside of the blood vessels (interstitial fluid) into the capillaries. This helps refill the blood vessels and restore some fluid volume so the heart has enough liquid to pump. However, in other forms of shock such as septic and anaphylactic shock, the capillaries leak, and volume from the blood vessels (intravascular volume) moves into the interstitial space. This loss of vascular fluid means there is less blood returning to the heart to pump.

Ultimately the effect of all types of shock is decreased availability of fuel for the cells and impairment of cellular metabolism. Once a certain level of tissue hypoperfusion is reached, cell damage proceeds in a similar manner regardless of the underlying cause of the shock.

Alteration of Cellular Metabolism

Impairment of cellular metabolism results in the inability to properly use oxygen and glucose at the cellular level.

As discussed, when there is inadequate oxygen, cells will create energy through anaerobic metabolism. Anaerobic metabolism serves as a temporary backup system to allow cells to function at low energy levels for a short time. Most cells are able to use alternative fuel supplies to help bridge the gap until perfusion is restored. For example, when a person is engaged in strenuous exercise, the demand for glucose by the muscles exceeds the available supply. The body begins to burn fats and turns them into glucose to meet this need.

Table 6-14 Types of Shock

Type	Description	Examples of Causes
Hypovolemic	Shock resulting from lack of blood volume. Circulating blood volume is inadequate to deliver sufficient oxygen and nutrients to the body	▪ Trauma (blood loss results in inability to transport oxygen and nutrients) ▪ Severe vomiting/diarrhea (substantial loss of water can lead to decreased circulating blood volume; there is less blood to transport oxygen and nutrients)
Cardiogenic	Shock associated with impaired heart function; compromised heart function prevents wastes and nutrients from moving around the body effectively	▪ Weakened heart muscles as a result of myocardial infarction (heart attack) or other conditions ▪ Very fast or very slow heart rate (can prevent blood from moving effectively, blood pressure drops, and perfusion is diminished)
Obstructive	Shock resulting from blocked blood flow back to or through the heart	▪ Severe lung collapse (tension pneumothorax) (pushes on the vena cava, preventing it from returning blood to the heart) ▪ Accumulation of fluid in the sac surrounding the heart (prevents heart from filling) ▪ Large blood clot in pulmonary artery (pulmonary embolus) (can prevent right ventricle from pumping blood out of the heart into the lungs)
Anaphylactic	Shock resulting from severe allergic reaction	▪ Severe allergic reaction (blood vessels dilate, blood pressure drops, and perfusion decreases)
Septic	Shock resulting from severe infection; blood vessels dilate and decreased blood pressure results; leads to dysfunction in multiple organ systems and death	▪ Severe infection (blood vessels dilate, blood pressure drops, and perfusion decreases)
Neurogenic	Shock resulting from injury to the nervous system; for example, spinal cord injury may result in dilation of vessels (vasodilation) below the level of the injury	▪ High spinal cord injury (blood vessels dilate, blood pressure drops, and perfusion decreases)

However, anaerobic metabolism has some important drawbacks. Recall that the use of fats as an alternative fuel supply results in a buildup of lactic acid. This ultimately can result in metabolic acidosis. The process of anaerobic metabolism requires more energy than when using glucose for fuel. Therefore, there are more wastes to be removed, and the body must work harder. Other conditions resulting from anaerobic metabolism include decreased ability for the blood to effectively carry oxygen to the cells and overall decreased functioning of oxygen within the cell.

Although most cells are able to use alternative fuels, brain cells cannot. They rely on a constant supply of glucose to function. When perfusion is impaired, there is less glucose for cells to use. If the supply of available glucose is dramatically decreased, brain cells will quickly become damaged or die.

Cellular injury may, up to a point, be repairable if normal tissue perfusion is restored. When irreversible injury occurs, however, no treatment will help. Cell death is followed by necrosis, a process in which the cell breaks down. The cell membrane becomes abnormally permeable, leading to an influx of electrolytes and fluids. The cell and its components (organelles) swell and are ultimately destroyed, resulting in cell death.

Therefore, when perfusion is ineffective, it needs to be restored so that cells can return to a state of aerobic metabolism and life can continue. Many interventions you perform as an EMT will be aimed at improving conditions that can result in impaired perfusion.

YOU are the Provider — SUMMARY

1. How will knowledge of anatomy and physiology help you provide appropriate patient care?

Knowledge of anatomy and physiology is important for anyone who provides patient care—emergency or otherwise. When a patient reports pain to any part of the body, your knowledge of human anatomy will help you form a logical field impression—that is, what you believe to be the primary problem—regarding which organ or organs may be affected. Your knowledge of physiology will help you predict the negative effects the patient may experience based on the organ or organs affected. From this information, an appropriate treatment plan can be formulated and implemented.

Although you are not expected to diagnose a patient's condition, a strong fundamental knowledge of anatomy, physiology, and medical terminology will help you communicate the correct information to the emergency department physician or nurse.

2. On the sole basis of the patient's chief complaint, which organ or organs should you suspect is/are the cause of his condition?

The major organs in the right upper quadrant (RUQ) are the liver, gallbladder, and a portion of the large intestine (colon). Although your initial thoughts should focus on dysfunction of one or more of these organs, the patient's true problem may exist elsewhere in his abdomen and the pain just happens to be manifesting in his RUQ. Although your objectives are to recognize that the patient has an acute abdominal problem and to find and treat life-threatening conditions, you will need to ask additional questions to clarify his complaint. His answers to your questions will help you formulate a field impression.

3. What additional questions should you ask to gather more information about his chief complaint?

After determining why the patient called 9-1-1, ask the patient to elaborate on the complaint; this is called the history of present illness. The OPQRST mnemonic is a useful tool for this purpose.

The patient has already told you that his pain began suddenly 20 minutes ago, so the "O" and "T" in the OPQRST have been established. Ask him if anything makes his pain better or worse; patients with abdominal pain often draw their knees into their abdomen to take pressure off the abdominal muscles, which may provide them slight relief of their pain. Ask the patient if the pain stays in the RUQ of his abdomen or moves/ travels somewhere else; determine if he has referred pain by asking if he hurts anywhere else in addition to his RUQ. Assess the severity of his pain by using the 0 to 10 scale, with 0 being no pain and 10 being the worst pain ever experienced. Pain severity should be assessed frequently, especially after any interventions have been performed. Although chronic pain can indicate a serious underlying problem, you should be especially concerned that his pain began acutely.

Other questions to ask the patient should focus on common symptoms associated with abdominal pain, such as nausea and/or vomiting, diarrhea, and urinary difficulty, among others. When possible, try not to ask leading questions (ie, "Are you nauseated?"); instead, simply ask him if he has any other symptoms.

4. What additional symptoms would you expect the patient to experience based on the function of the gallbladder?

The gallbladder contracts only when food enters the duodenum; patients with inflammation of the gallbladder (cholecystitis) typically have pain in the right upper quadrant within an hour or so after eating a meal. In many cases, the patient also reports referred pain to the right shoulder. Other symptoms of gallbladder disease include nausea, vomiting, and heartburn.

Most cases of cholecystitis occur when gallstones form and block the outlet of the gallbladder. In some cases, the gallstones spontaneously pass; however, if they do not, the patient experiences pain of varying intensity.

5. How does knowledge of anatomy, physiology, and medical terminology facilitate communication with other health care professionals?

As part of the health care team, everything you do should benefit the patient. An integral part of patient care is effective communication with other health care professionals. Your ability to speak the language of medicine will minimize communication barriers between you and other members of the health care team and therefore will directly benefit your patient.

Whether you are calling in your radio report from the ambulance or giving a verbal report at the hospital, the use of appropriate medical terminology ensures that the information you pass along is relevant and accurate.

Review human anatomy and physiology and medical terminology on a regular basis. Although the structure and function of the body and the terms used to describe it do not change, your ability to recall the information can deteriorate over time.

6. Should your documentation of an EMS call differ from your verbal communication with other health care professionals? Why or why not?

No. Your verbal communication and the patient care report (PCR) should reflect the same relevant and accurate information. When possible, use proper medical terminology when documenting the patient’s complaint, history of present illness, medical history, and any treatment provided in the prehospital setting. If you are unsure of the correct medical term to accurately describe a particular aspect of the patient’s complaint or physical examination, use plain English. The PCR is read by the personnel who assume patient care from you and may have a direct impact on future care that the patient receives. It also becomes part of the patient’s permanent medical record. The use of proper medical terminology, coupled with an accurate depiction of the care you provided, will facilitate continuity of the patient’s care.

EMS Patient Care Report (PCR)

Date: 6-10-16	**Incident No.:** 050109	**Nature of Call:** Abdominal pain		**Location:** 322 Azalea Trail	
Dispatched: 1740	**En Route:** 1741	**At Scene:** 1747	**Transport:** 1759	**At Hospital:** 1809	**In Service:** 1817

Patient Information

Age: 60 **Sex:** M **Weight (in kg [lb]):** 84 kg (185 lb)	**Allergies:** Sulfa, Codeine, Contrast dye **Medications:** Zyrtec, Pepcid **Past Medical History:** Gallbladder problems **Chief Complaint:** Abdominal pain

Vital Signs

Time: 1749	**BP:** 142/82	**Pulse:** 110	**Respirations:** 24	**Spo_2:** 98%
Time: 1759	**BP:** 138/88	**Pulse:** 112	**Respirations:** 24	**Spo_2:** 97%
Time: 1808	**BP:** 132/80	**Pulse:** 90	**Respirations:** 20	**Spo_2:** 99%

EMS Treatment (circle all that apply)

Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** Position of comfort

Narrative

9-1-1 dispatch for a male patient with abdominal pain. On arrival at the scene, found the patient, a 60-year-old man, lying on his side on the floor of his bedroom with his knees drawn up into his abdomen. He was conscious and alert; his airway was patent, and his breathing was adequate. Patient stated the pain (8 on a 0 to 10 scale) began suddenly approximately 20 minutes earlier. His past medical history is significant for gallbladder problems; no other medical history reported. Applied oxygen at 15 L/min via nonrebreathing mask and obtained vital signs. Further assessment of patient's abdomen revealed that it was soft; however, it was point tender to palpation of the RUQ. Patient denied chest pain, shortness of breath, nausea or vomiting, and any other symptoms. He further denied radiating and referred pain. Placed patient onto the stretcher, allowed him to assume a position of comfort, loaded him into the ambulance, and began transport to the hospital. En route, continued to monitor patient's condition, which remained unchanged. Vital signs reassessed and noted above. Shortly before arrival at the hospital, reassessment of the patient revealed that his vital signs remained stable and that his pain had decreased in severity. Transferred care of patient to receiving hospital without incident and gave verbal report to charge nurse. Departed the hospital and returned to service.**End of report**

Prep Kit

Ready for Review

- To properly care for your patients, you must have a thorough understanding of human anatomy and physiology so you can assess your patients' condition and communicate with hospital personnel and other health care providers.
- You must be able to identify superficial landmarks of the body and know what lies underneath the skin so that you can perform an accurate patient assessment.
- The skeleton gives the body its recognizable human form through a collection of bones, ligaments, tendons, and cartilage.
- The skeletal system provides protection for fragile organs, allows for movement, and gives the body its shape.
- The contraction and relaxation of the musculoskeletal system gives the body its ability to move.
- The respiratory system consists of all the structures of the body that contribute to the process of breathing. It includes the nose, mouth, throat, larynx, trachea, bronchi, and bronchioles.
- The function of the respiratory system is to provide the body with oxygen and eliminate carbon dioxide.
- The circulatory system is a complex arrangement of connected tubes, including the arteries, arterioles, capillaries, venules, and veins.
- The nervous system is perhaps the most complex organ system within the human body. It consists of the brain, spinal cord, and nerves.
- The skin is divided into two parts: the superficial epidermis, which is composed of several layers of cells, and the deeper dermis, which contains the specialized skin structures.
- The skin, the largest single organ in the body, serves three major functions: to protect the body in the environment, to regulate the temperature of the body, and to transmit information from the environment to the brain.
- The digestive system is composed of the gastrointestinal tract (stomach and intestines), mouth, salivary glands, pharynx, esophagus, liver, gallbladder, pancreas, rectum, and anus.
- Digestion of food, from the moment it is taken into the mouth until essential compounds are extracted and delivered by the circulatory system to nourish all of the cells in the body, is a complicated chemical process.
- The lymphatic system is composed of the spleen, lymph nodes, lymph, lymph vessels, thymus gland, and other components. It supports the circulatory system and the immune system, and relies on muscle contractions and movements of the body for lymph to flow.
- The endocrine system is a complex message and control system that integrates many body functions.
- The urinary system controls the discharge of certain waste materials filtered from the blood by the kidneys.
- The genital system controls the reproductive processes by which life is created.
- Solutions that are high in pH (>7.0) are considered alkaline. Solutions that are low in pH (<7.0) are considered acidic. A solution that is neither acidic nor alkaline is considered neutral (pH 7.0).
- Pathophysiology is the study of how normal physiologic processes are affected by disease.
- Respiratory compromise is the inability of the body to move gas effectively. Respiratory compromise results when either ventilation or respiration is impaired.
- Shock is a condition in which organs and tissue receive an inadequate flow of blood and oxygen, or perfusion. Impaired oxygen delivery causes cellular hypoxia, which in turn leads to anaerobic metabolism, lactic acid production, and organ dysfunction.
- Impairment of cellular metabolism results in the inability to properly use oxygen and glucose at the cellular level. When irreversible cellular injury occurs, no treatment will help. Therefore, when perfusion is ineffective, it needs to be restored quickly.

Vital Vocabulary

abdomen The body cavity that contains the major organs of digestion and excretion. It is located below the diaphragm and above the pelvis.

acetabulum The depression on the lateral pelvis where its three component bones join, in which the femoral head fits snugly.

Adam's apple A firm prominence of cartilage that forms the upper part of the larynx. It is more prominent in men than in women. Also called the thyroid cartilage.

adenosine triphosphate (ATP) The nucleotide involved in energy metabolism; used to store energy.

adrenal glands Endocrine glands located on top of the kidneys that release adrenaline when stimulated by the sympathetic nervous system.

adrenergic Pertaining to nerves that release the neurotransmitter norepinephrine, or noradrenaline (such as adrenergic nerves, adrenergic response); also pertains to the receptors acted on by norepinephrine.

aerobic metabolism Metabolism that can proceed only in the presence of oxygen.

agonal gasps Abnormal breathing pattern characterized by slow, gasping breaths, sometimes seen in patients in cardiac arrest.

alpha-adrenergic receptors Portions of the nervous system that, when stimulated, can cause constriction of blood vessels.

alveoli The air sacs of the lungs in which the exchange of oxygen and carbon dioxide takes place.

anaerobic metabolism The metabolism that takes place in the absence of oxygen; the main by-product is lactic acid.

anatomic position The position of reference in which the patient stands facing forward, arms at the side, with the palms of the hands forward.

aorta The main artery leaving the left side of the heart and carrying freshly oxygenated blood to the body.

appendicular skeleton The portion of the skeletal system that comprises the arms, legs, pelvis, and shoulder girdle.

appendix A small, tubular structure that is attached to the lower border of the cecum in the lower right quadrant of the abdomen.

arterioles The smallest branches of arteries leading to the vast network of capillaries.

articular cartilage A pearly layer of specialized cartilage covering the articular surfaces (contact surfaces on the ends) of bones in synovial joints.

atrium One of the two upper chambers of the heart.

autonomic nervous system The part of the nervous system that regulates functions, such as digestion and sweating, that are not controlled voluntarily.

axial skeleton The part of the skeleton comprising the skull, spinal column, and rib cage.

ball-and-socket joint A joint that allows internal and external rotation, as well as bending.

beta-adrenergic receptors Portions of the nervous system that, when stimulated, can cause an increase in the force of contraction of the heart, an increased heart rate, and bronchial dilation.

biceps The large muscle that covers the front of the humerus.

bile ducts The ducts that convey bile between the liver and the intestine.

blood pressure (BP) The pressure that the blood exerts against the walls of the arteries as it passes through them.

brachial artery The major vessel in the upper extremities that supplies blood to the arm.

brain The controlling organ of the body and center of consciousness; functions include perception, control of reactions to the environment, emotional responses, and judgment.

brain stem The area of the brain between the spinal cord and cerebrum, surrounded by the cerebellum; controls functions that are necessary for life, such as respiration.

capillary vessels The tiny blood vessels between the arterioles and venules that permit transfer of oxygen, carbon dioxide, nutrients, and waste between body tissues and the blood.

cardiac muscle The heart muscle.

cardiac output (CO) A measure of the volume of blood circulated by the heart in 1 minute, calculated by multiplying the stroke volume by the heart rate.

carotid artery The major artery that supplies blood to the head and brain.

cartilage The smooth connective tissue that forms the support structure of the skeletal system and provides cushioning between bones; also forms the nasal septum and portions of the outer ear.

cecum The first part of the large intestine, into which the ileum opens.

central nervous system (CNS) The brain and spinal cord.

cerebellum One of the three major subdivisions of the brain, sometimes called the little brain; coordinates the various activities of the brain, particularly fine body movements.

cerebrospinal fluid (CSF) Fluid produced in the ventricles of the brain that flows in the subarachnoid space and bathes the meninges.

cerebrum The largest part of the three subdivisions of the brain, sometimes called the gray matter; made up of several lobes that control movement, hearing, balance, speech, visual perception, emotions, and personality.

cervical spine The portion of the spinal column consisting of the first seven vertebrae that lie in the neck.

chordae tendineae Thin bands of fibrous tissue that attach to the valves in the heart and prevent them from inverting.

chyme The substance that leaves the stomach. It is a combination of all of the eaten foods with added stomach acids.

circulatory system The complex arrangement of connected tubes, including the arteries, arterioles, capillaries, venules, and veins, that moves blood, oxygen, nutrients, carbon dioxide, and cellular waste throughout the body.

clavicle The collar bone; it is lateral to the sternum and anterior to the scapula.

coccyx The last three or four vertebrae of the spine; the tail bone.

coronal plane An imaginary plane where the body is divided into front and back parts.

cranium The area of the head above the ears and eyes; the skull. The cranium contains the brain.

cricoid cartilage A firm ridge of cartilage that forms the lower part of the larynx.

cricothyroid membrane A thin sheet of fascia that connects the thyroid and cricoid cartilages that make up the larynx.

dead space Any portion of the airway that does contain air and cannot participate in gas exchange, such as the trachea and bronchi.

dermis The inner layer of the skin, containing hair follicles, sweat glands, nerve endings, and blood vessels.

diaphragm A muscular dome that forms the undersurface of the thorax, separating the chest from the abdominal cavity. Contraction of this (and the chest wall muscles) brings air into the lungs. Relaxation allows air to be expelled from the lungs.

diastole The relaxation, or period of relaxation, of the heart, especially of the ventricles.

diffusion Movement of a gas from an area of higher concentration to an area of lower concentration.

digestion The processing of food that nourishes the individual cells of the body.

dorsalis pedis artery The artery on the anterior surface of the foot between the first and second metatarsals.

endocrine system The complex message and control system that integrates many body functions, including the release of hormones.

enzymes Substances designed to speed up the rate of specific biochemical reactions.

epidermis The outer layer of skin, which is made up of cells that are sealed together to form a watertight protective covering for the body.

epiglottis A thin, leaf-shaped valve that allows air to pass into the trachea but prevents food and liquid from entering.

epinephrine A hormone produced by the adrenal medulla that has a vital role in the function of the sympathetic nervous system.

esophagus A collapsible tube that extends from the pharynx to the stomach; muscle contractions propel food and liquids through it to the stomach.

expiratory reserve volume The amount of air that can be exhaled following a normal exhalation; average volume is about 1,200 mL in the average adult man.

extension The straightening of a joint.

fallopian tubes Long, slender tubes that extend from the uterus to the region of the ovary on the same side and through which the ovum passes from the ovary to the uterus.

femoral artery The major artery of the thigh, a continuation of the external iliac artery. It supplies blood to the lower abdominal wall, external genitalia, and legs. It can be palpated in the groin area.

femoral head The proximal end of the femur, articulating with the acetabulum to form the hip joint.

femur The *thighbone*; the longest and one of the strongest bones in the body.

flexion The bending of a joint.

foramen magnum A large opening at the base of the skull through which the brain connects to the spinal cord.

frontal bone The portion of the cranium that forms the forehead.

gallbladder A sac on the undersurface of the liver that collects bile from the liver and discharges it into the duodenum through the common bile duct.

genital system The reproductive system in men and women.

germinal layer The deepest layer of the epidermis where new skin cells are formed.

greater trochanter A bony prominence on the proximal lateral side of the thigh, just below the hip joint.

hair follicles The small organs that produce hair.

heart A hollow muscular organ that pumps blood throughout the body.

heart rate (HR) The number of heartbeats during a specific time (usually 1 minute).

hinge joints Joints that can bend and straighten but cannot rotate; they restrict motion to one plane.

hormones Substances formed in specialized organs or glands and carried to another organ or group of cells in the same organism; they regulate many body functions, including metabolism, growth, and body temperature.

humerus The supporting bone of the upper arm.

hydrostatic pressure The pressure of water against the walls of its container.

hypoxic drive A "backup system" to control respiration; senses drops in the oxygen level in the blood.

ilium One of three bones that fuse to form the pelvic ring.

inferior vena cava One of the two largest veins in the body; carries blood from the lower extremities and the pelvic and the abdominal organs to the heart.

inspiratory reserve volume The amount of air that can be inhaled after a normal inhalation; the amount of air that can be inhaled in addition to the normal tidal volume.

interstitial space The space in between the cells.

involuntary muscle The muscle over which a person has no conscious control. It is found in many automatic regulating systems of the body.

ischium One of three bones that fuse to form the pelvic ring.

joint (articulation) The place where two bones come into contact.

joint capsule The fibrous sac that encloses a joint.

kidneys Two retroperitoneal organs that excrete the end products of metabolism as urine and regulate the body's salt and water content.

labored breathing The use of muscles of the chest, back, and abdomen to assist in expanding the chest; occurs when air movement is impaired.

lactic acid A metabolic by-product of the breakdown of glucose that accumulates when metabolism proceeds in the absence of oxygen (anaerobic metabolism).

large intestine The portion of the digestive tube that encircles the abdomen around the small bowel, consisting of the cecum, the colon, and the rectum. It helps regulate water balance and eliminate solid waste.

lesser trochanter The projection on the medial/ superior portion of the femur.

ligament A band of fibrous tissue that connects bones to bones. It supports and strengthens a joint.

liver A large, solid organ that lies in the right upper quadrant immediately below the diaphragm; it produces bile, stores glucose for immediate use by the body, and produces many substances that help regulate immune responses.

lumbar spine The lower part of the back, formed by the lowest five nonfused vertebrae; also called the dorsal spine.

lymph A thin, straw-colored fluid that carries oxygen, nutrients, and hormones to the cells and carries waste products of metabolism away from the cells and back into the capillaries so that they may be excreted.

lymph nodes Tiny, oval-shaped structures located in various places along the lymph vessels that filter lymph.

mandible The bone of the lower jaw.

manubrium The upper quarter of the sternum.

maxillae The upper jawbones that assist in the formation of the orbit, the nasal cavity, and the palate and hold the upper teeth.

medulla oblongata Nerve tissue that is continuous inferiorly with the spinal cord; serves as a conduction pathway for ascending and descending nerve tracts; coordinates heart rate, blood vessel diameter, breathing, swallowing, vomiting, coughing, and sneezing.

metabolism (cellular respiration) The biochemical processes that result in production of energy from nutrients within cells.

midbrain The part of the brain that is responsible for helping to regulate the level of consciousness.

midsagittal plane (midline) An imaginary vertical line drawn from the middle of the forehead through the nose and the umbilicus (navel) to the floor, dividing the body into equal left and right halves.

minute volume The volume of air that moves in and out of the lungs per minute; calculated by multiplying the tidal volume and respiratory rate; also called minute ventilation.

motor nerves Nerves that carry information from the central nervous system to the muscles of the body.

mucous membranes The lining of body cavities and passages that communicate directly or indirectly with the environment outside the body.

mucus The watery secretion of the mucous membranes that lubricates the body openings.

musculoskeletal system The bones and voluntary muscles of the body.

myocardium The heart muscle.

nasopharynx The part of the pharynx that lies above the level of the roof of the mouth, or palate.

nervous system The system that controls virtually all activities of the body, both voluntary and involuntary.

norepinephrine A neurotransmitter and drug sometimes used in the treatment of shock; produces vasoconstriction through its alpha-stimulator properties.

occiput The most posterior portion of the cranium.

oncotic pressure The pressure of water to move, typically into the capillary, as the result of the presence of plasma proteins.

orbit The eye socket, made up of the maxilla and zygoma.

oropharynx A tubular structure that extends vertically from the back of the mouth to the esophagus and trachea.

ovaries Female glands that produces sex hormones and ova (eggs).

pancreas A flat, solid organ that lies below the liver and the stomach; it is a major source of digestive enzymes and produces the hormone insulin.

parasympathetic nervous system A subdivision of the autonomic nervous system, involved in control of involuntary functions, mediated largely by the vagus nerve through the chemical acetylcholine.

parietal bones The bones that lie between the temporal and occipital regions of the cranium.

patella The knee cap; a specialized bone that lies within the tendon of the quadriceps muscle.

pathophysiology The study of how normal physiologic processes are affected by disease.

perfusion The circulation of oxygenated blood within an organ or tissue in adequate amounts to meet the cells' current needs.

peripheral nervous system (PNS) The part of the nervous system that consists of 31 pairs of spinal nerves and 12 pairs of cranial nerves; these may be sensory nerves, motor nerves, or connecting nerves.

peristalsis The wavelike contraction of smooth muscle by which the ureters or other tubular organs propel their contents.

plasma A sticky, yellow fluid that carries the blood cells and nutrients and transports cellular waste material to the organs of excretion.

platelets Tiny, disc-shaped elements that are much smaller than the cells; they are essential in the initial formation of a blood clot, the mechanism that stops bleeding.

pleura The serous membranes covering the lungs and lining the thorax, completely enclosing a potential space known as the pleural space.

pleural space The potential space between the parietal pleura and the visceral pleura; described as "potential" because under normal conditions, the space does not exist.

pons An organ that lies below the midbrain and above the medulla and contains numerous important nerve fibers, including those for sleep, respiration, and the medullary respiratory center.

posterior tibial artery The artery just behind the medial malleolus; supplies blood to the foot.

prostate gland A small gland that surrounds the male urethra where it emerges from the urinary bladder; it secretes a fluid that is part of the ejaculatory fluid.

pubic symphysis A hard, bony, and cartilaginous prominence found at the midline in the lowermost portion of the abdomen where the two halves of the pelvic ring are joined by cartilage at a joint with minimal motion.

pubis One of three bones that fuse to form the pelvic ring.

pulmonary artery The major artery leading from the right ventricle of the heart to the lungs; carries oxygen-poor blood.

pulmonary circulation The flow of blood from the right ventricle through the pulmonary arteries and all of their branches and capillaries in the lungs and back to the left atrium through the venules and pulmonary veins; also called the lesser circulation.

pulmonary veins The four veins that return oxygenated blood from the lungs to the left atrium of the heart.

pulse The wave of pressure created as the heart contracts and forces blood out the left ventricle and into the major arteries.

radial artery The major artery in the forearm; it is palpable at the wrist on the thumb side.

radius The bone on the thumb side of the forearm.

rectum The lowermost end of the colon.

red blood cells Cells that carry oxygen to the body's tissues; also called erythrocytes.

renal pelvis A cone-shaped area that collects urine from the kidneys and funnels it through the ureter into the bladder.

residual volume The air that remains in the lungs after maximal expiration.

respiration The inhaling and exhaling of air; the physiologic process that exchanges carbon dioxide from fresh air.

respiratory compromise The inability of the body to move gas effectively.

respiratory system All the structures of the body that contribute to the process of breathing, consisting of the upper and lower airways and their component parts.

reticular activating system Located in the upper brain stem; responsible for maintenance of consciousness, specifically one's level of arousal.

retroperitoneal Behind the abdominal cavity.

sacroiliac joint The connection point between the pelvis and the vertebral column.

sacrum One of three bones (sacrum and two pelvic bones) that make up the pelvic ring; consists of five fused sacral vertebrae.

sagittal (lateral) plane An imaginary line where the body is divided into left and right parts.

salivary glands The glands that produce saliva to keep the mouth and pharynx moist.

scalp The thick skin covering the cranium, which usually bears hair.

scapula The shoulder blade.

sebaceous glands Glands that produce an oily substance called sebum, which discharges along the shafts of the hairs.

semen Fluid ejaculated from the penis and containing sperm.

seminal vesicles Storage sacs for sperm and seminal fluid, which empty into the urethra at the prostate.

sensory nerves The nerves that carry sensations such as touch, taste, smell, heat, cold, and pain from the body to the central nervous system.

shock An abnormal state associated with inadequate oxygen and nutrient delivery to the cells of the body, also known as hypoperfusion.

shoulder girdle The proximal portion of the upper extremities, made up of the clavicle, the scapula, and the humerus.

skeletal muscle Muscle that is attached to bones and usually crosses at least one joint; striated, or voluntary, muscle.

skeleton The framework that gives the body its recognizable form; also designed to allow motion of the body and protection of vital organs.

small intestine The portion of the digestive tube between the stomach and the cecum, consisting of the duodenum, jejunum, and ileum.

smooth muscle Involuntary muscle; it constitutes the bulk of the gastrointestinal tract and is present in nearly every organ to regulate automatic activity.

somatic nervous system The part of the nervous system that regulates activities over which there is voluntary control.

sphincters Muscles arranged in circles that are able to decrease the diameter of tubes. Examples are found within the rectum, bladder, and blood vessels.

sphygmomanometer A device used to measure blood pressure.

spinal cord An extension of the brain, composed of virtually all the nerves carrying messages between the brain and the rest of the body. It lies inside of and is protected by the spinal canal.

sternum The breast bone.

stratum corneal layer The outermost or dead layer of the skin.

stroke volume (SV) The volume of blood pumped forward with each ventricular contraction.

subcutaneous tissue Tissue, largely fat, that lies directly under the dermis and serves as an insulator of the body.

superior vena cava One of the two largest veins in the body; carries blood from the upper extremities, head, neck, and chest into the heart.

sweat glands The glands that secrete sweat, located in the dermal layer of the skin.

symphysis A type of joint that has grown together to form a very stable connection.

synovial fluid The small amount of liquid within a joint used as lubrication.

synovial membrane The lining of a joint that secretes synovial fluid into the joint space.

systemic circulation The portion of the circulatory system outside of the heart and lungs.

systemic vascular resistance (SVR) The resistance that blood must overcome to be able to move within the blood vessels; related to the amount of dilation or constriction in the blood vessel.

systole The contraction, or period of contraction, of the heart, especially that of the ventricles.

temporal bones The lateral bones on each side of the cranium; the temples.

tendons The fibrous connective tissue that attaches muscle to bone.

testicle A male genital gland that contains specialized cells that produce hormones and sperm.

thoracic cage The chest or rib cage.

thoracic spine The 12 vertebrae that lie between the cervical vertebrae and the lumbar vertebrae. One pair of ribs is attached to each of these vertebrae.

thorax The chest cavity that contains the heart, lungs, esophagus, and great vessels.

thyroid cartilage A firm prominence of cartilage that forms the upper part of the larynx; the Adam’s apple.

tibia The shinbone; the larger of the two bones of the lower leg.

tidal volume The amount of air moved in and out of the lungs in one relaxed breath; about 500 mL for an adult.

topographic anatomy The superficial landmarks of the body that serve as guides to the structures that lie beneath them.

trachea The windpipe; the main trunk for air passing to and from the lungs.

transverse (axial) plane An imaginary line where the body is divided into top and bottom parts.

triceps The muscle in the back of the upper arm.

tunica media The middle and thickest layer of tissue of a blood vessel wall, composed of elastic tissue and smooth muscle cells that allow the vessel to expand or contract in response to changes in blood pressure and tissue demand.

ulna The inner bone of the forearm, on the side opposite the thumb.

ureter A small, hollow tube that carries urine from the kidneys to the bladder.

urethra The canal that conveys urine from the bladder to outside the body.

urinary bladder A sac behind the pubic symphysis made of smooth muscle that collects and stores urine.

urinary system The organs that control the discharge of certain waste materials filtered from the blood and excreted as urine.

vagina A muscular, distensible tube that connects the uterus with the vulva (the external female genitalia); also called the birth canal.

vasa deferentia The spermatic duct of the testicles; also called vas deferens.

ventilation The movement of air between the lungs and the environment.

ventricle One of two lower chambers of the heart.

vertebrae The 33 bones that make up the spinal column.

voluntary muscle Muscle that is under direct voluntary control of the brain and can be contracted or relaxed at will; skeletal, or striated, muscle.

V/Q ratio A measurement that examines how much gas is being moved effectively and how much blood is flowing around the alveoli where gas exchange (perfusion) occurs.

white blood cells Blood cells that have a role in the body’s immune defense mechanisms against infection; also called leukocytes.

xiphoid process The narrow, cartilaginous lower tip of the sternum.

zygomas The quadrangular bones of the cheek, articulating with the frontal bone, the maxillae, the zygomatic processes of the temporal bone, and the great wings of the sphenoid bone.

Assessment *in Action*

© Jones & Bartlett Learning. Courtesy of MIEMSS.

You are dispatched to an unresponsive person at an automotive garage. On arrival, you find a middle-aged man lying on the ground by a tire rack.

1. You observe the patient as you approach. He is lying face-up. As you look at the front side of his body, which plane of the body are you observing?

   A. Coronal
   B. Midsagittal
   C. Sagittal
   D. Transverse

2. After opening the patient's airway and confirming spontaneous respirations, you check for a pulse on his neck just lateral to the trachea. What artery are you palpating?

   A. Radial
   B. Carotid
   C. Femoral
   D. Brachial

3. You determine the patient has a strong pulse and perform a rapid assessment. While assessing the lower extremities, you observe marked swelling in the right thigh. What bone is in this location?

   A. Fibula
   B. Tibia
   C. Femur
   D. Patella

4. Which of the following substances is the main element that the bone cells use to create a hard and resilient structure?

   A. Sodium
   B. Potassium

C. Magnesium
D. Calcium

5. You perform an assessment while en route to the hospital. You note bruising and instability of the right cheekbone. What is the proper name for this bone?

   A. Zygoma
   B. Maxilla
   C. Sphenoid
   D. Mandible

6. The larger bone of the forearm at the wrist is the:

   A. humerus.
   B. ulna.
   C. radius.
   D. clavicle.

7. The forearm makes up part of the elbow. The elbow is an example of what type of joint?

   A. Hinge
   B. Ball-and-socket
   C. Saddle
   D. Immovable

8. Explain what occurs in the body as a result of respiratory compromise.

9. On the basis of your assessment findings, you suspect that your patient may have sustained a closed head injury. What structure of the brain is responsible for the level of consciousness and maintenance of vital signs?

10. Just before arriving at the hospital, you take your final set of vital signs. The patient's initial pulse rate was 89 beats/min and now it is 116 beats/min. What part of the nervous system is responsible for this increase, and how does it work?

CHAPTER 7

Life Span Development

© Digital Vision/Thinkstock.

National EMS Education Standard Competencies

Preparatory

Applies fundamental knowledge of the emergency medical services (EMS) system, safety/well-being of the emergency medical technician (EMT), medical/legal, and ethical issues to the provision of emergency care.

Life Span Development

Applies fundamental knowledge of life span development to patient assessment and management.

Knowledge Objectives

1. Know the terms used to designate the following stages of life: infants, toddlers and preschoolers, school-age children, adolescents (teenagers), early adults, middle adults, and older adults. (pp 241–251)
2. Describe the major physical and psychosocial characteristics of an infant's life. (pp 241–244)
3. Describe the major physical and psychosocial characteristics of a toddler and preschooler's life. (pp 245–247)
4. Describe the major physical and psychosocial characteristics of a school-age child's life. (p 247)
5. Describe the major physical and psychosocial characteristics of an adolescent's life. (pp 247–249)
6. Describe the major physical and psychosocial characteristics of an early adult's life. (pp 249–250)
7. Describe the major physical and psychosocial characteristics of a middle adult's life. (pp 250–251)
8. Describe the major physical and psychosocial characteristics of an older adult's life. (pp 251–255)

Skills Objectives

There are no skills objectives for this chapter.

Introduction

As living organisms, humans develop throughout their lives. The period from birth to death—the life span—is marked by constant change. Newborns and infants are completely dependent on others for every aspect of their care, while toddlers and preschoolers learn to move from gross motor activities (eg, kicking and crawling) to fine motor activities (eg, holding toys and writing). School-age children begin to learn various types of reasoning from more environmental and social interactions, and adolescents struggle to create their own identity and image as they start to transition out of childhood. Adulthood is marked by three stages, early, middle, and older, and ranges from age 19 to death. Each stage brings its rewards and challenges. As an EMT, you must be aware of the obvious and not so obvious changes a person undergoes physically and mentally at various stages of life and understand how these changes may alter your approach to patient care.

Neonates (Birth to 1 Month) and Infants (1 Month to 1 Year)

As any parent can attest, **infants** (ages 1 month to 1 year) develop at a surprising rate Figure 7-1. **Neonates** (from birth to 1 month) are covered in detail in Chapter 33, *Obstetrics and Neonatal Care*. The leading cause of death for this age group is congenital abnormalities, according to the Centers for Disease Control and Prevention (CDC).

Figure 7-1 An infant.

Physical Changes

Vital Signs

As a general rule the younger the person, the faster the pulse rate and respirations. At birth, a pulse rate of 90 to 180 beats/min and a respiratory rate of 30 to 60 breaths/min are considered normal. Within the first half hour after birth, a neonate's pulse rate often drops to 120 beats/min and the respiratory rate falls between 30 to 40 breaths/min. By age 1 year, the respiratory rate slows to 20 to 30 breaths/ min. Tidal volume in neonates starts at 6 to 8 mL/kg. By the end of the first year, the volume increases to 10 to 15 mL/kg. Table 7-1 lists the normal ranges of vital signs for various age groups.

YOU are the Provider — PART 1

You and your partner are outside washing the ambulance when a man in his 50s drives up to the front of the ambulance bay door. He requests that you check his vital signs, which your EMS system offers as part of its community outreach program. As your partner is retrieving the blood pressure cuff and stethoscope from the ambulance, the man tells you he is light-headed and needs to sit down. The time is 1310 hours according to the dispatch operator, who acknowledges that you have a walk-in patient.

1. How does a patient's age affect your assessment?
2. What are some physical differences between middle adults and older adults?

Blood pressure directly corresponds to the patient's weight, so it typically increases with age. At birth, the average systolic blood pressure of a neonate is 50 to 70 mm Hg. By 1 year of age, it ranges between 70 and 95 mm Hg.

Weight

A neonate usually weighs 6 to 8 lb (3 to 3.5 kg) at birth. Remarkably, the head accounts for 25% of a neonate's body weight. In the first week after birth, neonates usually have a 5% to 10% loss of their birth weight due to fluid loss. By week 2, the neonate begins to gain weight. From here on, infants grow at a rate of about 1 oz (30 g) per day, doubling their weight by 4 to 6 months and tripling it by the end of the first year.

Special Populations

Infants often land head first when they fall because their heads account for 25% of their total body weight. Also, most infants cannot stretch out their arms in time to cushion or slow their fall. Keep this point in mind when considering spinal stabilization on an infant.

Cardiovascular System

Prior to birth, fetal circulation occurs through the placenta. During the birthing process, hormones and pressure changes help the neonate make the transition from fetal circulation to independent circulation. See Chapter 33, *Obstetrics and Neonatal Care*, for more information about fetal circulation.

Pulmonary System

Prior to a neonate's first breath, the lungs have never been inflated. A neonate's first breath is therefore forceful—it has to be!

Neonates are primarily "nose breathers." Infants younger than 6 months are particularly prone to nasal congestion, which can cause viral upper respiratory infections. If you respond to a call for a baby choking, make sure the nasal passages are clear and unobstructed by mucus.

The rib cage of an infant is less rigid and the ribs sit horizontally. This explains the diaphragmatic breathing ("belly breathing") in infants.

An infant's airway is different from an adult's airway. The infant's tongue is larger in proportion to the oral cavity, and the airway is proportionally shorter and narrower. As a result, airway obstruction is more common in infants than in adults or older children.

Table 7-1 Vital Signs at Various Ages

Age	Pulse Rate (beats/min)	Respirations (breaths/min)	Systolic Blood Pressure (mm Hg)	Temperature (°F)
Neonate (0 to 1 month)	90 to 180	30 to 60	50 to 70	98 to 100 (37 to 38°C)
Infant (1 month to 1 year)	100 to 160	25 to 50	70 to 95	96.8 to 99.6 (36 to 37.5°C)
Toddler (1 to 3 years)	90 to 150	20 to 30	80 to 100	96.8 to 99.6 (36 to 37.5°C)
Preschool age (3 to 6 years)	80 to 140	20 to 25	80 to 100	98.6 (37°C)
School age (6 to 12 years)	70 to 120	15 to 20	80 to 110	98.6 (37°C)
Adolescent (12 to 18 years)	60 to 100	12 to 20	90 to 110	98.6 (37°C)
Early adult (19 to 40 years)	60 to 100	12 to 20	90 to 140	98.6 (37°C)
Middle adult (41 to 60 years)	60 to 100	12 to 20	90 to 140	98.6 (37°C)
Older adult (61 and older)	60 to 100	12 to 20	90 to 140	98.6 (37°C)

When providing bag-valve mask ventilations to an infant, you need to be aware that an infant's lungs are fragile. Ventilations that are too forceful can result in trauma from pressure, or **barotrauma**. Due to the large size of the infant's occiput and the increased flexibility of the trachea, the airway can easily be inadvertently blocked by incorrect positioning, either over-extension or over-flexion. Infants have very little reserves available to assist with breathing. The muscles they use to breathe are immature. They can manage normal breathing requirements easily but can become fatigued when stressed. The number of alveoli in the infant's lungs is relatively low. Fortunately, the amount of oxygen that the infant needs is also relatively low. As the infant grows and moves more, the need for greater amounts of oxygen triggers a growth in the number of alveoli. However, in very small infants, respiratory problems can quickly turn life threatening. Infants who struggle to breathe can quickly tire and become overheated and even dehydrated.

Special Populations

When you are counting respirations in an infant, count the number of times the abdomen rises instead of concentrating solely on the chest rise.

Nervous System

Although the infant's nervous system is developed at birth, its evolution continues after birth. For example, the neonate lacks the ability to isolate a particular response to sensation. When neonates are born, they tend to move their extremities together. They do not have independent arm or leg movements until many weeks later.

A neonate is born with certain reflexes. The **Moro reflex** (startle reflex) happens when a neonate is caught off guard by something or someone; the neonate opens his or her arms wide, spreads the fingers, and seems to grab at things. A **palmar grasp** occurs when an object is placed into the neonate's palm. The **rooting reflex** takes place when something touches a neonate's cheek; the neonate will instinctively turn his or her head toward the touch. In conjunction with the **sucking reflex**, which occurs when a neonate's lips are stroked, these reflexes are often evident when feeding.

A neonate's **fontanelles** allow the head to be molded—for example, when the neonate passes through the birth canal **Figure 7-2**. The fontanelles are the area or space between the bones that eventually fuse to form the skull. The posterior fontanelle normally fuses by the third month of life. The anterior fontanelle fuses between 9 and 18 months of age. On assessment, if either of the fontanelles is depressed, the infant is most likely dehydrated.

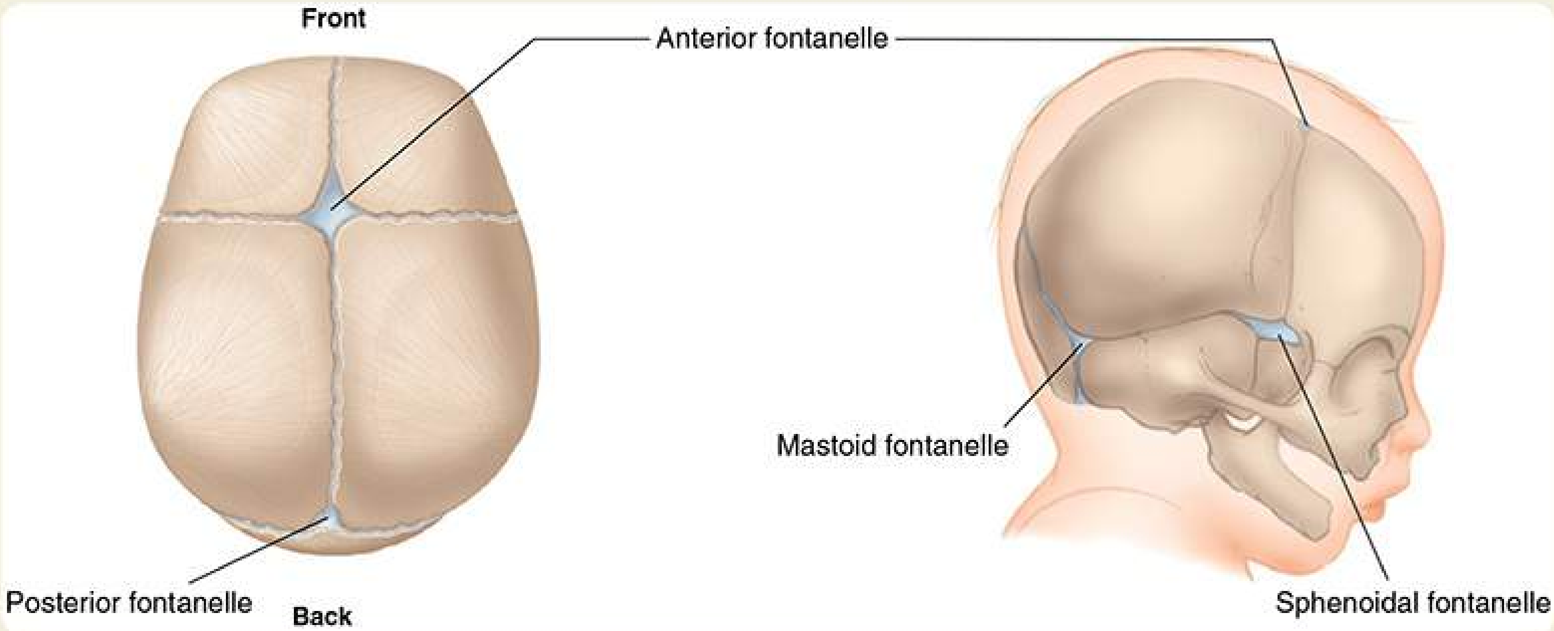

Figure 7-2 Fontanelles.

A bulging fontanelle is indicative of increased intracranial pressure.

At birth, the neonate is not able to do much without assistance. He or she cannot turn over or even focus his or her eyes beyond a very short distance. Sleep patterns begin to develop. But by 2 months of age, the infant is able to track objects with his or her eyes and should recognize familiar faces. At 6 months of age, the infant is able to sit upright and begins to make cooing and babbling sounds. By 12 months of age, the infant can walk with assistance and even knows his or her name.

Immune System

While in the womb, fetuses collect antibodies from the maternal blood. During the first year of life, infants maintain some of their mother's immunities, so they have naturally acquired passive immunities. Infants can also receive antibodies via breastfeeding, which strengthen their immune system.

Special Populations

Another development that occurs during infancy includes the emergence of "baby" teeth. Teething (ie, teeth breaking through the gums) can be painful and accompanied by a low-grade fever.

Psychosocial Changes

An infant's psychosocial development begins at birth and continues to evolve as the infant interacts with, and reacts to, the environment. Table 7-2 outlines typical ages at which major psychosocial changes are noticed.

In most infants, the primary method of communicating distress is through crying. Parents can often tell what is upsetting their child simply by listening to the tone of the child's crying—that is, they know the difference between tears for anger, frustration, pain, fear, hunger, discomfort, and sleepiness. Infants occasionally make another distinct cry—an alarming distressed cry. This cry may be heard when an unexpected event occurs, causing a situational crisis for the infant.

Infants develop relationships with their parents or caregivers at different rates. *Bonding*, or the formation of a close, personal relationship, is usually based on a secure attachment. A *secure attachment* occurs when an infant understands that parents or caregivers will respond to their needs. This realization encourages a child to reach out and explore, knowing their parents will provide a "safety net."

Table 7-2 Noticeable Characteristics at Various Ages

Age	Characteristic
2 months	Recognizes familiar faces; tracks objects with the eyes
3 months	Brings objects to the mouth; smiles and frowns
4 months	Reaches out to people; drools
5 months	Sleeps throughout the night; recognizes family members from strangers
6 months	Teething begins; sits upright; speaks one-syllable words
7 months	Afraid of strangers; mood swings
8 months	Responds to "no"; can sit alone; plays peek-a-boo
9 months	Pulls up to stand; places objects in mouth to explore them
10 months	Responds to his or her name; crawls efficiently
11 months	Starts to walk without help; frustrated with restrictions
12 months	Knows his or her name; walks

Another type of attachment, referred to as *anxious-avoidant attachment*, is observed in infants who are repeatedly rejected. In this attachment style, children show little emotional response to their parents or caregivers and treat them as they would strangers. These children often develop an isolated lifestyle where they do not have to depend on the support and care of others.

Separation anxiety is common in older infants. This normal reaction peaks between 10 and 18 months and involves clingy behavior and fear of unfamiliar places and people. It is normal for older infants to protest by crying. As infants become accustomed to their homes and families, they begin to need the security of a predictable environment. If the infant's environment is too unpredictable, the infant may despair and become withdrawn, which leads to trust issues.

Trust and mistrust refers to a stage of development from birth to about 18 months of age that involves an infant's needs being met by his or her parents or caregivers. When caregivers and parents provide consistent care in an organized, routine environment, the infant gains trust in them. If the infant does not perceive the environment as secure, a sense of mistrust will develop **Figure 7-3**.

Figure 7-3 Infants develop a sense of mistrust if they perceive their parents or caregivers will not provide an organized, predictable environment.

Special Populations

When caring for patients who are very young, keep their routine the same by keeping family and familiar items nearby.

Toddlers (1 to 3 Years) and Preschoolers (3 to 6 Years)

Physical Changes

In **toddlers** (ages 1 to 3 years), the pulse rate is normally 90 to 150 beats/min and the respiratory rate is 20 to 30 breaths/min, slower than the corresponding vital signs in infants, whereas the systolic blood pressure is higher (80 to 100 mm Hg). The average body temperature of children this age is 96.8°F (36°C) to 99.6°F (38°C), usually leveling off at 98.6°F (37°C) by school age **Figure 7-4**.

In **preschoolers** (ages 3 to 6 years), the pulse rate is 80 to 140 beats/min and the respiratory rate is 20 to 25 breaths/min. The systolic blood pressure is 80 to 100 mm Hg. Weight gain should level off by this time **Figure 7-5**.

A toddler's cardiovascular system is not dramatically different from an adult's system. A toddler's lungs continue to develop more terminal bronchioles and alveoli. Although toddlers and preschoolers have more lung tissue, they do not have well-developed lung musculature. This anomaly prevents them from sustaining deep or rapid respirations for an extended period of time.

The loss of passive immunity is possibly the most obvious development at this stage of human life. Viral infections (colds) often develop that may manifest as gastrointestinal distress or upper respiratory tract infections. As toddlers spend more time around playmates and classmates, they acquire immunity as their bodies are exposed to various viruses and germs.

YOU are the Provider — PART 2

After sitting the man down in a chair inside your station, he tells you he has been stressed lately, although he does not know why, and he has had several episodes of light-headedness over the past few days. He denies having chest pain, shortness of breath, or any other symptoms. As you are assessing the patient, your partner prepares to take his vital signs.

Recording Time: 0 Minutes	
Appearance	Calm
Level of consciousness	Conscious and alert
Airway	Open; clear of secretions or foreign bodies
Breathing	Normal rate; adequate depth
Circulation	Radial pulses, strong and regular; skin is pink, warm, and dry

3. What are some common psychosocial concerns experienced by middle adults?

Figure 7-4 A toddler.

© EML/ShutterStock.

Neuromuscular growth also makes considerable progress at this age. Toddlers and preschoolers spend a great deal of time exploring how to use their expansive nervous system and the muscles it controls by walking, running, jumping, and playing catch **Figure 7-6**. Watching the changes in how children play from age 1 to 6 years demonstrates how they move from gross motor activities (grabbing an object with the full palm) to fine motor activities (picking up a crayon). By the end of this stage, preschoolers will have a brain that weighs 90% of its final adult weight. In addition, all of this playing places stress on the muscles and bones. As a result, muscle mass increases as does bone density.

This stage also includes the continued development of the renal system and of elimination patterns (ie, toilet training). Physiologically, toddlers have the neuromuscular control capable of bladder control by 12 to 15 months of age. However, the child may not be psychologically ready until 18 to 30 months of age. The average age for toddlers to complete toilet training is 28 months of age. In addition, parents and toddlers are fascinated with sensory development—for example, tickling. According to the CDC, the leading cause of death for this age group is unintentional injuries (accidents).

Figure 7-5 A preschooler.

Psychosocial Changes

Parents are often excited for this period of development. Toddlers or preschoolers are learning to speak and express themselves, thereby taking a major step toward independence. At the same time, toddlers are very attached to their parents and feel safe with them. Separation anxiety peaks between 10 and 18 months of age.

At 36 months of age, in most toddlers, basic language is mastered. By the age of 3 or 4 years, most children can use and understand full sentences. As they progress through this stage, they will go from using language to communicate what they want, to using language creatively and playfully.

This is also the time when toddlers begin to interact with other children and start to play games. Playing games teaches control, following of rules, and even competitiveness. Significant learning and development takes place by the child watching his or her peers during group outings, such as “play dates” with other children. By 18 to 24 months, toddlers begin to understand cause and effect. Of course, behavior observed on television and the Internet can also be learned, which is why some parents limit their children’s viewing choices or the amount of time they devote to these activities. During this phase of development, children also learn to recognize gender differences by observing their role models.

Figure 7-6 A toddler learns to walk, one of the major milestones in life.

© monkeybusinessimages/iStock.

School-Age Children (6 to 12 Years)

Physical Changes

From ages 6 to 12 years, a school-age child's vital signs and body gradually approach those observed in adulthood Figure 7-7. The pulse rate is approximately 70 to 120 beats/min, the respiratory rate 15 to 20 breaths/min, and blood pressure is 80 to 110 mm Hg. Obvious physical traits and body function changes become apparent as most children grow about 4 lb (2 kg) and 2.5 inches (6 cm) each year. Permanent teeth also come in during this period, and brain activity in both hemispheres increases. Unintentional injuries are cited by the CDC as the leading cause of death in this age group.

Figure 7-7 A school-age child.

Psychosocial Changes

School-age children are engaged in a lot of psychosocial growth. Parents generally do not devote as much time to their children during this phase. Nevertheless, it is at this critical time in human development that children learn various types of reasoning. In **preconventional reasoning**, children act almost purely to avoid punishment and to get what they want. In **conventional reasoning**, they look for approval from their peers and society. In **postconventional reasoning**, children make decisions guided by their conscience.

During this stage, children begin to develop their self-concept and self-esteem. *Self-concept* is our perception of ourselves; *self-esteem* is how we feel about ourselves and how we "fit in" with our peers.

Adolescents (12 to 18 Years)

Physical Changes

In **adolescents** (ages 12 to 18 years), vital signs begin to level off within the adult ranges, with a systolic blood pressure generally between 90 and 110 mm Hg, a pulse rate between 60 and 100 beats/min, and respirations in the range of 12 to 20 breaths/min **Figure 7-8**.

Adolescence is the time of life when humans experience a 2- to 3-year growth spurt (ie, an increase in muscle and bone growth) and body changes. Growth begins with hands and feet, then moves to the long bones of the extremities, and finishes with growth of the torso. Boys typically experience this growth spurt later in life than girls. Girls usually finish their growth spurt by 16 years of age and boys by 18 years of age. Boys, however, are generally taller than girls when this period of growth has finished. Muscle mass and bone density are nearly at adult levels.

One change during adolescence is the maturation of the human reproductive system. Secondary sexual development begins, along with enlargement of the external reproductive organs. Pubic hair and axillary hair begin to appear. Voices start to change in range and depth. In girls, the breasts and thighs increase in size as adipose (fat) tissue is deposited there. Menstruation begins during this time. *Menarche*, the first menstrual bleeding, occurs during this time; however, it is not uncommon to begin menstruation prior to becoming a teenager.

These changes in the endocrine and reproductive systems provide the platform for reproduction. By the middle of adolescence, boys are able to produce sperm, and in girls, eggs begin to develop. Acne can also occur due to hormonal changes. Unintentional injuries are also the leading cause of death for adolescents according to the CDC.

Figure 7-8 An adolescent.

© Jamie Wilson/ShutterStock.

YOU are the Provider PART 3

As your partner takes the patient's vital signs, he tells you he and his wife are taking care of his father, who is 82 years old and has Alzheimer disease. He further tells you, although this situation is very stressful for him, he does not want to put his father in a nursing home. He is still light-headed and now reports a headache. After applying oxygen via nasal cannula, you advise him he should be transported to the hospital via EMS, but he tells you he would rather drive himself.

Recording Time: 5 Minutes	
Respirations	14 breaths/min; regular and adequate
Pulse	76 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	174/98 mm Hg
Oxygen saturation (Spo_2)	98% (on oxygen)

4. Are the patient's vital signs consistent with his age?
5. Why should you transport this patient to the hospital?

Psychosocial Changes

Adolescents and their families often deal with conflict as adolescents try to gain control of their lives from their parents. The need for privacy and personal space from siblings and parents becomes an important issue for adolescents. Self-consciousness also increases. Adolescents may struggle to create their own identity—to define themselves **Figure 7-9**, for example, by dressing in a certain style of clothing that fits their personality. Adolescents use the feedback from their family and peers to help create their adult image. Adolescents are often caught between two worlds. They want to be treated like an adult, yet they want to be cared for like a young child.

Rebellious behavior is common when an adolescent is trying to find his or her own identity. Typically, antisocial behavior and peer pressure tend to peak at around age 14 to 16 years. Smoking, illicit drug use, unprotected sex, and other high-risk behaviors also peak during this period. Adolescents may exhibit self-control through what they eat, which can lead to eating disorders. Although these behaviors can be very troubling to parents, the adolescent is trying to determine if he or she is ready to take control of his or her life. An adolescent's struggle toward independence may have devastating setbacks. Patience and support from family and friends are essential in assisting an adolescent's transition into adulthood.

Adolescents may show greater interest in sexual relations. Many adolescents are fixated on their public image and are terrified of being embarrassed. At this age, a code of personal ethics is developed, based partly on parents' ethics and values and partly on the influence of the adolescent's environment. During this confusing time, adolescents are at a higher risk than other populations for suicide and depression.

Figure 7-9 Adolescents want to fit in and may struggle to create identity.

Special Populations

When you interview adolescents in the presence of their family, they may not tell you the complete truth in an attempt to protect their privacy or image. It is best to ask these patients certain questions in total privacy, where they feel they can answer without constraint.

Early Adults (19 to 40 Years)

Physical Changes

Early adults range in age from 19 to 40 years **Figure 7-10**. Their vital signs do not vary greatly from those seen throughout adulthood. Ideally, the human pulse rate will average around 70 beats/min, the respiratory rate will stay in the range of 12 to 20 breaths/min, and the systolic blood pressure will be approximately between 90 and 140 mm Hg.

From age 19 years to shortly after 25 years, the human body should be functioning at its optimal level. Lifelong habits, whether positive or negative, such as eating preferences, exercise, and tobacco use are solidified. At the beginning of this period, the body is working at peak efficiency, but as early adulthood continues, subtle wear and tear on bones and changes in body tissues and muscles begin.

The disks in the spine begin to settle, and height can sometimes be affected, causing a “shrinking.” Being able to eat anything without gaining weight becomes more difficult. Fatty tissue increases, which leads to weight gain. Muscle strength decreases, and reflexes slow. The leading cause of death in this age group is unintentional injury, according to the CDC.

Psychosocial Changes

Three words best describe the average human’s world during this stage of life: work, family, stress. During this period, adults strive to create a place for themselves in the world, and many do everything they can to "settle down." Along with this natural tendency to settle down often come marriage and family. Despite all of this stress and change, this age group enjoys one of the more stable periods of life.

Figure 7-10 An early adult.

Middle Adults (41 to 60 Years)

Physical Changes

Middle adults are ages 41 to 60 years **Figure 7-11**. The average pulse rate for this age remains at 70 beats/ min, the respiratory rate continues at 12 to 20 breaths/ min, and the blood pressure also remains between 90 and 140 mm Hg. This group is vulnerable to vision and hearing loss. Cardiovascular health also becomes an issue in many middle adults, as does the greater incidence of cancer. In women, menopause—the end of menstruation—begins in the late 40s or early 50s. Middle adults may begin having medical problems or be unaware of conditions such as diabetes and hypertension. Medications or underlying conditions may affect patient response to treatments. Other concerns include an increase in cholesterol levels, a decrease in the efficiency of the heart, and weight control maintenance. However, many of the effects of aging can be diminished with exercise and a healthy diet. The CDC sites unintentional injuries as the leading cause of death in ages 41 to 44 years. For ages 45 to 60, the leading cause of death is cancer.

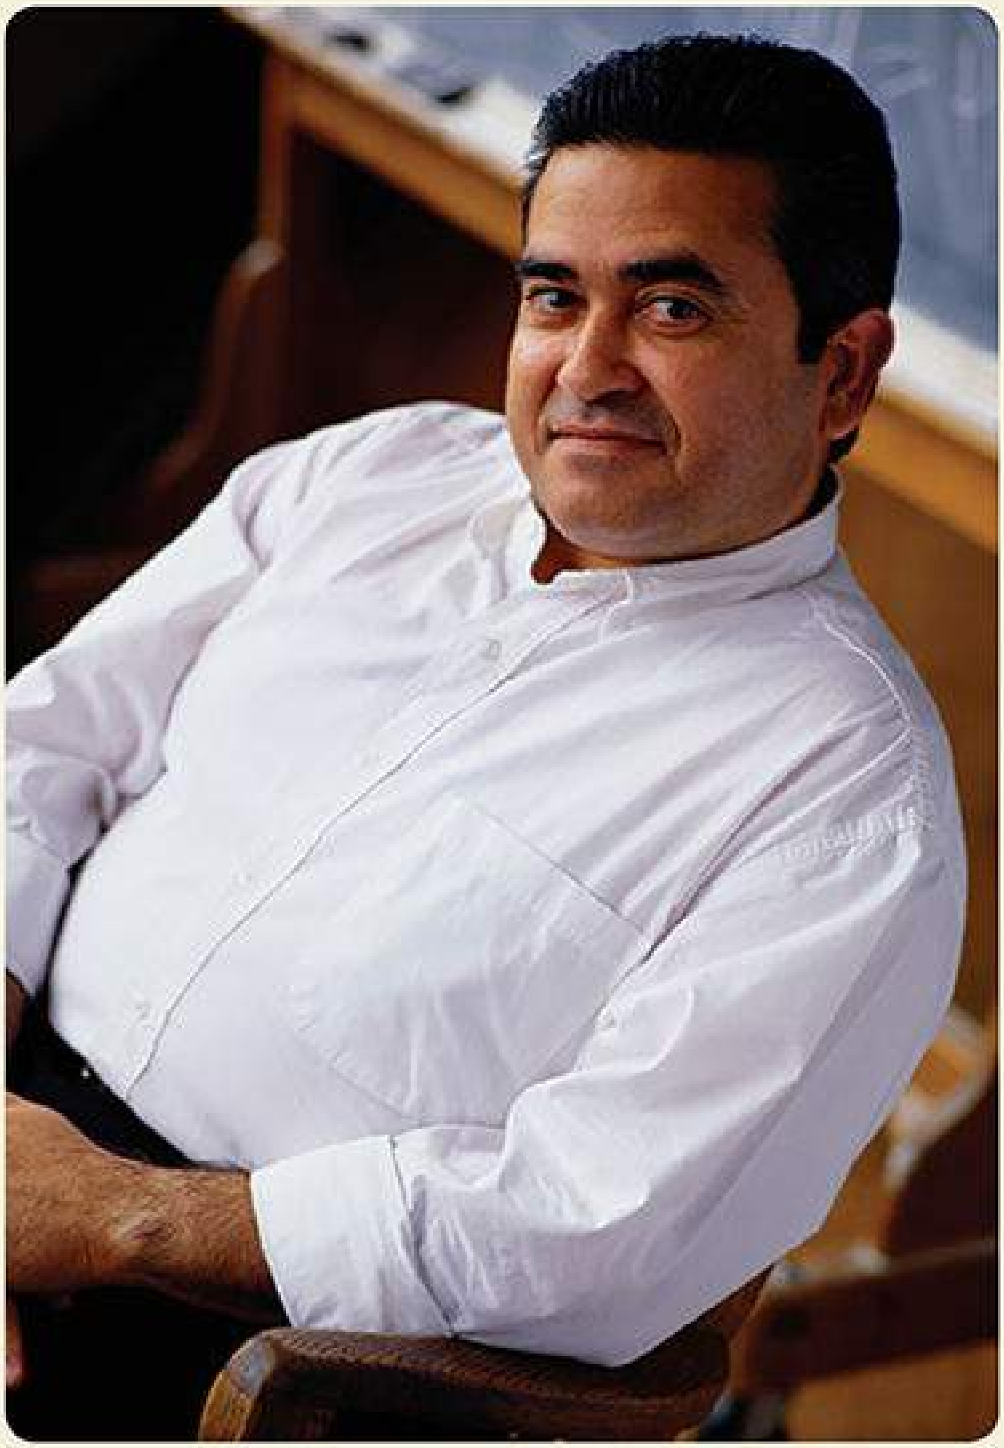

Figure 7-11 A middle adult.

Psychosocial Changes

Middle adults tend to focus on achieving their life's goals, as they approach the halfway point in human life expectancy. After years of nurturing and having children living at home, parents must readjust their lifestyle as children leave home, commonly called the "empty nest" syndrome. Finances may become a worrisome issue, as people prepare for retirement while still managing everyday financial demands. During this time people often view crisis as a challenge to be overcome and not a threat to be avoided. Generally, their health is stable and they have the physical, emotional, and spiritual reserves to handle life's difficulties.

The parents of adults in this age group are getting older and now need care. Most of the older adults in the United States are cared for by family members inside the home. Therefore, a middle adult may need to manage children who are leaving for college while at the same time care for parents who require greater assistance.

Older Adults (61 Years and Older)

Physical Changes

Older adults include those ages 61 and older **Figure 7-12**. **Life expectancy** is constantly changing. In the early 1900s, life expectancy was 47 years. It is now approximately 78 years, with maximum life expectancy estimated at 120 years. How long a person lives is based on many factors. Perhaps surprisingly, the year you were born and the country you live in can affect your life expectancy. These two facts are based on public health advances, changes within diets, attitudes regarding exercise, advances in medical care, access to that medical care, and personal behaviors. Cancer is the leading cause of death in ages 61 to 64 according to the CDC. In ages 65 and older, the leading cause of death is heart disease.

Special Populations

Be patient when interviewing older patients. Some older patients may have physical, cognitive, and psychologic barriers that may slow or interfere with their ability to communicate effectively.

YOU are the Provider — PART 4

After expressing your concern about the patient's health and advising him that driving himself to the hospital would not be safe, he agrees to be transported via EMS. You place the patient onto the stretcher, load him into the ambulance, and begin transport to a hospital located a short distance away. En route, you reassess his vital signs; assess his blood glucose level, which reads 100 mg/dL; and then call your radio report to the hospital.

Recording Time: 11 Minutes	
Level of consciousness	Conscious and alert
Respirations	14 breaths/min; regular and adequate
Pulse	80 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	180/102 mm Hg
Spo_2	99% (on oxygen)

6. What additional treatment, if any, does this patient require?

Figure 7-13 Older people are often prescribed multiple medications to help them stay active.

© Yuri_Arcurs/iStock.

Later in life, the vital signs depend on the patient's overall health, medical conditions, and use of medications. Today's older adults are staying active longer than their ancestors. Thanks to medical advances, they are often able to overcome numerous medical conditions, but may need multiple medications to do so **Figure 7-13**.

Cardiovascular System

Cardiac function declines with age as a result of anatomic and physiologic changes largely related to **atherosclerosis**. In this disorder, which most commonly affects coronary vessels, cholesterol and calcium build up inside the walls of blood vessels, forming plaque. The accumulation of plaque eventually leads to a partial or complete blockage of blood flow. More than 60% of people older than 65 years have atherosclerotic disease. This can lead to decreased blood supply to the organs of the body.

Other age-related changes typically include a decrease in heart rate, a decline in cardiac output (the amount of blood circulated each minute), and the inability to elevate cardiac output to match the demands of the body. This translates into a heart that is less able to respond to exercise or disease. In the event of a life-threatening illness, the body typically needs to increase the heart rate to ensure adequate blood pressure. Because heart muscle may weaken with age, the increase in heart rate can actually cause damage to the heart.

The vascular system also becomes stiff. For example, the diastolic blood pressure increases with age. Compensation for blood pressure changes is hampered because these vessels are less able to dilate and contract. As the blood vessels become stiffer, the heart must work harder to be able to move the blood effectively. These stiff blood vessels increase the workload of the heart.

Aging also affects blood cells. The body's blood cells originate from within the bone marrow. As a person ages, more of the bone marrow is replaced with fatty tissue. The decreased amount of bone marrow results in a decrease in the ability of the bones to manufacture more blood cells when needed. Although this change alone typically does not pose a problem, if an older adult sustains trauma, it will decrease the body's ability to produce new blood cells to replace lost cells. Finally, functional blood volume gradually declines over time.

Respiratory System

In older adults, the size of the airway increases and the surface area of the alveoli decreases. The natural elasticity of the lungs also decreases, forcing people to use the muscles between their ribs, called intercostal muscles, more to breathe. As the elasticity of the lungs decreases, the overall strength of the intercostal muscles and diaphragm also decreases. These factors together make breathing more labor intensive for older adults. You might think a rigid chest would offer more protection, but this rigidity actually makes the chest more fragile. Instead of the chest being able to bend and give if struck, the calcified chest can fracture. However, as with all of the physical changes related to aging, the changes in the respiratory system are often gradual and go unnoticed until a severe, life-threatening condition occurs. The older person will then have less respiratory reserve to use to maintain adequate breathing.

As the patient ages, the structures that protect the upper airway tend to decrease in function. For example, cough and gag reflexes diminish, as does the ability to clear secretions. The cilia that line the airways diminish and the innervation of the structures in the airway provides increasingly less sensation. This results in making it more difficult to maintain the upper airway, resulting in a greater risk of aspiration and airway obstruction.

When a younger patient inhales, the airway maintains its shape, allowing air to enter. As the smooth muscles of the lower airway weaken with age, strong inhalation can make the walls of the airway collapse inward and cause inspiratory wheezing. The collapsing airways result in low flow rates, because less air can move through the smaller airways, and air trapping, because air does not completely exit the alveoli (incomplete expiration). Also within the airways, the cells of the immune system are less functional. As a result of the overall decrease in the metabolic activity of the older body, the white blood cells found within the airways are less aggressive at fighting invading organisms. This leads to an increased risk of lung infections.

By age 75 years, the vital capacity (the volume of air moved during the deepest inspiration and expiration) may amount to only 50% of the vital capacity of a young adult. Factors contributing to this decline include loss of respiratory muscle mass, increased stiffness of the thoracic cage, and decreased surface area available for the exchange of air.

Physiologically, vital capacity decreases and residual volume (the amount of air left in the lungs after expiration of the maximum possible amount of air) increases with age. A lifetime of breathing, especially breathing air with high levels of pollution, causes the accumulation of pollutants in the lungs. As a consequence, stagnant air remains in the alveoli and hampers diffusion of gases. The net effect is that the respiratory system is increasingly less able to handle the stresses of disease. This is why a simple cold, which for a 30-year-old would mean a runny nose and body aches, could mean pneumonia and possible death for an 80-year-old.

Endocrine System

As with the other systems of the body, the function of the endocrine system gradually declines with age. Insulin production begins to drop off and metabolism decreases. As people get older, they tend to slow down their physical activity. Unfortunately, they do not decrease their food intake. When a person gains weight, more insulin is needed to control the body's metabolism and blood glucose (sugar) level. The pancreas may not be able to produce enough insulin for the person's body size, which can lead to diabetes mellitus.

The reproductive systems of both men and women change with age. Men are able to produce sperm long into their 80s but the rigidity of the penis tends to decrease over time. Women have a decrease in the size of the uterus and vagina. Hormone production gradually decreases for both genders as they age. Sexual desire may diminish with age but does not stop.

Digestive System

Changes in gastric and intestinal functions may inhibit nutritional intake and utilization in older adults. For example, taste bud sensitivity to salty and sweet sensations decreases. The sense of smell can also be diminished. A decrease in smell together with a decreased taste response is why older adults may find food bland and flavorless.

Saliva secretion decreases, which reduces the body's ability to process complex carbohydrates. Older people may have loss of teeth that impacts their ability to chew. The ability of the intestines to contract and move food along diminishes with age. This can lead older adults to feel constipated or not hungry. Likewise, gastric acid secretion diminishes. Blood flow may drop by as much as 50%, decreasing the ability of the intestines to extract vitamins and minerals from digested food. Gallstones become increasingly common with age, and anal sphincter changes reduce elasticity and can produce fecal incontinence.

Renal System

In the kidneys, both structural and functional changes occur in older adults. The filtration function of these organs, for example, declines by 50% from age 20 to 90 years. Kidney size decreases by 20% over the same span. This is due in part to the decreased effectiveness of the blood vessels that supply blood to the nephrons. **Nephrons** are sophisticated capillaries that perform filtering in the kidney. One of the portions of the nephron is called the *glomerulus*. The decreased blood supply causes more abnormal glomeruli to be present as a person ages. The number of nephrons also declines between the ages of 30 and 80 years. This loss of renal function means a decrease in the ability to clear waste from the body. It also means a decreased ability to conserve fluids when needed.

Nervous System

Nervous system changes can result in the most debilitating of age-related illnesses. In the central nervous system, the brain weight may shrink 10% to 20% by age 80. Motor and sensory neural networks become slower and less responsive. The metabolic rate in the older brain does not change, however, and oxygen consumption remains constant throughout life. Generally, you have fewer brain cells (neurons) today than you had yesterday. If measured strictly by numbers of brain cells, infants are far more intelligent than any of us.

However, this is not how the brain works. Although it is true older adults have a lower number of brain cells, there is great flexibility in the operation of the brain. Interconnections between brain cells continue as people age. These new connections provide redundancy within the brain, allowing for loss of neurons without loss of knowledge or skill.

One of the consequences of the loss of neurons is a change in the sleep patterns of older adults. Instead of sleeping through the night, they may take a nap during the day and be up late at night. Their sleep cycle may move into a biphasic (two-phased) sleep cycle—sleep from 0100 to 0600 hours and then a nap from 1200 to 1500 hours.

The brain, which is surrounded by the meninges, takes up almost all of the space in the skull. Cerebrospinal fluid protects the brain inside these membranes. In older adults, age-related shrinkage creates a void between the brain and the outermost layer of the meninges, which creates room for the brain to move when stressed **Figure 7-14**. If trauma forcefully moves the brain, the bridging veins can tear and bleed. Blood can empty into this void and may go unnoticed for some time.

Functioning of the peripheral nervous system also slows with age. Sensation becomes diminished and misinterpreted. The ability to know where the body is in space, the kinesthetic sense, can be diminished. Slower reactions cause longer delays between stimulation and motion. Slower reflexes and the decreased kinesthetic sense may contribute to the higher incidence of falls and trauma in older adults. Nerve endings deteriorate, and the ability of the skin to sense the surroundings becomes hindered. Hot, cold, sharp, and wet objects can all create dangerous situations because the body cannot sense them quickly enough.

Sensory Changes

It is often assumed that older people are hard of hearing and have difficulty seeing. There are changes that diminish the effectiveness of the eyes and ears; however, many older adults hear well and have good vision. They may need eyeglasses or hearing aids, but you should not assume that your older patient is deaf and nearly blind. Pupillary reaction and ocular movements become more restricted with age. The pupils are generally smaller in older patients, and the opacity of the eye's lens diminishes visual acuity and makes the pupils sluggish when responding to light. Visual distortions are also common in older people. Thickening of the lens makes it harder for the eye to focus, especially at close range. Peripheral fields of vision become narrower, and a greater sensitivity to glare constricts the visual field.

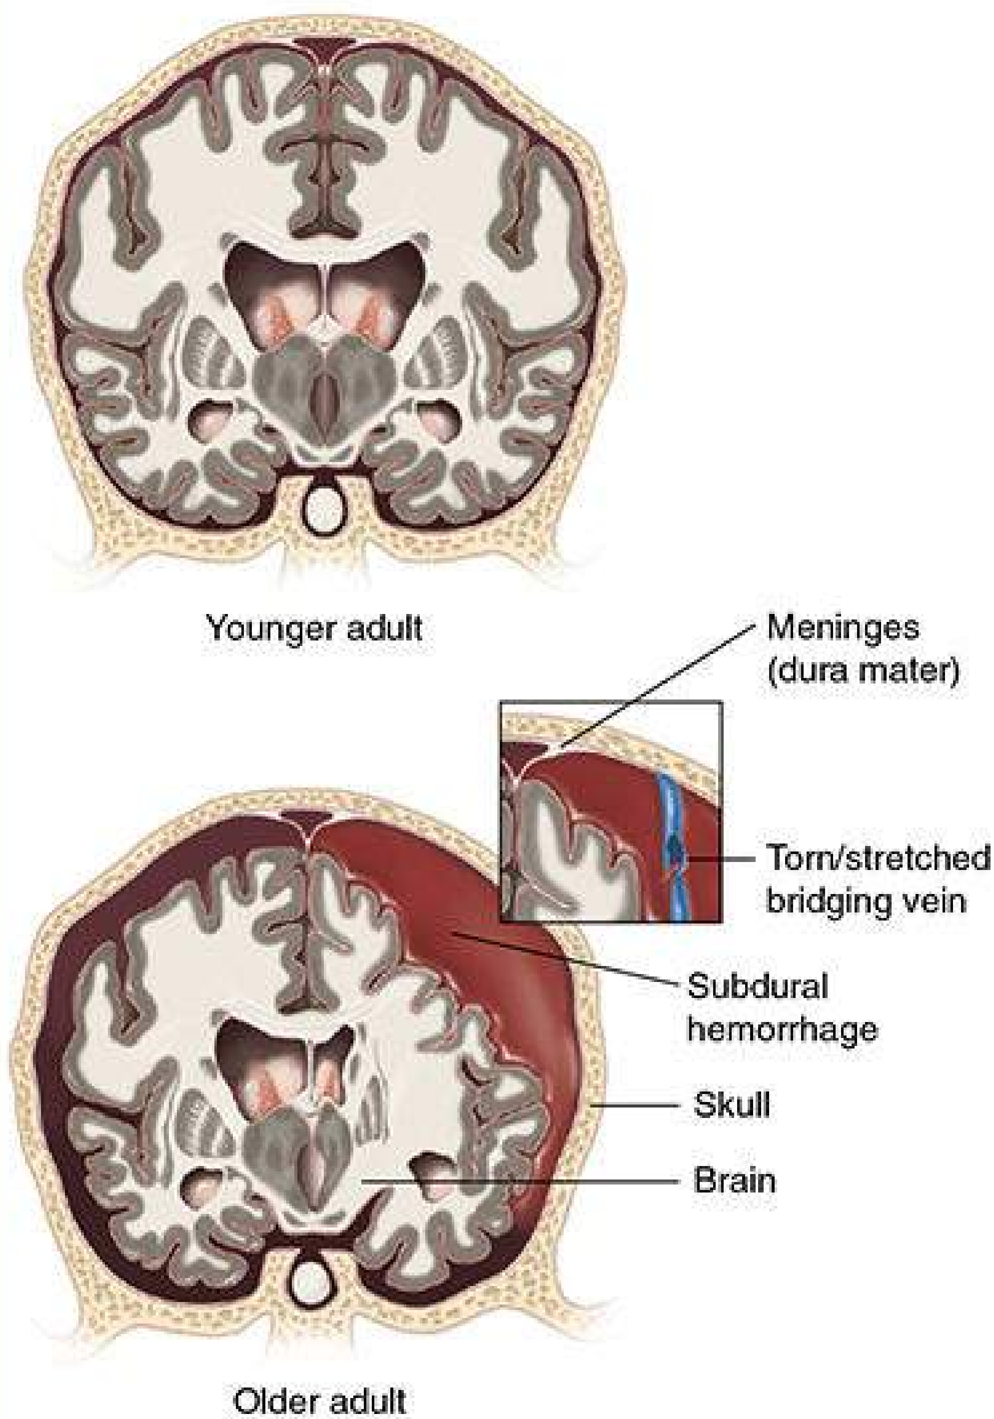

Figure 7-14 Age-related atrophy or shrinkage of the brain results in a space between the brain and its cover, the dura mater. Bleeding into this area can occur because veins are stretched.

Hearing loss is about four times more common than loss of vision in late adulthood. Changes in several hearing-related structures may lead to a loss of high-frequency hearing or even deafness.

Psychosocial Changes

You should value your opportunity to care for older adults as you do any patient. Many older adults have amazing stories and experiences to share, yet we often take them for granted. They share with us a great amount of wisdom, and we need to remind them of their self-worth. Until about 5 years before death, most late-stage adults retain high brain function; however, in the 5 years preceding death, mental function often declines.

As the older adult population continues to grow, you have the responsibility to seek out unique ways to accommodate their needs during their last 20 to 40 years of life. Statistics indicate 95% of older adults live at home. They may have the assistance of family, friends, or home health care, but they are shown to be relatively healthy, active, and independent. The increasing number of older adults in the United States as a result of the baby boom of the 1940s through the 1960s has produced a need for additional assisted-living facilities. These facilities allow older adults to live in campus-based communities with people in their own age group, while enjoying the independence and privacy of their own apartment and the security of nursing care, maintenance, and food preparation, if desired Figure 7-15. Unfortunately, these facilities can be expensive.

Most people need to deal with financial issues throughout their lives. Few things in life cause more worry and stress than money problems. Older adults, in particular, may constantly worry about rising health care costs and are often forced to make decisions such as whether to pay for groceries or their medication. Compared with earlier generations, many families today often take less responsibility for their older family members. Today, more than 50% of all single women in the United States who are 60 years of age or older are living at or below the poverty level. This problem is unresolved.

One of the important issues older adults face is their mortality. The fact is everyone dies; yet, for most of us, this concept is an intellectual exercise with a distant connection to reality. Older adults witness their friends and loved ones, with some of whom they have shared this life journey for half a century or more, die. As a result, older adults are challenged by isolation and depression.

Figure 7-15 A small percentage of older adults live in assisted-living facilities.

© Photodisc.

Fortunately, many older adults are happy and actively participate in life. With good financial resources and a good support system of family and friends, adults in their 80s can enjoy life and continue to feel productive.

YOU are the Provider — SUMMARY

1. How does a patient's age affect your assessment?

The fundamental concepts of patient assessment are the same for all age groups. However, factors such as physical development, communication skills, behavior, and vital sign values vary with age. Communication with the patient is an integral part of the patient assessment process—especially the history-taking phase. Depending on the patient's age, communication can be relatively easy or extremely difficult.

Certain medical conditions that are common in one age group are uncommon in others. Determining a patient's risk factors for disease is an important part of the history-taking process and affects your index of suspicion. For example, it is rare—although not impossible—for an otherwise healthy 8-year-old child with chest pain to be experiencing a cardiac problem because children generally have healthy hearts. However, you should be suspicious of a cardiac problem if a 55-year-old patient with a history of high blood pressure—a major risk factor for cardiovascular disease—has the same symptoms.

Understanding which illnesses are common in various age groups will help you formulate a plausible field impression—that is, what you believe is wrong with the patient based on your assessment findings.

2. What are the physical differences between middle adults and older adults?

Middle adults (41 to 60 years of age) have reached the halfway point in human life expectancy. However, provided they are otherwise healthy, their vital signs and physical abilities usually remain consistent with those of early adults. Their average pulse rate is 70 beats/min, their respiratory rate is between 12 and 20 breaths/min, and their systolic blood pressure is between 90 and 140 mm Hg.

The age-related physical changes that occur in older adults (61 years of age and older) are more pronounced than they are in middle adults and affect nearly every organ and organ system in the body.

The vital signs of older adults are largely dependent on their underlying health and are often affected by medications taken. In general, however, age-related vital sign changes include a decrease in heart rate and an increase in diastolic blood pressure. The elasticity of the lungs also decreases, forcing this group to rely more on their intercostal muscles to breathe. In addition, the ribs become more rigid due to calcification, which adds to their breathing difficulty.

Other physical changes that occur during late adulthood include a decrease in metabolism and insulin production, which can lead to diabetes, decreased gastrointestinal function, decreased taste bud sensation, decreased kidney size and filtration (kidney function declines by 50% from age 20 to age 90), nervous system changes (including a 10% to 20% decrease in brain weight by 80 years of age) and sensory and motor nerve deterioration, and vision and hearing loss, among others.

The anatomic and physiologic changes that occur between middle and late adulthood must be taken into consideration during your assessment.

Keep in mind, however, that compared with middle adults, older adults often have fewer classic signs and symptoms of a wide variety of medical conditions.

3. What are some common psychosocial concerns experienced by middle adults?

During middle adulthood, many people's concerns center around finances. This often causes stress and uncertainty.

A unique psychosocial concern in middle adults relates to their children and their parents. As their children move away from home—which forces them to readjust their lifestyle ("empty nest" syndrome)—their own parents are getting older and now need care. Most middle adults prefer to care for their parents in their own home or in their parents' home; however, this often increases the stress and anxiety they are already experiencing from other factors such as finances or retirement.

4. Are the patient's vital signs consistent with his age?

The patient's heart rate and respiratory rate are consistent with his age. However, his blood pressure is not. A typical middle adult's systolic blood pressure ranges between 90 and 140 mm Hg; the diastolic blood pressure usually ranges between 70 and 80 mm Hg.

Ask the patient if he keeps a journal of his vital signs. If he does, ask him what his blood pressure typically reads; clearly, hypertension cannot be diagnosed based on a single blood pressure reading. If he keeps a journal and tells you his current blood pressure is consistent with what it normally reads, ask him if he is under a physician's care or being treated with any medication. If he is not, you should advise him to be evaluated by a physician; he may have hypertension and not be aware of it. Hypertension is often referred to as the "silent killer," and a blood pressure of 174/98 mm Hg is abnormal at any age.

5. Why should you transport this patient to the hospital?

This patient should not drive himself to the hospital. He experienced a syncopal episode, which could indicate a variety of underlying medical conditions—some of them potentially life threatening. The patient is light-headed, reports a headache, and is hypertensive. He should be informed that if he drives himself to the hospital, he could experience another syncopal episode while driving; this would jeopardize not only his own safety but also the safety of other motorists.

Although the patient is of legal age and has the decision making capacity to legally refuse EMS transport, you should make every effort to convince him to agree to EMS transport and advise him that his refusal could potentially result in death.

6. What additional treatment, if any, does this patient require?

Further treatment of this patient should be supportive. Continue to monitor his mental status and ABCs and make him comfortable. Dimming the lights in the back of the ambulance may provide him with some relief from his headache.

Remain alert for any changes in his neurologic status, such as slurred speech, unilateral weakness (weakness to one side of the body), or confusion, and contact the receiving facility if any changes are noted.

EMS Patient Care Report (PCR)

Date: 7-17-16	**Incident No.:** 060109	**Nature of Call:** Vital sign check		**Location:** EMS Station 2	
Dispatched: 1310	**En Route:** 1310	**At Scene:** 1310	**Transport:** 1324	**At Hospital:** 1330	**In Service:** 1339

Patient Information

Age: 50 **Sex:** M **Weight (in kg [lb]):** 86 kg (190 lb)	**Allergies:** No known drug allergies **Medications:** Vitamins **Past Medical History:** None **Chief Complaint:** Light-headedness, fainting, headache

Vital Signs

Time: 1315	**BP:** 174/98	**Pulse:** 76	**Respirations:** 14	**Spo_2:** 98%

Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** Blood glucose level assessment

Narrative

50-year-old man presented to EMS station 2 for routine vital sign check. Shortly after arrival, the patient stated he felt light-headed and needed to sit down. He stated he has been "stressed" about caring for his ill father, and has experienced several episodes of light-headedness over the past few days. He further stated he experienced a syncopal episode earlier today, but did not know how long he was unconscious. Upon presentation, he was conscious and alert; his airway was patent and his breathing was adequate. He denies any past medical history and stated he only wanted his vital signs checked. He further denies any medication allergies and states he only takes vitamins. Initial vital signs revealed an elevated blood pressure. After vital sign assessment, the patient reported a headache. Applied oxygen at 4 L/min via nasal cannula and reassessed his mental status; he remained conscious and alert. Advised patient that because of his elevated blood pressure, syncopal episode, light-headedness, and headache, EMS transport to the hospital for evaluation by a physician was wise. He stated he preferred to drive himself, because he did not feel transport via ambulance was necessary. Advised patient that driving himself was unsafe because he could experience another syncopal episode while driving. He was further advised that his signs and symptoms could signal a potentially life-threatening condition that only a physician could diagnose. After being informed of these potential consequences, the patient agreed to EMS transport. Placed patient onto the stretcher, loaded him into the ambulance, and began transport. The patient's condition remained unchanged en route. After dimming the lights in the back of the ambulance, he stated his headache improved slightly, but he was still light-headed. Reassessed his vital signs and assessed his blood glucose level, which read 100 mg/dL. Duration of transport was uneventful, and the patient was delivered to the emergency department without incident. After giving verbal report to the charge nurse, Medic 2 returned to service.**End of report**

Prep Kit

Ready for Review

- Each developmental stage is marked by different physical and psychosocial changes and characteristics; infants (1 month to 1 year) develop at a surprising rate.
- The vital signs of toddlers (ages 1 to 3 years) and preschoolers (ages 3 to 6 years) differ somewhat from those of an infant. During this stage, children learn to speak and express themselves.
- From ages 6 to 12 years, the school-age child's vital signs and body gradually approach those observed in adulthood. During this stage, children develop self-esteem.
- The vital signs of adolescents (ages 12 to 18 years) begin to level off within the adult ranges. Adolescents focus on creating their self-image.
- Early adults are people who are age 19 to 40 years. Early adults focus on work and family.
- Middle adults are people who are age 41 to 60 years. Middle adults focus on achieving life goals.
- Older adults are people who are age 61 years and older. Older adults focus on their mortality and the mortality of friends and loved ones.
- Vital signs do not vary greatly throughout adulthood.

Vital Vocabulary

adolescent A young person age 12 to 18 years.

atherosclerosis A disorder in which cholesterol and calcium build up inside the walls of the blood vessels, forming plaque, which eventually leads to a partial or complete blockage of blood flow.

barotrauma Injury caused by pressure to enclosed body surfaces, for example from too much pressure in the lungs.

conventional reasoning A type of reasoning in which a child looks for approval from peers and society.

early adult A young adult age 19 to 40 years.

fontanelles Areas where the neonate's or infant's skull has not fused together; usually disappear at approximately 18 months of age.

infant A young child age 1 month to 1 year.

life expectancy The average number of years a person can be expected to live.

middle adult An adult age 41 to 60 years.

Moro reflex An infant reflex in which, when an infant is caught off guard, the infant opens his or her arms wide, spreads the fingers, and seems to grab at things.

neonate A newborn age birth to 1 month.

nephrons The basic filtering units in the kidneys.

older adult An adult age 61 years or older.

palmar grasp An infant reflex that occurs when something is placed in the infant's palm; the infant grasps the object.

postconventional reasoning A type of reasoning in which a child bases decisions on his or her conscience.

preconventional reasoning A type of reasoning in which a child acts almost purely to avoid punishment to get what he or she wants.

preschooler A child age 3 to 6 years.

rooting reflex An infant reflex that occurs when something touches an infant's cheek, and the infant instinctively turns his or her head toward the touch.

school age A person who is 6 to 12 years of age.

sucking reflex An infant reflex in which the infant starts sucking when his or her lips are stroked.

toddler A young child age 1 to 3 years.

trust and mistrust Refers to a stage of development from birth to approximately 18 months of age, during which infants gain trust of their parents or caregivers if their world is planned, organized, and routine.

Assessment *in Action*

© Jones & Bartlett Learning. Courtesy of MIEMSS.

You are called to an assisted-living facility where a 72-year-old woman has fallen. While en route, you consider the implications of a fall for someone 72 years old.

When you arrive you are greeted in the lobby by one of the nurses. He tells you the patient takes several medications and he found her on the floor in the bathroom.

1. Which of the following is the LEAST likely cause of a fall in a patient of this age?
   - **A.** Hypertension
   - **B.** Hypotension
   - **C.** Balance issues
   - **D.** Muscle weakness
2. Which of the following should be expected when you assess the patient's pupils?
   - **A.** Slower pupillary reaction
   - **B.** Vision deficit
   - **C.** Fixed, dilated pupils
   - **D.** Unequal pupils
3. Which of the following statements is true regarding communication with older adults?

A. You must speak loudly so the patient will hear you.
B. Communication may be difficult since the weight of the brain shrinks up to 40% by age 80.
C. It may take older adult patients more time to respond to your questions.
D. Place yourself directly in front of the patient since peripheral vision narrows as the patient becomes older.

4. Changes in which of the following body systems can result in the most debilitating of age-related illnesses?

A. Nervous
B. Renal
C. Sensory
D. Endocrine

5. Which of the following affects vital signs the most in older adults?

A. Patient's immune system
B. Overall health of the patient
C. Patient's cardiovascular system
D. Patient's diet

6. Who provides the most care for older adults in the United States?

A. Home health nurses
B. Nursing homes
C. Family members
D. An assisted-living facility

7. What influence will the medications the patient takes have on the potential reason for the fall?
8. Describe some of the contributors that affect life expectancy.
9. List at least three psychosocial issues people experience during late adulthood.
10. Why is there an increased need for additional extended care facilities?

CHAPTER

8

Lifting and Moving Patients

Courtesy of Rhonda Hunt.

National EMS Education Standard Competencies

EMS Operations

Knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

Knowledge Objectives

1. Explain the need and use of the most common patient-moving equipment, the stretcher and backboard. (pp 261–263)
2. Explain the technical skills and general considerations required of EMTs during patient packaging and patient handling. (p 263)
3. Define the term body mechanics. (p 264)
4. Discuss how following proper patient lifting and moving techniques can help prevent work-related injuries. (pp 263–264)
5. Identify how to avoid common mistakes when lifting and carrying a patient. (pp 265–267)
6. Explain the power grip and sheet or blanket methods for lifting a patient. (pp 267–269)
7. Explain the general considerations required of EMTs to safely move patients without causing the patient further harm and while protecting themselves from injury. (pp 271–274)
8. Explain how to carry patients safely on stairs, including the selection of appropriate equipment to aid in the process. (pp 274–276)
9. Describe specific situations in which an urgent move or rapid extrication may be necessary to move a patient; include how each one is performed. (pp 283–287)
10. Describe specific situations in which a nonurgent move may be necessary to move a patient; include how each one is performed. (pp 288–293)
11. Explain the special considerations and guidelines related to moving and transporting geriatric patients. (pp 293–296)
12. Define the term bariatrics. (p 296)
13. Discuss the guidelines for lifting and moving bariatric patients. (pp 295–297)
14. Explain the need and use for additional patient–moving equipment (specialized); include examples. (pp 296–300)
15. Know the importance of decontaminating equipment in the prevention of disease transmission. (p 300)

16. Describe proper positioning for the following conditions: (p 301)
    - Unresponsive patients without suspected spine injury
    - Patients with chest pain, discomfort, or difficulty breathing
    - Patients with suspected spine injury
    - Pregnant patients with hypotension
    - Patients who are nauseated or vomiting
17. Discuss situations that may require the use of medical restraints on a patient. (pp 301–302)
18. Explain guidelines and safety considerations for the use of medical restraints. (pp 301–302)

Skills Objectives

1. Perform a power lift to lift a patient. (p 266, Skill Drill 8–1)
2. Demonstrate a power grip. (p 267)
3. Demonstrate the body mechanics and principles required for safe reaching and pulling, including the technique used for performing log rolls. (pp 267–269)
4. Perform the diamond carry to move a patient. (p 272, Skill Drill 8–2)
5. Perform the one–handed carry to move a patient. (p 273, Skill Drill 8–3)
6. Perform a patient carry using a stair chair to move a patient down the stairs. (p 275, Skill Drill 8–4)
7. Perform a patient carry to move a patient down the stairs on a backboard. (pp 276–277, Skill Drill 8–5)
8. Demonstrate how to load a stretcher into an ambulance. (pp 276–281, Skill Drill 8–6)
9. Demonstrate how to perform an emergency or urgent move. (pp 281–287)
10. Perform the rapid extrication technique to move a patient from a vehicle. (pp 283–287, Skill Drill 8–7)
11. Perform the direct ground lift to lift a patient. (pp 288–289, Skill Drill 8–8)
12. Perform the extremity lift to move a patient. (pp 290–291, Skill Drill 8–9)
13. Perform the direct carry to move a patient. (pp 291–292, Skill Drill 8–10)
14. Demonstrate how to use the draw sheet method to transfer a patient onto a stretcher. (pp 291–293)
15. Use a scoop stretcher to move a patient. (pp 292–294, Skill Drill 8–11; p 300)
16. Demonstrate the correct use of medical restraints on a patient. (pp 301–302)

Introduction

In the course of a typical call, you will have to move the patient several times to provide emergency medical care and transport. Once you have assessed the patient and provided emergency care, the patient is generally moved onto a backboard or stretcher. At a minimum, you will have to lift and carry the patient to the stretcher, move the stretcher to the ambulance, and load the stretcher into the patient compartment. Upon arrival at the hospital, the patient must be removed from the ambulance, wheeled into the emergency department (ED), and transferred to the ED bed. To avoid injury to the patient, yourself, or your team, you need to learn how to lift and carry a patient properly, using proper body mechanics and a power grip.

To move a patient safely and properly in the various situations that you may encounter in the field, it is necessary to learn how to perform emergency body drags and lifts, rapidly extricate a patient from a vehicle onto the stretcher, assist a patient from a chair or bed onto the stretcher, lift a patient from the floor onto the stretcher, and manually carry a patient up or down stairs. You and your team should know how to place a patient with a suspected spinal injury onto an immobilization device and how to package patients with and without suspected spinal injury. At times, you and your team may need to move a patient who is very heavy or carry a patient on a trail or across rugged terrain. Special techniques for loading and unloading the stretcher and transferring the patient from the stretcher to an examining table or bed in the ED are necessary.

Lifting and carrying are dynamic processes. To avoid unexpected, dangerous shifts in weight and to reduce the risk of injury to yourself, your partner, and the patient, you and your team should practice these techniques often. You must know where each EMT should be positioned and how to give and receive lifting commands so that all parties act simultaneously. You also need to know how to properly use patient-moving devices, such as a wheeled ambulance stretcher, stair chair, backboard, scoop stretcher, folding ambulance stretcher, basket stretcher, flexible stretcher, and any other equipment your service may carry. You must also know which device or combination of devices is appropriate for the current situation. This chapter will cover lifting, carrying, and reaching techniques as well as principles of moving patients, including emergency, urgent, and nonurgent moves, and the use of physical restraints to protect the patient and your team from further harm. In addition, different types of equipment and patient positioning will be discussed in detail.

The Wheeled Ambulance Stretcher

The **wheeled ambulance stretcher** (also called an ambulance stretcher, gurney, or simply the stretcher) is the most commonly used device to move and transport patients. The wheeled ambulance stretcher is a specially designed stretcher that can be rolled along the ground and weighs between 40 and 145 lb (18 and 66 kg), depending on its design and features **Figure 8-1**. Because its weight must be added to that of the patient and any equipment needed for immediate patient care, it is generally not taken up or down stairs or to other locations where the patient must be carried for any significant distance. Moving a patient by rolling, using a stretcher or other wheeled device, is preferred when the situation allows and helps prevent injuries from carrying.

Figure 8-1 The wheeled ambulance stretcher is specially designed to roll along the ground.

Words of Wisdom

Patients are typically transported on the wheeled ambulance stretcher. Only when you must transport two patients in the same ambulance should it be necessary to transport one patient on a folding stretcher or backboard placed on the long squad bench.

The modern stretcher is available in a number of different models, which may include different features. Before going on a call, familiarize yourself with the specific features of the stretcher that your ambulance carries. You must know where to locate the controls to adjust and lock each feature and how each works.

The stretcher has a specific head end and foot end. The stretcher has a strong, rectangular, tubular metal main frame to which all of its other parts are attached. The stretcher should be pulled, pushed, and lifted only by its main frame or handles, which are attached to the main frame specifically for this purpose.

On most models, a second tubular frame made up of three sections is attached within or above the main frame. A metal plate is fastened to each of the three sections between its sides. This plate serves as the platform on which the stretcher mattress and patient are supported. The head section runs from the head end of the stretcher to near the center of the stretcher, where the patient's hips will be. Hinges at the area where the hips will be allow the head end to be elevated and the patient's back to be positioned at any desired angle from flat to fully upright. The head end of the stretcher is designed to be elevated or moved down only when a tilt control is purposely released. At all other times, the back will remain locked at the position in which it was placed. The frame and plates that lie from the hips to the foot end of the stretcher are divided into two hinged sections. These sections may be connected so that the foot end can be drawn in toward the knees, causing the frame and plates to hinge upward under the patient's knees to elevate them as desired. This feature is not found in all models.

A retractable guardrail is attached along the central portion of the main frame of the stretcher at each side and is lowered out of the way when a patient is being loaded onto the stretcher. Once the patient has been properly placed on the stretcher, the handle is drawn up and locked in an elevated position perpendicular to the surface of the stretcher. The patient cannot roll off either side of the stretcher even if a securing strap becomes released. The guardrail at each side can be lowered only if its locking handle is released.

The underside of the main frame of the stretcher is supported on a folding undercarriage that has a smaller, horizontal, rectangular frame and four large rubber casters at its bottom end. The folding undercarriage is designed so that the litter can be adjusted to any height from about 12 inches (30 cm) above the ground, which is the desired height when the stretcher is secured in the ambulance, to 32 to 36 inches (81 to 91 cm) above the ground, which is the desired height when the stretcher is being rolled. Because you are able to lock the stretcher at any height between its lowest height and its fully extended height, it can be locked at the same height as any bed or examining table to allow the patient to be slid from one to the other. This permits you to transfer the patient without the need for any additional lifting. The controls for folding the undercarriage are designed so that the stretcher remains locked at its present height when the controls are not being activated. As an additional safety feature on most stretchers, the main frame must be slightly lifted to remove all weight from the undercarriage before it will fold, even if the control is pulled. Therefore, if the handle is accidentally pulled, the elevated stretcher will not suddenly drop. Controls for elevating and lowering most stretchers are located at the foot end and at one or both sides. You and your partner must use the proper lifting mechanics to lift the wheeled ambulance stretcher.

The mattress on a stretcher must be fluid resistant so that it does not absorb any type of potentially infectious material, including water, blood, or other body fluid.

Patients must always be secured with the straps on the stretcher. In the event of a crash while en route to the hospital, these help prevent the patient from further injury.

Backboards

A **backboard** is a long, flat board made of rigid, rectangular material Figure 8-2. Backboards are also called long backboards, spine boards, trauma boards, or longboards. A backboard is used to carry patients and to immobilize supine patients with suspected hip, pelvic, spinal, and lower extremity injuries or other multiple trauma in accordance with local protocols. Backboards can also be used to move patients out of awkward places.

Backboards are 6 to 7 feet long (approximately 2 m) and are commonly used for patients who are found lying down. Parallel to the sides and ends of the backboard are a number of long holes that are about 0.5 to 1 inch (1 to 2.5 cm) from the outer edge. These holes form handles and handholds so that the board can be easily grasped, lifted, and carried. The handles and adjacent holes also allow the patient to be secured to the board using straps located at each side and end of the backboard.

Figure 8-2 A backboard is used to transfer patients who must be moved in a supine or immobilized position.

For many years, backboards were made of thick marine plywood whose surface was sealed with polyurethane or another marine varnish. Wooden backboards are still used in some places. If your service uses wooden backboards, you must follow infection control procedures before you can reuse them. Where wooden backboards are no longer used, they have generally been stored so that they will be available in the event of a mass-casualty situation. Newer backboards are made of lighter plastic materials that will not absorb blood or other infectious substances.

Moving and Positioning the Patient

Every time you have to move a patient, special care must be taken so that neither you, your team, nor the patient is injured. Patient packaging and handling are technical skills that you will learn and perfect through repeated training and practice. Every year, a significant number of EMTs are injured when they attempt to lift and move patients. Even when you are lifting, moving, or transferring relatively lightweight patients, the need for proper body mechanics should remain paramount. Occasionally injuries occur when proper lifting techniques are utilized; however, using proper body mechanics and maintaining physical fitness greatly reduce the chance of injury.

Moving a patient should normally be done in an orderly, planned, and unhurried manner. This approach will protect you and the patient from further injury and reduce the risk of worsening the patient's condition when he or she is moved. Therefore, practice each technique with your team often so that when you must move a patient, you can perform the move quickly, safely, and efficiently. You must also master the skills necessary for the use of all equipment and understand the advantages and limitations of each device before you use it in the field. After each patient transfer, you and your team should evaluate the appropriateness of the technique that you used, as well as your technical skill in completing the transfer. You must also be sure to maintain your equipment according to the manufacturer's instructions. Using clean, well-maintained equipment is a critical part of providing high-quality patient care.

After delivering the patient to the ED, you and your team must begin preparation for your next call by reviewing the positive points about the transport and discussing changes that would improve the next run. This process of evaluation should help you identify the following:

- Procedures that need more practice
- Equipment that needs to be cleaned or serviced
- Skills that you need to review or acquire

YOU are the Provider PART 1

You are dispatched to a motor vehicle crash with an overturned vehicle. You arrive on scene to find a 4-door sedan lying on the passenger's side in a deep ditch partially filled with water. The vehicle is resting on a concrete pipe and a metal signpost. There are two patients who were unrestrained at the time of the crash. Patient 1 (the driver) is an older man who is unresponsive. You note that his skin is ashen with cyanosis around his lips. He is crumpled in a semi-supine position over the second patient. Only the top of the head of Patient 2 (the passenger) is visible, but she is obviously alert and able to speak with you. She tells you the water inside the vehicle is up to her waist.

1. What immediate challenges do you face?
2. Why is knowledge of body mechanics important when lifting and moving a patient?
3. What other resources are needed?

Most important, a critical review helps you and your team to become more confident and better skilled EMTs.

Body Mechanics

Anatomy Review

The shoulder girdle rests on the rib cage and is supported by the vertebrae that lie inferior to it. The arms are connected to and hang from the shoulder girdle. When a person stands upright, the individual weight-bearing vertebrae are stacked on top of each other and aligned over the sacrum. The sacrum is both the mechanical weight-bearing base of the spinal column and the fused central posterior section of the pelvic girdle. **Body mechanics** is the relationship between the body's anatomical structures and the physical forces associated with lifting, moving and carrying; in other words, the ways in which the body moves to achieve a specific action. Maintaining proper posture and body movement during daily activities is applying the use of body mechanics. Using good body mechanics while lifting and moving patients reduces your risk of injury.

When a person stands upright, the weight of anything being lifted and carried in the hands is reflected onto the shoulder girdle, the spinal column inferior to it, the pelvis, and then the legs **Figure 8-3**. In lifting, if the shoulder girdle is aligned over the pelvis and the hands are held close to the legs, the force that is exerted against the spine occurs in an essentially straight line down the vertebrae in the spinal column. Therefore, with the back properly maintained in an upright position, very little strain occurs against the muscles and ligaments that keep the spinal column in alignment, and significant weight can be lifted and carried without injury to the back **Figure 8-4**. However, you may injure your back if you lift while leaning forward, or even if straight, bent significantly forward at the hips **Figure 8-5**. With the back in either of these positions, the shoulder girdle lies significantly anterior to the pelvis, and the force of lifting is exerted primarily across, rather than down, the spinal column. When this occurs, the weight is supported by the muscles of the back and ligaments that run from the base of the skull to the pelvis, keeping the spinal column in alignment, rather than by each vertebral body and disk resting on those aligned below it. In addition, the upper spine and torso serve as a lever so that the force that is exerted against the muscles and ligaments in the lumbar and sacral regions, as a result of the mechanical advantage produced, is many times that of the combined weight of your upper body and the object you are lifting. Therefore, the first key rule of lifting is to always keep your back in a straight, upright (vertical) position and lift without twisting. Always face the patient and point your feet in the same direction. After lifting the patient, change the direction of your feet as opposed to twisting or turning from the waist.

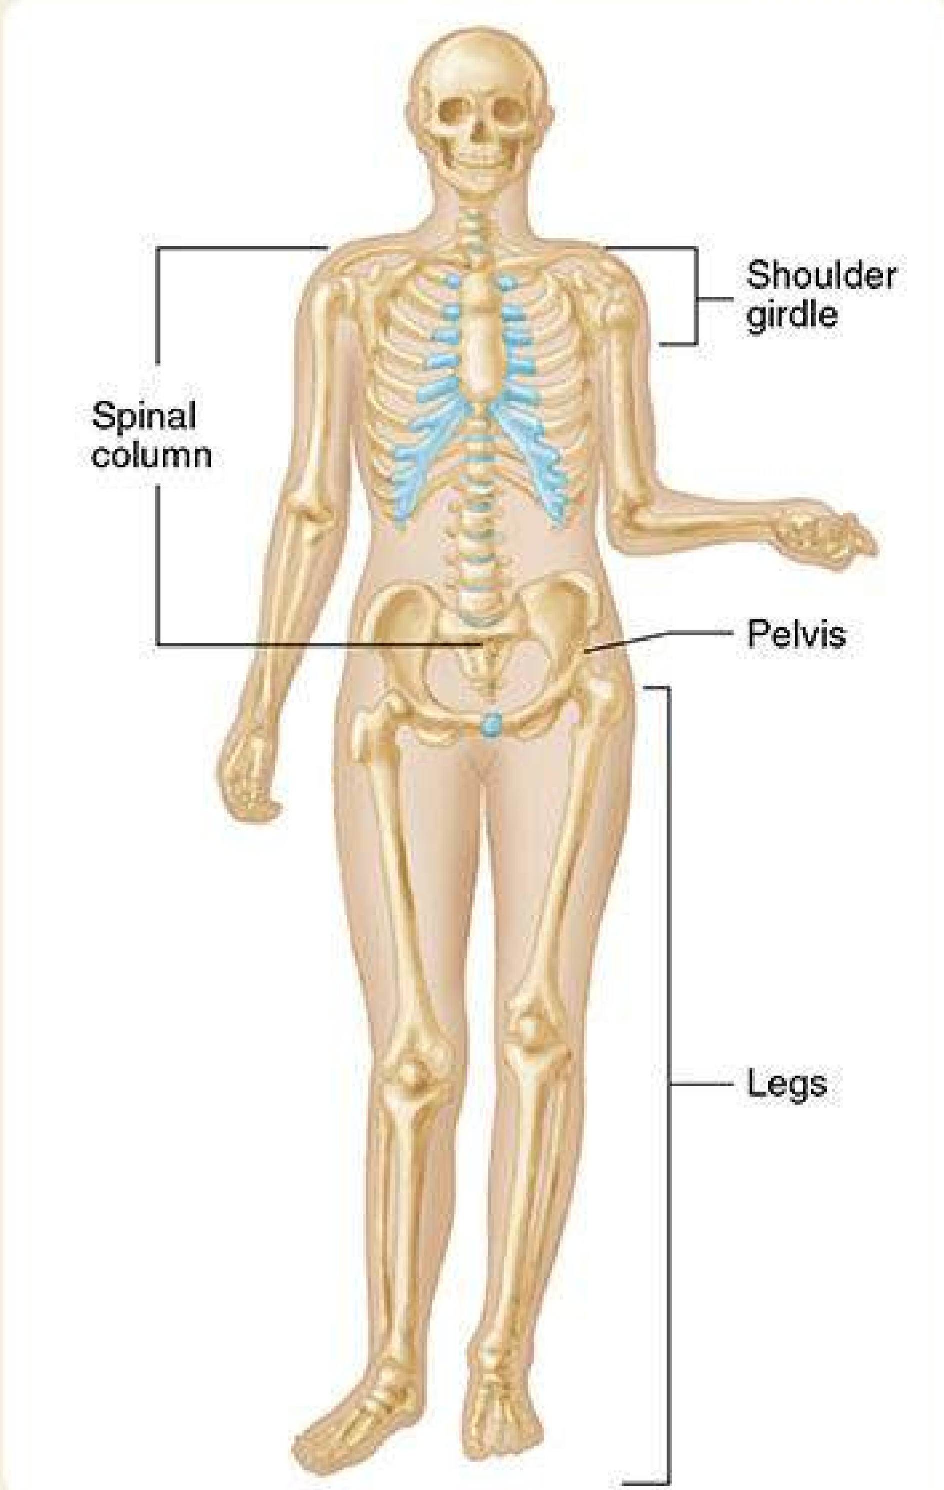

Figure 8-3 When you stand upright, the weight of anything that you lift and carry in your hands is borne by the shoulder girdle, the spinal column, the pelvis, and the legs.

When lifting, spread your legs about 15 inches (38 cm) apart (shoulder width) and place your feet so that your center of gravity is properly balanced between them. Then, with the back held upright, bring your upper body down by bending the legs. Once you have properly grasped the patient or stretcher and made any necessary adjustments in the location of your feet, lift the patient by straightening your legs until you are in a standing position and then curling your arms up to waist height. If you have still not reached the desired height, reposition your legs so they are closer together and repeat the process. Because the leg muscles are regularly exercised by walking, climbing stairs, or running, they are well developed and extremely strong. Therefore, as well as being the safest method, lifting by extending the properly placed flexed legs is also the most powerful way to lift. This method is appropriately called a **power lift**. The power lift position is also useful if you have weak knees or thighs.

Figure 8-4 If your body is properly aligned when you lift, the line of force exerted against the spine occurs in an essentially straight line down the vertebrae. In this way, the vertebrae support the lift.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Figure 8-5 This photo demonstrates an incorrect method of lifting. You may be injured if you lift with your back curved because the lifting force is exerted primarily across, rather than down, the spinal column. When this occurs, the muscles of the back, not the vertebrae, are supporting the lift.

Words of Wisdom

The stretcher is designed so that the patient's head is slightly higher than the feet. Always position the tallest EMTs at the head of the stretcher when lifting to offset the difference in the height of the stretcher.

One mistake to avoid while performing a lift is lifting a patient or other heavy object with your arms outstretched. Even if your back is held properly upright, adverse forces across the spinal column and leverage against the low back will occur if your hands are significantly anterior to the plane described by the front of the torso (the plane consists of the anterior torso and imaginary lines extended vertically above and below it). Whenever you lift or carry a patient, be sure to hold your arms so that your hands are almost adjacent to the plane described by your anterior torso, and always keep the weight that you are lifting as close to your body as possible.

Another rule to remember when lifting is to avoid placing lateral force across the spine and sideways leverage against the low back. If you lift with only one arm or with the arms extended more to one side than the other, more force will be exerted against one side of the shoulder girdle than the other, causing lateral force to be exerted across the spinal column. To prevent this, keep your arms approximately the same distance apart as when hanging at each side of the body, with the weight distributed equally and properly centered between them. If the weight is not balanced between both arms or properly centered between the shoulders when you are preparing to lift, turn and/or move to the left or right until the weight is properly balanced and centered. To lift safely and produce the maximal power lift, take the following steps **Skill Drill 8-1**:

1. Tighten your back in its normal upright position, and use your abdominal muscles to lock it in a slight curve.
2. Spread your legs apart about 15 inches (38 cm), and bend your legs to lower your torso and arms.
3. With arms extended down each side of the body, grasp the stretcher or backboard with your hands held palm up and just in front of the plane described by the anterior torso and imaginary lines extending vertically from it to the ground.

4. Adjust your orientation and position until the weight is balanced and centered between both arms Step 1.
5. Reposition your feet as necessary so that they are about 15 inches (38 cm) apart with one slightly farther forward and rotated so that you and your center of gravity will be properly balanced between them. Be sure to straddle the object, keep your feet flat, and distribute your weight to the balls of the feet or just behind them. The knees should not bend more than 90 degrees, nor extend past the toes.
6. With the arms extended downward, lift by straightening your legs until you are fully standing. Make sure your back is held upright and that your upper body comes up before your hips Step 2.

Skill Drill 8-1 Performing the Power Lift

Step 1

Lock your back in a slight curve. Spread and bend your legs. Grasp the backboard, palms up and just in front of you. Balance and center the weight between your arms.

Step 2

Position your feet, straddle the object, and distribute your weight evenly. Lift by straightening your legs, keeping your back locked in.

Reverse these steps whenever you are lowering the stretcher. Always remember to avoid bending at the waist and twisting as you stand.

Your safety, as well as that of the other EMTs and the patient, depends on the use of proper lifting techniques and maintaining a proper hold when lifting or carrying a patient. If you do not have proper hold of the stretcher or of the patient in a body lift, you will not be able to bear a proper share of the weight, and there is an increased chance that you can suddenly lose your grasp with one or both hands. If you temporarily lose your grasp, the position and weight distribution of the stretcher will change suddenly, and the other team members must quickly overextend beyond a safe distance to avoid dropping the patient. As a result, sudden excessive force may be placed across each one’s spine, causing low back injury.

You should use the **power grip** to get the maximum force from your hands whenever you are lifting a patient **Figure 8-6**. The arm and hand have their greatest lifting strength when facing palm up. Whenever you grasp a stretcher or backboard, your hands should be at least 10 inches (25 cm) apart. Each hand should be inserted under the handle with the palm facing up and the thumb extended upward. Next, advance the hand until the thumb prevents further insertion and the cylindrical handle lies firmly in the crease of your curved palm. Curl your fingers and thumb tightly over the top of the handle. All your fingers should be at the same angle. To have the proper power grip, make sure that the underside of the handle is fully supported on your curved palm with only the fingers and thumb preventing it from being pulled sideways or upward out of the palm.

Figure 8-6 To perform the power grip, grasp the handle of the stretcher or backboard with your palms up and your thumbs extending up. Make sure your hands are about 10 inches (25 cm) apart and that your fingers are all at the same angle. The underside of the handle should be fully supported by the palms of your hands.

If you must lift the object higher once you have lifted by extending your legs, you will be able to "curl" the object higher by using your biceps to flex the arms while maintaining the power grip and weight supported in the palms.

Never grasp a stretcher or backboard with the hand placed palm down over the handle. When you are lifting with the palm down, the weight is supported by the fingers rather than the palm. This hand orientation places the tips of the fingers and thumb under the handle. If the weight forces them apart, your grasp on the handle will be lost.

When directly lifting a patient, tightly grip the patient in a place and manner that will ensure that you will not lose your grasp on the patient. If at all possible, use a draw sheet or other approved lifting device so you are not pulling directly on the patient's skin (discussed later in the chapter). This is especially important when lifting patients who are either heavy and/or older.

Words of Wisdom

Regardless of patient size or use of proper body mechanics, the potential for injury is present. There are many commercial devices available for lifting and moving patients that help to protect you, including soft stretchers, tarps, and sliding boards. Patients may also be lifted with equipment such as a sling lift, which does not require additional assistance for lifting and moving. With a sling lift, a sling is slid under the patient's body. Loops on the corners of the sling's fabric attach to a hydraulic lift, and the patient is safely hoisted from the bed or chair into position (a method similar to the draw sheet method).

Principles of Safe Reaching and Pulling

The same basic body mechanics and principles apply to moving, lifting, and carrying a patient.

When you use a body drag to move a patient, your back should always be locked in a slight curve created by tightening your abdominal muscles, not curved laterally or bent laterally. It should be held in its normal upright position. Avoid any twisting so that the vertebrae remain in their normal alignment. When you reach overhead, avoid hyperextending your back. When you pull a patient who is on the ground, always kneel to minimize the distance that you will have to lean over **Figure 8-7A**. To keep your reach within the recommended distance, reach forward and grasp the patient so that your elbows are just beyond the anterior torso **Figure 8-7B**. When you pull a patient who is at a different height from you, bend your knees until your hips are just below the height of the plane across which you will be pulling the patient. During pulling, extend your arms no more than about 15 to 20 inches (38 to 50 cm) in front of your torso. Reposition your feet (or knees, if kneeling) so that the force of pull will be balanced equally between both arms and the line of pull will be centered between them **Figure 8-7C**. Pull the patient by slowly flexing your arms. When you can pull no farther because your hands have reached the front of your torso, stop and move back another 15 to 20 inches (38 to 50 cm). Then, when properly positioned, repeat the steps. Alternate between pulling the patient by flexing your arms and then repositioning yourself so that your arms are again extended with your hands about 15 inches (38 cm) in front of your torso. By not moving yourself and the patient simultaneously, you will prevent undesirable jostling of the patient and the chance that sudden force will occur across your spine. You should also try to prevent injury to yourself by avoiding situations that involve strenuous effort lasting more than 1 minute.

If you must drag a patient across a bed, kneel on the bed to avoid reaching beyond the recommended distance. Then follow the steps described previously until the patient is within 15 to 20 inches (38 to 50 cm) of the bed's edge (see Figure 8-7). You can then complete the drag while standing at the side of the bed. Rather than dragging the patient by his or her clothing, use the sheet or blanket under the patient for this purpose. You can roll the bedding under the patient until it is about 6 inches (15 cm) wider than the patient. Pull on the rolled bedding smoothly and evenly to glide the patient to the bedside.

Unless the patient is on a backboard, transfer the patient from the stretcher to a bed in the ED or the patient's hospital room with a body drag. With the stretcher at the same height as the bed or slightly higher and held firmly against the bed's side, you and another EMT should kneel on the hospital bed and, in the manner previously described, drag the patient in increments until he or she is properly centered on the bed. When transferring the patient onto a narrow examining table, rather than kneeling on the table, you can usually drag the patient while standing against the opposite side. A third person may need to take both sides of the head to move the patient safely.

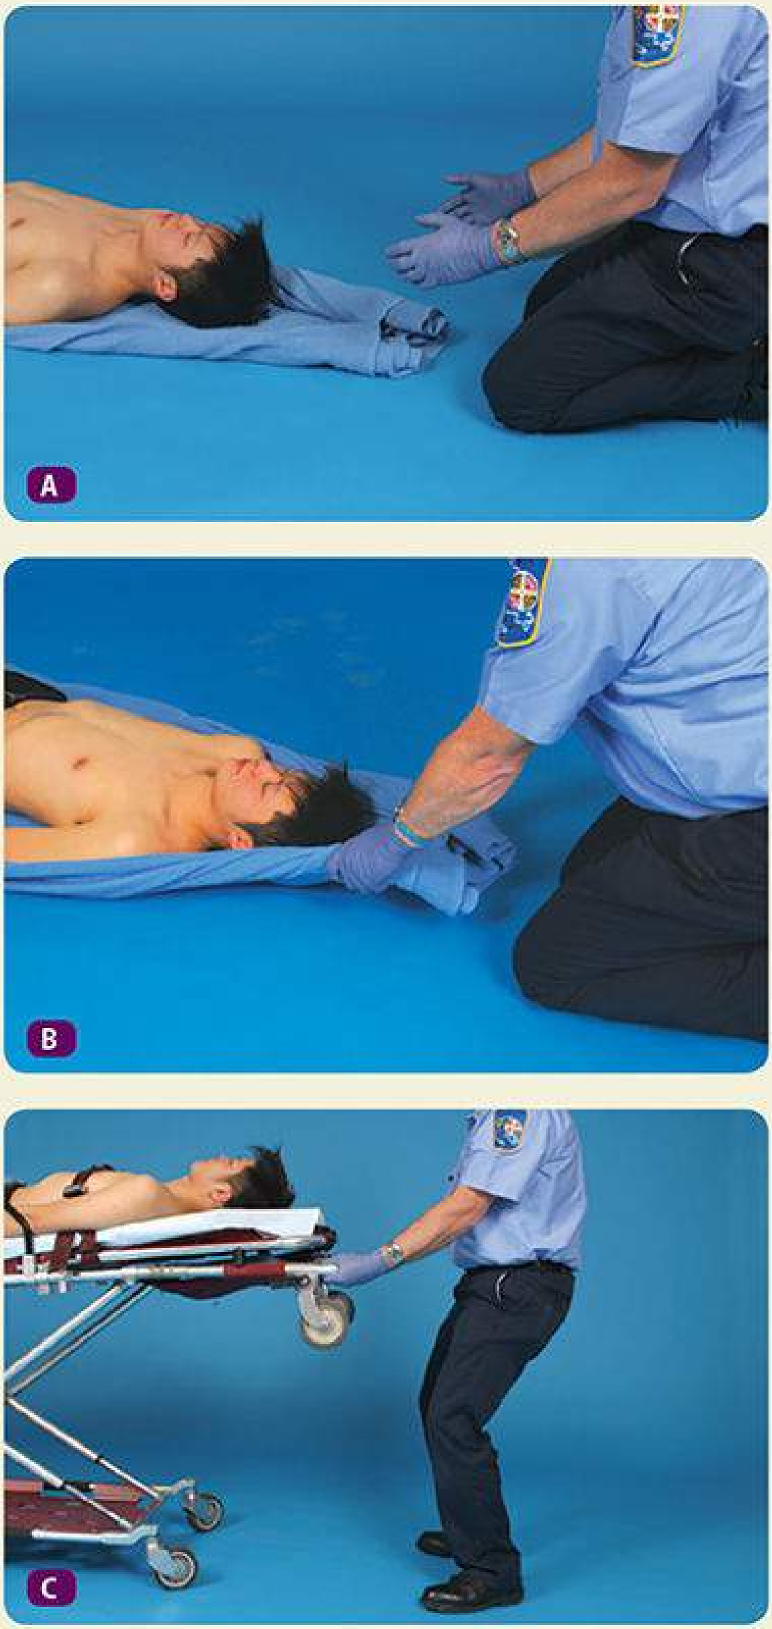

Figure 8-7 Reaching and pulling safely. **A.** Kneel to pull a patient who is on the ground. **B.** When pulling, your elbows should only extend just beyond the anterior torso. **C.** Bend your knees to pull a patient who is at a different height than you are. Position your feet or knees to balance the force of pull.

Sometimes during a body drag, you and another EMT may have to pull the patient with one of you on each side of the patient. You will have to alter the usual pulling technique to prevent pulling sideways and producing adverse lateral leverage against your lower back. Position yourself by kneeling just beyond the patient's shoulder and facing toward his or her groin **Figure 8-8A**. By extending one arm across and in front of your chest, you can grasp the armpit and, with your other arm extended in front and to the side of the patient's torso, the patient's belt. Then, by raising your elbows and flexing your arms, you can pull the patient with the line of force at the minimum angle possible **Figure 8-8B**.

Words of Wisdom

When moving a patient, you may grab his or her belt to assist with the move. However, do not use pockets or belt loops that may tear with the patient's weight.

Figure 8-8 A body drag with an EMT on each side of the patient. **A.** Kneel just beyond the patient's shoulder facing his or her groin. Extend one arm across and in front of your chest, and grasp the armpit. Extend your other arm in front and to the side of the patient's torso, and grasp the patient's belt. **B.** Raise your elbows and flex your arms to pull the patient.

Generally, when log rolling a patient onto his or her side, you will initially have to reach farther than 18 inches (46 cm) **Figure 8-9**. To minimize this distance, kneel as close to the patient's side as possible, leaving only enough room so that your knees will not prevent the patient from being rolled. When you lean forward, keep your back straight and lean solely from the hips. Be sure to use your shoulder muscles to help with the roll. To minimize the amount of time you are extended like this and to support the patient's weight, roll the patient without stopping until the patient is resting on his or her side and braced against your thighs. Pulling toward you allows your legs to prevent the patient from rolling over completely and from rolling beyond the intended distance.

Words of Wisdom

You will often be called upon to lift a patient in tandem with someone you have never worked with before. Pay attention to what each other is doing, and verbalize your actions to decrease the risk of dropping the patient or hurting one another. If you have the chance to practice lifts with a new partner prior to your first call together, do so.

Figure 8-9 When placing a patient onto a backboard, log roll the patient onto his or her side. Kneel as close to the patient's side as possible, leaving only enough room so that your knees will not prevent the patient from being rolled. Lean forward, keeping your back straight and leaning solely from the hips. Use your shoulder muscles to help with the roll.

YOU are the Provider — PART 2

Due to the critical condition of Patient 1, you immediately request paramedic backup. Because of the position of the vehicle and the patients, you determine that the patients are entrapped and that the vehicle is potentially unstable. You ask dispatch to send a rescue unit to assist with stabilizing the vehicle and extricating the victims. The rear driver's side door was wedged open as a result of the crash. You are able to look through and perform a modified primary assessment on the patients while waiting for further assistance.

Patient 1

Recording Time: 0 Minutes	
Appearance	Motionless; ashen skin with cyanosis around the mouth
Level of consciousness	Unresponsive
Airway	Snoring respirations
Breathing	Increased rate; shallow depth
Circulation	Unable to reach patient to feel for pulse; no obvious bleeding

Patient 2

Recording Time: 0 Minutes	
Appearance	Unable to visualize due to patient's position, but she is anxious and reports some pain to her back and right side
Level of consciousness	Alert and oriented
Airway	Open; clear of secretions and foreign bodies
Breathing	Unable to assess, but talking in complete sentences with no sounds of distress and she denies any dyspnea
Circulation	Unable to assess due to patient's position

Patient 2 tells you that Patient 1, her husband, is normally on oxygen and the tube was pulled off during the crash. She thinks she may be sitting on the portable oxygen machine. She also thinks that she may have "cracked a rib or two" when she was thrown against the door. She begs you to please help her husband before it is too late.

4. Do you consider Patient 1 to be in stable or unstable condition? Should you wait for further assistance or proceed to gain access to him?
5. Once you are able to gain access, what are your concerns for the use of proper body mechanics while removing these patients?
6. Once Patient 1 is no longer entrapped, how will you attempt to remove him from the vehicle while maintaining cervical spine support?

Principles of Safe Lifting and Carrying

Whenever possible, use a device that can be rolled to move a patient. However, in a situation where a wheeled device is not available, you must make sure that you understand and follow certain guidelines for carrying a patient on a stretcher. Table 8-1 shows the guidelines.

Patient Weight

You should estimate how much the patient weighs before you attempt to lift. Commonly, adult patients weigh between 120 and 220 lb (54 and 100 kg). If you use the correct technique, you and one other EMT should be able to safely lift this weight. Depending on your individual strength, you and another EMT may be able to safely lift an even heavier patient. However, due to safety concerns, try to use four providers to lift when possible. There is more stability with a four-person carry, and the carry requires less strength. You should know how much you can comfortably and safely lift, and do not attempt to lift a proportional weight (the share of the weight that you will bear) that exceeds this amount. If you find that lifting the patient places a strain on you, stop the lift and lower the patient. You should then obtain additional help before again attempting to lift the patient. Be sure to communicate clearly and frequently with your partner and other providers whenever you are lifting a patient.

Do not attempt to lift a patient who weighs more than 250 lb (114 kg) with fewer than four providers, regardless of individual strength. Protocols should include a method to rapidly summon additional help to lift and carry such a patient or, as in the case of a cardiac arrest, provide and maintain the necessary care in the field. In addition, you must know, or be able to find out, the weight limitations of the equipment you are using and how to handle patients who exceed the weight limitations. Special bariatric techniques, equipment, and resources are generally required to move any patient who weighs more than 350 lb (159 kg) to the ambulance (discussed later in the chapter). These resources should be summoned when you arrive on scene and have assessed the situation.

Table 8-1 Guidelines for Carrying a Patient on a Stretcher

- Estimate the weight of both the patient and the associated equipment to be lifted and gauge the limitations of your team's abilities.
- Coordinate your movements with those of the other team members while constantly communicating with them.
- Do not twist your body as you are carrying the patient.
- Keep the weight that you are carrying as close to your body as possible while keeping your back in a locked-in position.
- Do not bend at the waist; this could hyperextend your back. Instead, flex at the hips, and bend at the knees.

Lifting and Carrying a Patient on a Backboard or Stretcher

If a patient is supine on a backboard or is lying in a semi-Fowler position on the stretcher, his or her weight is not equally distributed between the two ends of the device. Between 68% and 78% of the body weight of a patient in a horizontal position is in the torso. Therefore, more of the patient's weight rests on the head half of the device than on the foot half.

A patient on a backboard or stretcher can be lifted and carried by four providers in a **diamond carry**, with one provider at the head end of the device, one at the foot end, and one at each side of the patient's torso **Figure 8-10**. Follow these steps to perform the diamond carry **Skill Drill 8-2**:

1. To best balance the weight, the providers at each side should be located so that they are able to grasp the backboard or stretcher with one hand adjacent to the distal edge of the patient's pelvis and the other midthorax. All four providers lift the device while facing toward the patient Step 1.

Figure 8-10 The diamond carry requires four providers: one at the head of the backboard, one at the foot end, and one at each side of the patient's torso.

2. The provider at each side should grasp the backboard or stretcher with the head-end hand Step 2.
3. The providers at each side turn toward the patient's feet. The provider at the foot end turns to face forward. All four providers should face the same direction and walk forward when carrying the patient Step 3.

A patient on a backboard or stretcher should be carried feetfirst to place the lightest load on the provider at the patient's feet, who, to walk forward, must turn and grasp the handles with his or her back to the device. Carrying the patient feetfirst will also allow a conscious patient to see in the direction of movement, which may reduce anxiety.

It is important that you and your team use the correct lifting techniques to lift the stretcher. One method of lifting and carrying a patient on a backboard is the one-handed carry. With this method, four or more providers each use one hand to support the backboard so that they are able to face forward as they are walking. To perform the one-handed carry, follow the steps in Skill Drill 8-3:

Skill Drill 8-2 Performing the Diamond Carry

Step 1

Position yourselves facing the patient.

Step 2

The providers at each side turn the head-end hand palm down and release the other hand.

Step 3

The providers at each side turn toward the foot end. The provider at the foot end turns to face forward.

1. Before lifting the backboard, be sure that at least two providers are on each side of the backboard facing across from each other and using both hands Step 1.
2. Lift the backboard to carrying height using correct lifting techniques, including a locked-in back Step 2.
3. Once you have lifted the backboard to carrying height, you and your partners turn in the direction you will be walking and switch to using one hand Step 3.

Be sure to pick up and carry the backboard with your back in the upright position. If you need to lean to either side to compensate for a weight imbalance, you have probably exceeded your weight limitation. If this occurs, reevaluate the carry; you may need additional providers or else you might injure yourself or drop the patient.

In most instances, it is best if you push the head of the stretcher while your partner guides the foot of the stretcher. When the stretcher must be carried, it is best if four providers are available to carry it. One provider should be positioned at each corner of the stretcher to provide an even lift. If only two providers are available, or if limited space allows room for only two providers to carry the stretcher, there is a risk that the stretcher will become unbalanced. In a two-person carry, the two providers should stand facing each other, with one person at the head end of the stretcher and the other at the foot end. With this type of carry, one provider will have to walk backward.

Skill Drill 8-3 Performing the One-Handed Carry

Step 1

Face each other and use both hands.

Step 2

Lift the backboard to carrying height.

Step 3

Turn in the direction you will walk, and switch to using one hand.

When you are rolling the wheeled ambulance stretcher, make sure that it is in the fully elevated position. If you are guiding the stretcher from the foot end, make sure your arms are held close to your body, and be careful to avoid reaching significantly behind you or hyperextending your back **Figure 8-11**. Recall that your back should be locked, straight, and untwisted. While you are walking and guiding the stretcher, bend slightly forward at the hips. As you walk, your legs are pulled back with your feet on the ground, your pelvis is moved forward, and the movement of the pelvis is transferred to the stretcher through your straight torso and firmly held arms. Try to keep the line of the pull through the center of your body by bending your knees.

Your partner should control the head end and assist you by pushing with his or her arms held with the elbows bent so that the hands are about 12 to 15 inches (30 to 38 cm) in front of the torso. To protect your elbows from injury, never push an object with your arms fully extended in a straight line and the elbows locked. When you push with the elbow bent but firmly held from bending further, the strong muscles of the arm serve as a shock absorber if the wheels or foot end of the stretcher strikes an obstacle that causes its progress to be suddenly slowed or stopped. Be sure that you push from the area of your body that is between the waist and shoulder. If the weight you are pushing is lower than your waist, push from a kneeling position. Remember not to push or pull from an overhead position.

Figure 8-11 Push the stretcher from the head end. If you are guiding the stretcher from the foot end, make sure your arms are held close to your body, and be careful to avoid reaching significantly behind you or hyperextending your back. Your back should be locked, straight, and untwisted.

▶ Moving a Patient With a Stair Chair

When you must carry a conscious patient up or down a flight of stairs or other significant incline, use a stair chair if the patient's condition allows him or her to be placed in a sitting position. A **stair chair** is a lightweight folding chair with a molded seat, adjustable safety straps, and fold-out handles at both the head and feet **Figure 8-12**. Most models have rubber wheels in the back with casters in front so that they can roll along the floor and make turns. Some have a specially designed track to facilitate movement down steps with little lifting required. Stair chairs serve as an adjunct for moving a patient up or down stairs to the ground floor, where the prepared wheeled ambulance stretcher is waiting. You can roll the stair chair on the floor until you reach the stairwell, and then both providers carry it (rather than roll and bump it) up or down the stairs.

Figure 8-12 A wheeled stair chair can be used to transfer a conscious patient up or down a flight of stairs.

When the patient is upstairs, you should take the wheeled ambulance stretcher to the ground floor landing and prepare it for the patient. Place it at the proper height, lower the side rails, turn down the cover sheet, and remove any equipment that you may have secured on the top. You should then take the stair chair upstairs and load the patient into it. Once reaching the bottom of the stairs, transfer the patient from the stair chair onto the stretcher.

Follow these steps to use a stair chair **Skill Drill 8-4**:

1. Secure the patient to the stair chair with straps. At a minimum, use a lap belt at the hips and a strap around the chest. You should also use some method to secure the arms and hands so the patient does not reach out to grasp something and throw the carrying team off-balance, and ensure that the feet are either strapped or placed in the footrest.

2. Take your places around the patient seated on the chair: one provider at the head end and one at the foot end Step 1. The provider at the head will give directions to coordinate the lift and movement. If a third provider is on scene, he or she may precede you and your partner. Keeping his or her hand on the back of the second provider who is at the feet, the third provider can assist by opening doors and providing guidance and support. For lengthy carries, a third provider can also rotate into the carrying team to provide breaks for the other two.

3. When reaching landings and other flat intervals in the move, lower the chair to the ground and roll the chair to the next position. Upon reaching the ground level where the stretcher awaits, roll the chair into position next to the stretcher in preparation for transferring the patient Step 2.

Skill Drill 8-4 Using a Stair Chair

Step 1

Position and secure the patient on the chair with straps. Take your places at the head and foot of the chair.

Step 2

Lower the chair to roll on landings and for transfer to the stretcher.

As with other carries, always remember to keep your back in a locked-in position and to flex at the hips, not the waist. Bend at the knees and keep the patient's weight and your arms as close to your body as possible. Twisting while carrying or moving a patient will increase your risk of injury. Try to avoid any unnecessary lifting and carrying of the patient. You may find that a log roll or a body drag will aid you in moving your patient onto the backboard or the stretcher. If these techniques will not harm or jeopardize your patient's condition, use one of these moves.

▶ Moving a Patient on Stairs With a Stretcher

When a patient is unresponsive, must be moved in a supine position, or must be immobilized, do not use a stair chair; instead, secure the patient onto a backboard. Be sure that the patient is anatomically secured to the device so that he or she cannot slide significantly when the stretcher is at an angle. Carry the patient on the backboard down the stairs to the prepared stretcher. When moving on stairs, more than half of a patient's weight is distributed to the head end of the backboard, so make sure the strongest provider is positioned at the head end. (Even with four or more providers carrying the patient, the strain on the provider at the head end will be increased when you must negotiate a narrow flight of stairs.) In carrying a patient up or down a flight of stairs, proportionally greater weight will also be distributed to the provider who carries the foot end when the device becomes angled because of the incline or decline. You should anticipate this and, in such cases, make sure the two strongest providers are positioned at the head and foot ends of the board. Because of the incline of the stairway, if one of the two strongest providers is considerably taller than the other, it will be easier if the shorter provider is at the head end and the taller provider is at the foot end. This minimizes bending while lifting and moving the patient. Once you reach the stretcher, place both the backboard and the patient on the stretcher; then secure both to the stretcher with additional straps.

To carry a patient on stairs on a backboard, follow the steps in **Skill Drill 8-5**:

1. Apply a strap that passes tightly across the upper torso and through each armpit, but not over the arms, to hold the patient in place while leaving the arms free. The strap is secured to the handles at both sides of the backboard so that it cannot slide toward the foot end of the backboard. Strap the patient securely to the backboard Step 1.
2. When you carry the patient down stairs or an incline, make sure the backboard or stretcher is carried with the foot end first so that the head end is elevated higher than the foot end. The straps will prevent the patient from sliding down or off the backboard Step 2.

Words of Wisdom

When you encounter a patient in a confined space, such as a bathroom, it can pose a unique set of problems. Prior to moving a patient in a confined space, it is important to discuss the process with your fellow team members. Ensure that everyone agrees with the extrication plan and understands his or her role. Remember that communication with the crew, as well as the patient, will assist in minimizing potential problems.

Loading a Wheeled Stretcher Into an Ambulance

Most patients are placed directly on the wheeled ambulance stretcher. Exceptions include patients with a possible spinal injury or multisystem trauma; you will need to place and secure them onto a backboard. Also, patients who are unresponsive or must be carried down (or up) a flight of stairs while supine should be placed on a backboard. The backboard and patient are then secured onto the stretcher.

Whenever a patient has been placed onto the stretcher, one EMT must hold the main frame to prevent movement. When the stretcher is elevated, the main frame and the patient extend considerably beyond the wheels at both the head end and foot end of the stretcher. Therefore, whenever a patient is on an elevated stretcher, you must ensure that it is held firmly between two hands at all times so that even if the patient moves, the stretcher cannot tip **Figure 8-13**.

Skill Drill 8-5 Carrying a Patient on Stairs

Step 1

Strap the patient securely. Make sure one strap is tight across the upper torso, under the arms, and secured to the handles to prevent the patient from sliding.

Step 2

Carry a patient downstairs with the foot end first, always keeping the head elevated.

Inside the ambulance are strong clamps that fasten around the undercarriage when the stretcher is pushed into them. The clamps are located in a rack on the floor or side of the patient compartment and will hold the stretcher in place until they are released at the hospital. You can control and release the clamps with a single handle when standing on the ground at the open back doors of the ambulance when the stretcher is to be unloaded. The stretcher is designed to be rolled on flat surfaces. Ensure the intended travel path is free from debris and potential obstacles. If the patient must be moved over a lawn or other irregular surface, you must lift and carry the stretcher over the terrain. A four-person carry is much safer if the stretcher must be moved over rough ground.

If the loaded stretcher must be carried down a short flight of steps, be sure to first retract the undercarriage; however, this is not necessary when the stretcher must be lifted over a curb, a single step, or an obstacle of a similar height **Figure 8-14**.

Some older or less expensive wheeled ambulance stretchers do not feature extra wheels below the head end of the main frame. These stretchers are not self-loading. When you reach the back of the ambulance with such a stretcher, you must lower it until the undercarriage is in its lowest retracted position and then, with you and your partner at each side of the stretcher, lift it to the height of the floor of the ambulance and roll it into the track that locks it into place.

An intravenous (IV) pole is attached to many stretchers. The IV pole can be unfolded or extended above the main frame to hold an IV bag above the patient while you move the stretcher to the ambulance. Some wheeled ambulance stretchers even include a carrier to hold a cardiac monitor or automated external defibrillator (AED) and portable oxygen unit. If the model you use does not include these features, you will have to secure the portable oxygen unit and cardiac monitor or AED to the top surface of the stretcher mattress at the patient's legs. If possible, remove these items before lifting the stretcher to avoid the excess weight.

Figure 8-13 Make sure that you hold the main frame of the stretcher when it is elevated so that even when the patient moves, the stretcher does not tip over.

Figure 8-14 You need not retract the undercarriage of the stretcher when lifting it over a curb, a single step, or an obstacle of similar height.

Table 8-2 shows the guidelines that you must follow to load the stretcher into the ambulance.

Follow these steps to load the stretcher into an ambulance **Skill Drill 8-6**:

1. Tilt the head end of the main frame upward, and place it into the patient compartment with the wheels on the floor. The two additional wheels that extend just below the head end are attached to the main frame and will enable this movement. Ensure that the safety bar under the head of the stretcher catches on the hook prior to lifting the stretcher Step 1.

Table 8-2 Guidelines for Loading the Stretcher Into the Ambulance

- Make sure there are enough providers for sufficient lifting power.
- Follow the manufacturer's directions for safe and proper use of the stretcher.
- Make sure that all stretchers and patients are fully secured before the ambulance is moved.

2. With the patient's weight supported by these two head-end wheels and the EMT at the foot end of the stretcher, move to the side of the main frame and release the undercarriage lock to lift the undercarriage up to its fully retracted position. The wheels of the undercarriage and the two on the head end of the main frame will now be on the same level Step 2.
3. Simply roll the stretcher the rest of the way into the back of the ambulance, where it will rest on all six wheels Step 3.
4. Secure the stretcher in the ambulance with the strong clamps that fasten around the undercarriage when the stretcher is pushed into them. The clamps are located in a rack on the floor or side of the patient compartment Step 4.

Safety Tips

Choose one EMT to be the team leader and direct all movements to prevent confusion. He or she should explain the procedure in advance and verbalize instructions such as, "We will lift on 3," or "We will count to 3 and then lift."

Directions and Commands

To safely lift and carry a patient, you and your team must anticipate and understand every move, and each move must be executed in a coordinated manner. Before any lifting is initiated, the team leader should indicate where each team member is to be located and rapidly describe the sequence of steps that will be performed to ensure the team knows what is expected. If you must lift and move the patient through a number of separate stages, the team leader should first give an abbreviated overview of the stages, followed by a more detailed explanation of each stage just before it will occur.

Orders that will initiate the actual lifting or moving or any significant changes in movement should be given in two parts: a preparatory command and a command of execution. For example, if the team leader says, "All ready to stop. STOP!," the phrase "All ready to stop" will get your attention, identify who should act, and prepare you to act; the declarative "STOP!" will indicate the exact moment of execution. Commands of execution should be delivered in a louder voice. Often, a countdown is helpful when you need to lift a patient. To avoid confusion in using a countdown, the leader should always clarify whether "three" is to be a part of the preparatory command or whether it is to serve as the order to execute. He or she can say, "We're going to lift on three. One, two, THREE!" or "I'm going to count to three, and then we're going to lift. One, two, three, LIFT!"

Words of Wisdom

Remember that moving a patient is a dynamic process and the team leader must be prepared to alter the sequence of moves as needed.

YOU are the Provider PART 3

Once the vehicle has been stabilized by the fire department, you are able to gain access through the rear driver's side door that is about halfway open. The vehicle is still lying on the passenger's side. A paramedic unit is standing by awaiting removal of Patient 1. You are able to wedge about half of a backboard through the doorway with a firefighter holding the other end, but there is no room inside for additional providers.

Patient 1

Recording Time: 5 Minutes	
Appearance	Motionless; ashen skin with cyanosis around the mouth
Level of consciousness	Unresponsive
Airway	Snoring respirations
Breathing	Increased rate; shallow depth
Circulation	Weak and rapid radial pulse; no obvious bleeding

Patient 2

Recording Time: 5 Minutes	
Respirations	Seems to be a little rapid, but still unable to visualize patient
Pulse	Unable to assess due to patient's position
Skin	Pink where visualized
Blood pressure	Unable to assess
Oxygen saturation (Spo_2)	Unable to assess

7. What type of move is best for removing Patient 1?
8. What steps can you take to maximize safety while lifting a patient?

Skill Drill 8-6 Loading a Stretcher Into an Ambulance

Step 1

Tilt the head of the stretcher upward, and place it into the patient compartment with the wheels on the floor and the safety bar latched on the hook.

Step 2

The second EMT on the side of the stretcher releases the undercarriage lock and lifts the undercarriage.

Step 3

Roll the stretcher into the back of the ambulance.

Step 4

Secure the stretcher to the clamps mounted in the ambulance.

You will often have to perform several additional steps to place the patient onto a backboard and/or carry him or her down a flight of stairs. You will also have to add a stop at the top of the stairway so that everyone can reposition before carrying the patient down the stairs. Repositioning usually requires lowering the backboard to the ground and lifting it again when all providers are in their proper places. If you are carrying the patient in a stair chair, the additional step occurs after you have descended the stairs and reached the stretcher. At that point, you will have to assist or lift the patient from the stair chair onto the stretcher.

You should carefully plan ahead and select the methods that will involve the least amount of lifting and carrying. Remember to always consider whether there is an option that will cause less strain to you and the other providers.

Safety Tips

Follow these rules to keep you and your patient safe:

- Minimize the number of total body lifts you have to perform.
- Coordinate every lift in advance.
- Minimize the total amount of weight you have to lift.
- *Never* lift with your back.
- Do not carry what you can put on wheels.
- Do not hesitate to ask for help at any time.

Emergency Moves

When there is a potential for danger, use an **emergency move** to drag or pull a patient to a safe place before assessment and care are provided. The risk of serious harm or death due to fire, explosives, or hazardous materials, your inability to protect the patient from other hazards, or your inability to gain access to others in a vehicle who need lifesaving care are all situations in which you should use an emergency move.

The only other time you should use an emergency move is if you cannot properly assess the patient or provide critical emergency care because of the patient's location or position.

If you are alone and danger at the scene makes it necessary for you to use an emergency move, regardless of a patient's injuries, you should use a drag to pull the patient along the long axis of the body. This will help to keep the spinal column in line as much as possible. When performing an emergency move, one of your primary concerns is the danger of aggravating an existing spinal injury. Remember that it is impossible to remove a patient quickly from a vehicle while providing as much protection to the spine as would a spinal immobilization device such as a KED. However, if you follow certain guidelines during the move, you can usually remove a patient from a life-threatening situation without causing further injury to the patient.

You can move a patient on his or her back along the floor or ground by using one of the following methods:

- Pull on the patient's clothing in the neck and shoulder area **Figure 8-15A**. If the shirt has buttons, the top two should be undone to prevent the patient from choking.
- Place the patient onto a blanket, coat, or other item that can be pulled **Figure 8-15B**.
- Rotate the patient's arms so that they are extended straight on the ground beyond his or her head, grasp the wrists, and, with the arms elevated above the ground, drag the patient **Figure 8-15C**.
- Place your arms under the patient's shoulders and through the armpits, and, while grasping your opposite wrist, drag the patient backward **Figure 8-15D**.

If you are alone and must remove an unresponsive patient from a vehicle, first move the patient's legs so they are clear of the pedals and are against the seat. Then rotate the patient so that his or her back is positioned toward the open vehicle door. Next, place your arms through the armpits and support the patient's head against your body **Figure 8-16A**. While supporting the patient's weight, drag the patient from the seat. If the legs and feet clear the vehicle easily, you can rapidly drag the patient to a safe location by continuing this method **Figure 8-16B**. If the legs and feet do not clear the vehicle easily, you can slowly lower the patient until he or she is lying on his or her back next to the vehicle, clear the legs from the vehicle, and, as previously described, use a long-axis body drag to move the patient a safe distance from the vehicle.

You should use one-person techniques to move a patient only if an immediately life-threatening danger exists and you are alone or, because of the pressing nature of the danger, your partner is moving a second patient simultaneously. Additional one-provider drags, carries, and lifts are shown in **Figure 8-17**.

Figure 8-15 Dragging methods. **A.** Emergency clothes drag. **B.** Blanket drag. **C.** Arm drag. **D.** Arm-to-arm drag.

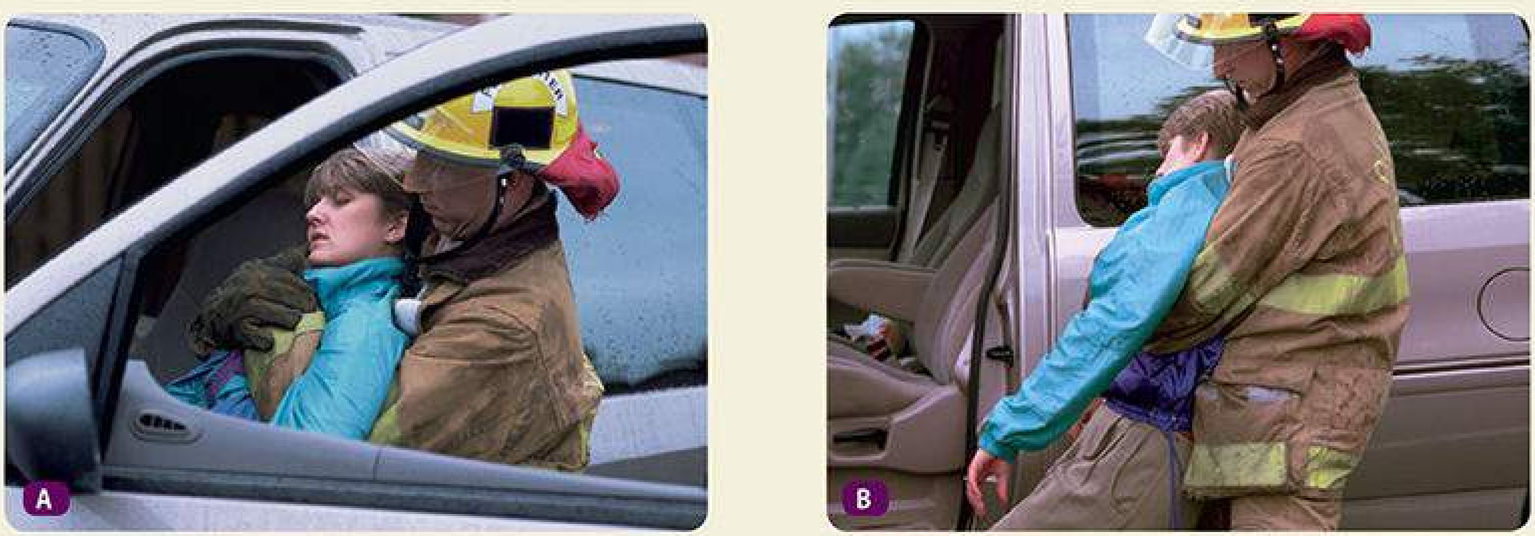

Figure 8-16 One-person technique for moving an unresponsive patient from a vehicle. **A.** Grasp the patient under the arms. **B.** Lower the patient down into a supine position.

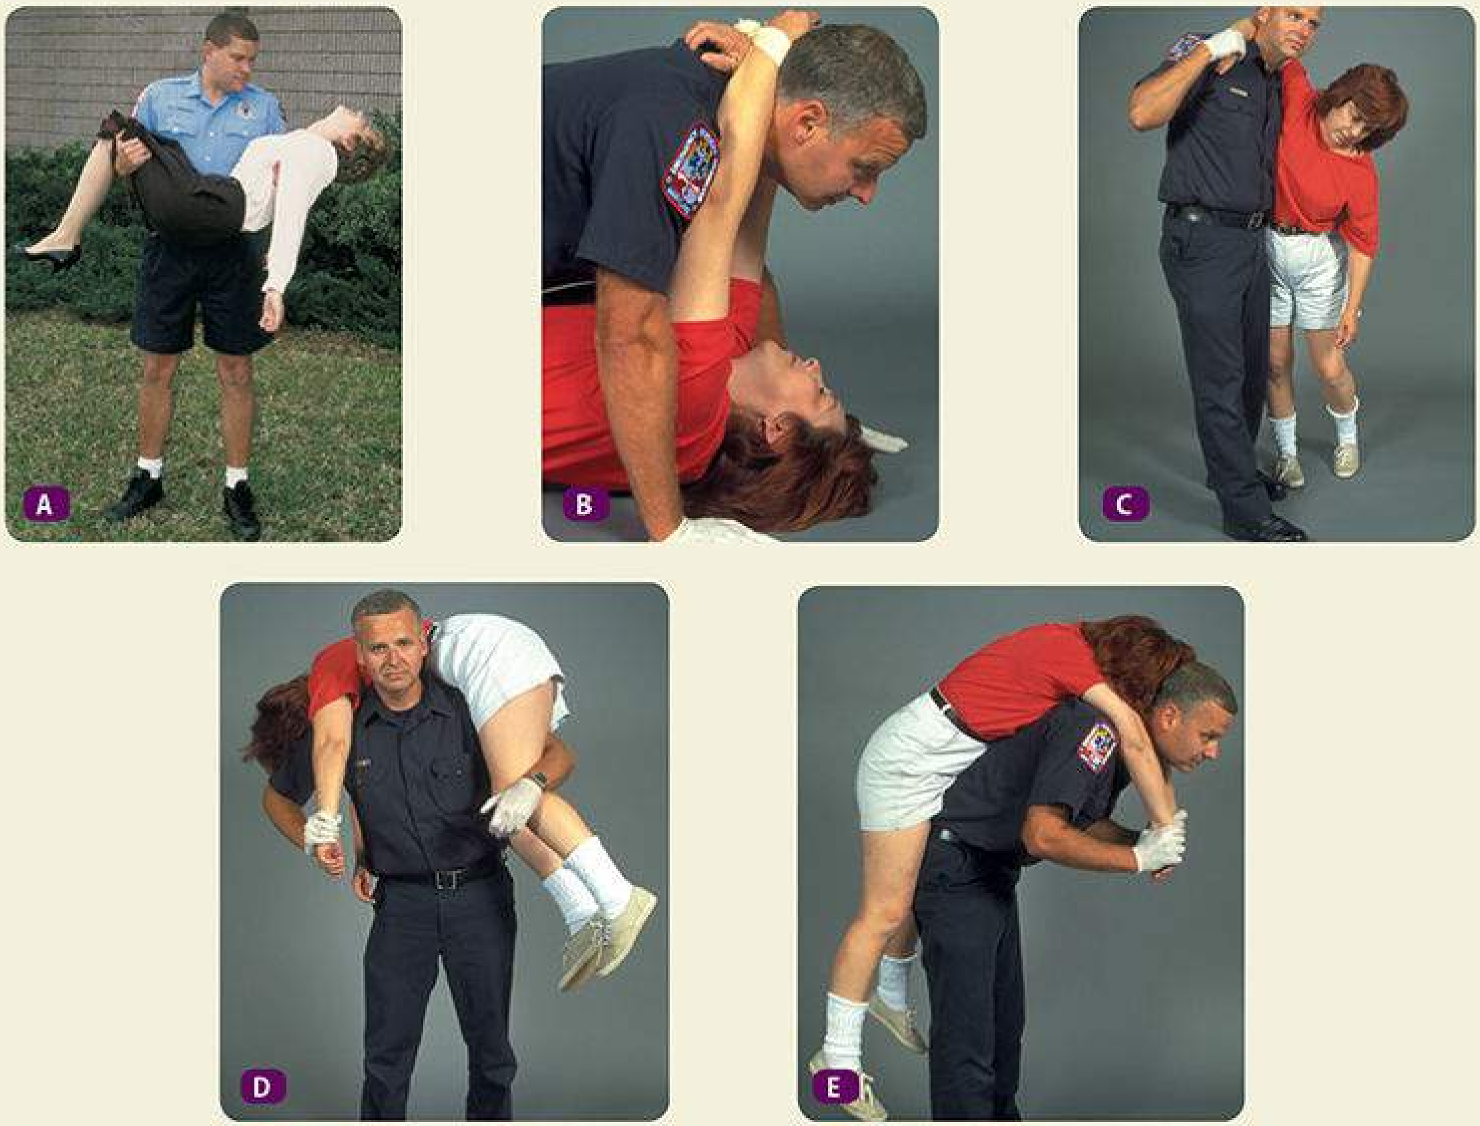

Figure 8-17 One-person drags, carries, and lifts. **A.** Front cradle. **B.** Firefighter's drag. **C.** One-person walking assist. **D.** Firefighter's carry. **E.** Pack-strap carry.

Urgent Moves

An urgent move may be necessary to move a patient with an altered level of consciousness, inadequate ventilation, or shock (hypoperfusion). An extreme weather condition may also make an urgent move necessary. In some cases, patients must be urgently moved from the location or position in which they are found. When a patient who is sitting in a vehicle must be urgently moved, use the rapid extrication technique.

Rapid Extrication Technique

The backboard, short backboard, and vest-type devices are known as spinal immobilization devices. Normally, you would use an extrication-type vest or short backboard device to immobilize a seated patient with a suspected spinal injury before removing the patient from the vehicle (see Chapter 38, *Vehicle Extrication and Special Rescue*). However, proper placement of either of these devices on the patient usually requires between 6 and 8 minutes, and in some cases even longer. By using the **rapid extrication technique** instead, the patient can be moved from sitting in the vehicle to supine, on a backboard if required, in 1 minute or less. However, the rapid nature of this type of extrication can potentially increase the risk of damage if the patient has a spinal injury. Because of this possible patient injury, all available options need to be considered prior to performing a rapid extrication. Table 8-3 describes the situations in which you should use the rapid extrication technique.

Table 8-3 Situations in Which to Use the Rapid Extrication Technique

- The vehicle or scene is unsafe.
- Explosives or other hazardous materials are on the scene.
- There is a fire or a danger of fire.
- The patient cannot be properly assessed before being removed from the vehicle.
- The patient needs immediate intervention that requires a supine position.
- The patient has a life-threatening condition that requires rapid transport to the hospital.
- The patient blocks your access to another seriously injured patient.

In such cases, the delay that occurs in applying immobilization devices is a contraindication. However, the manual support and stabilization that you provide when using the rapid extrication technique produce a greater risk of spine movement. Because of this increased risk, do not use the rapid extrication technique if no urgency exists.

The rapid extrication technique requires a team of three providers who are knowledgeable and practiced in the procedure. Take the following steps when using the rapid extrication technique Skill Drill 8-7. Whether a backboard is used for this skill will depend on your local protocols. Here, use of a backboard is included.

1. The first provider applies manual in-line support of the patient's head and cervical spine from behind. Support may be applied from the side, if necessary, by reaching through the driver's side doorway Step 1.
2. The second provider serves as team leader and, as such, gives the commands until the patient is supine on the backboard. Because the second provider lifts and turns the patient's torso, he or she must be physically capable of moving the patient. The second provider works from the driver's side doorway. If the first provider is also working from that doorway, the second provider should stand closer to the door hinges toward the front of the vehicle. The second provider applies a cervical collar and may perform the primary assessment Step 2.
3. The second provider provides continuous support of the patient's torso until the patient is supine on the backboard. Once the second provider takes control of the patient's torso, usually in the form of a body hug, he or she should not let go of the patient for any reason. Some type of cross-chest shoulder hug usually works well, but you will have to decide what method works best for you on any given patient. You must remember that you cannot simply reach into the vehicle and grab the patient; this will only twist the patient's torso. You must rotate the patient as a complete unit.
4. The third provider works from the front passenger's seat and is responsible for rotating the patient's legs and feet as the torso is turned, ensuring that they are free of the pedals and any other obstruction. With care, the third provider should first move the patient's nearer leg laterally without rotating the patient's pelvis and lower spine. The pelvis and lower spine rotate only as the third provider moves the patient's second leg during the next step. Moving the nearer leg

early makes it much easier to move the second leg in concert with the rest of the body. After the third provider moves the legs together, they should be moved as a unit Step 3.

5. These initial steps of the rapid extrication technique direct the team to its starting positions and responsibilities. The first provider applies in-line support and stabilization of the head and neck. The second provider gives orders and supports the torso. The third provider moves and supports the patient's legs. The team is now ready to move the patient.
6. The patient is rotated 90 degrees so that the patient's back is facing out the driver's door and the feet are on the front passenger's seat. This coordinated movement is done in three or four short, quick "eighth turns." The second provider directs each quick turn by saying, "Ready, turn," or "Ready, move." Hand position changes should be made between moves.
7. In most cases, the first provider will be working from the back seat and will have removed the headrest (if possible). At some point, either because the doorpost is in the way or because he or she cannot reach farther from the back seat, the first provider will be unable to follow the torso rotation. At that time, the third provider should assume temporary inline support of the head and neck until the first provider can regain control of the head from outside the vehicle. If a fourth provider is present, the fourth provider stands next to the second provider. The fourth provider takes control of the patient's head and neck from outside the vehicle without involving the third provider. As soon as the change has been made, the rotation can continue Step 4.
8. Once the patient has been fully rotated, the backboard should be placed against the patient's buttocks on the seat. Do not try to wedge the backboard under the patient. If only three providers are present, be sure to place the backboard within arm's reach of the driver's door before the move so that the backboard can be pulled into place when needed. In such cases, the far end of the backboard can be left on the ground. When a fourth provider is available, the first provider exits the back seat of the vehicle, places the backboard against the patient's buttocks, and maintains pressure toward the interior of the vehicle from the far end of the backboard. (Note: when the door opening allows, some providers prefer to insert the backboard onto the seat before the patient is rotated.)
9. As soon as the patient has been rotated and the backboard is in place, the second provider and the third provider lower the patient onto the backboard while supporting the head and torso so that neutral alignment is maintained. The first provider holds the backboard until the patient is secured Step 5.
10. Next, the third provider must move across the front seat to be in position at the patient's hips. If the third provider stays at the patient's knees or feet, he or she will be ineffective in helping to move the body's weight. The knees and feet follow the hips.
11. The fourth provider maintains manual in-line support of the head and now takes over giving the commands. The second provider maintains the direction of the extrication. The second provider stands with his or her back to the door, facing the rear of the vehicle. The backboard should be immediately in front of the third provider. The second provider grasps the patient's shoulders or armpits. Then, on command, the second provider and the third provider slide the patient 8 to 12 inches (20 to 30 cm) along the backboard, repeating this slide until the patient's hips are firmly on the backboard Step 6.
12. At that time, the third provider gets out of the vehicle and moves to the opposite side of the backboard, across from the second provider. The third provider now takes control at the shoulders, and the second provider moves back to take control of the hips. On command, these two providers move the patient along the backboard in 8-to-12-inch (20-to-30-cm) slides until the patient is placed fully on the backboard Step 7.
13. The first (or fourth) provider continues to maintain manual in-line support of the patient's head. The second provider and the third provider now grasp their side of the backboard and then carry it and the patient away from the vehicle onto the prepared stretcher nearby Step 8.

In some cases, you will be able to rest the head end of the backboard on the stretcher while the patient is moved onto the backboard. In other situations, you will not be able to do this. Once the backboard and patient have been placed on the stretcher, begin lifesaving treatment immediately. If you used the rapid extrication technique because the scene was dangerous, you and your team should immediately move the stretcher a safe distance away from the scene before you assess or treat the patient.

The steps of the rapid extrication technique must be considered a general procedure to be adapted as needed. Two-door vehicles differ from four-door models. Larger vehicles differ from smaller compact models, pickup trucks, full-size sedans, and four-wheel-drive vehicles. You will handle a large, heavy adult differently from a small adult or child. Every situation will be different—a different vehicle, a different patient, and different partners. Your resourcefulness and ability to adapt are necessary elements to successfully perform the rapid extrication technique.

Skill Drill 8-7 Performing the Rapid Extrication Technique

Step 1

The first provider provides in-line manual support of the head and cervical spine.

Step 2

The second provider gives commands, applies a cervical collar, and performs the primary assessment.

Step 3

The second provider supports the torso. The third provider frees the patient's legs from the pedals and moves the legs together, without moving the pelvis or spine.

Step 4

The second provider and the third provider rotate the patient as a unit in several short, coordinated moves. The first provider (relieved by the fourth provider as needed) supports the patient's head and neck during rotation (and later steps).

Step 5

The first (or fourth) provider places the backboard on the seat against the patient's buttocks. (Use of a backboard may depend on local protocols.)

Step 6

The third provider moves to an effective position for sliding the patient. The second and the third providers slide the patient along the backboard in coordinated 8-to-12-inch (20-to-30-cm) moves until the patient's hips rest on the backboard.

Step 7

The third provider exits the vehicle, moves to the backboard opposite the second provider, and they continue to slide the patient until the patient is fully on the backboard.

Step 8

The first (or fourth) provider continues to stabilize the head and neck while the second provider and the third provider carry the patient away from the vehicle and onto the prepared stretcher.

Nonurgent Moves

When both the scene and the patient are stable, carefully plan how to move the patient. If your patient move is rushed or poorly planned, it may result in discomfort or injury to the patient, you, and/or your team. Before you attempt any move, the team leader must be sure that there are enough providers, any obstacles have been identified or removed, the proper equipment is available, and the procedure and path to be followed have been clearly identified and discussed. Remember, communication is the key to success.

In nonurgent situations, you and your team may choose one of several methods for lifting and carrying a patient and should coordinate your movements through direct verbal commands. Three general methods are presented here, which may serve as a basis for your plan. You may adapt these procedures to meet your needs on a case-by-case basis.

Direct Ground Lift

The **direct ground lift** is used for patients with no suspected spinal injury who are found lying supine on the ground. Use this lift when you have to lift and carry the patient some distance to be placed on the stretcher. If you find the patient semiprone or lying on his or her side, first log roll the patient onto his or her back. Ideally, the direct ground lift should be performed by three providers; however, it can be done with only two. Perform the direct ground lift as follows **Skill Drill 8-8**:

1. Take your places on one side of the patient with the first provider at the patient's head, the second provider at the patient's waist, and the third provider at the patient's knees. All providers kneel on one knee, preferably the same knee.
2. The patient's arms should be placed on his or her chest if possible **Step 1**.

YOU are the Provider — PART 4

There is no easy way to remove Patient 1, but by bracing yourself through the seats you are able to grab his belt and pull him toward you. Once you get the patient's head and shoulders between the headrests, the firefighter helps pull him onto the backboard. As soon as he is secured on the backboard, several other providers help the firefighter pull the backboard out of the vehicle and transfer Patient 1 to the waiting paramedic unit for evaluation, treatment, and transport. You now have access to Patient 2, who is sitting waist-deep in water and still reporting pain in her back and right side. She tells you that she has a history of back pain and thinks she can move a little with help.

Patient 2

Recording Time: 20 Minutes	
Level of consciousness	Alert and oriented
Respirations	20 breaths/min; adequate depth
Pulse	112 beats/min; strong and regular
Skin	Pink, cool, and moist
Blood pressure	148/92 mm Hg
Spo_2	99% (on room air)

9. How is a patient's weight distributed when he or she is on a carrying device? Why is it important to know this?
10. Considering her complaints and the fact that her condition is stable, what are your best options for removing Patient 2?

3. The first provider places one arm under the patient's neck and shoulders and cradles the patient's head. The first provider then places the other arm under the patient's low back.
4. The second provider places one hand under the patient's waist, and the other under the knees.
5. The third provider places one arm under the patient's knees and the other under the ankles.
6. On command, the team lifts the patient up to knee level as each provider rests an arm on his or her knee **Step 2**.
7. As a team and on command, each provider rolls the patient in toward his or her chest. Again on command, the team stands and carries the patient to the stretcher **Step 3**.

Note: The steps are reversed to lower the patient onto the stretcher.

Skill Drill 8-8 The Direct Ground Lift

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 1

Line up on one side of the patient, with one provider at the head, one at the waist, and one at the patient's knees. All providers should be kneeling. Place the patient's arms on his or her chest, if possible.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 2

On command, lift the patient to knee level.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 3

On command, roll the patient toward your chest, and then stand and carry the patient to the stretcher.

Extremity Lift

The extremity lift may also be used for patients with no suspected extremity or spinal injuries who are supine or in a sitting position. The extremity lift may be especially helpful when the patient is in a very narrow space or there is not enough room for the patient and several EMTs to stand side by side. Perform the extremity lift as follows Skill Drill 8-9:

1. Kneel behind the patient's head as your partner kneels at the patient's feet. You and your partner should be facing each other.
2. The patient's hands should be crossed over his or her chest.
3. Place one hand under each of the patient's armpits. Grasp the patient's wrists or forearms and pull the upper torso until

the patient is in a sitting position Step 1.

4. Your partner moves to a position between the patient's legs, facing in the same direction as the patient, and slips his or her hands under the patient's knees Step 2.

5. As you give the command, stand fully upright and move the patient to the stretcher Step 3.

Skill Drill 8-9 Extremity Lift

Step 1

The patient's hands are crossed over the chest. Grasp the patient's wrists or forearms and pull the patient to a sitting position.

Step 2

Your partner moves to a position between the patient's legs, facing in the same direction as the patient, and places his or her hands under the knees.

Step 3

Rise to a crouching position. On command, lift and begin to move.

You will be less likely to injure yourself if you bend at the hips and knees and use your legs for lifting. However, this lift and carry method increases pressure on the patient's chest, so the patient may be uncomfortable in this position.

Transfer Moves

There are several ways to transfer the patient from a bed onto the stretcher.

Direct Carry

Transfer a supine patient from a bed to the stretcher using the direct carry method Skill Drill 8-10.

1. Position the stretcher parallel to the bed, facing the same direction as the bed. Prepare the stretcher by unbuckling the straps and removing any other items from it. Secure the stretcher to prevent movement.
2. Position yourself at the head of the bed facing towards the patient. Your partner should be positioned between the bed and the stretcher facing both you and the patient.
3. Slide your arms under the patient's neck and shoulders. Your partner should slide his or her hands under the patient's knees and lock them together or use them to grasp the posterior part of the patient's thighs Step 1.
4. Lift the patient upwards slowly and smoothly. Your partner should move the patient's knees from the left side of his body to the right to facilitate placing the patient onto the stretcher Step 2.
5. Slowly carry the patient from the bed to the stretcher Step 3.
6. Gently lower the patient to the stretcher and secure with straps Step 4.

This carry can also be performed with three providers. If a third provider is available, he or she can be positioned to support the patient's feet and legs from the bottom of the bed.

Draw Sheet Method

To move the patient from a bed onto a stretcher, use the draw sheet method. Place the stretcher next to the bed, making sure it is at the same height or slightly lower than the bed and that the rails are lowered and straps are unbuckled. Be sure to hold or secure the stretcher to keep it from moving. Loosen the bottom sheet underneath the patient, or log roll the patient onto a blanket Figure 8-18A. Reach across the stretcher, and grasp the sheet or blanket firmly at the patient's head, chest, hips, and knees Figure 8-18B. Gently slide the patient onto the stretcher Figure 8-18C.

Skill Drill 8-10 Direct Carry

Step 1

Position the stretcher parallel to the bed. Secure the stretcher to prevent movement. Face the patient while standing between the bed and the stretcher. Position your arms under the patient's neck and shoulders. Your partner should position his hands under the patient's knees.

Step 2

Lift the patient from the bed in a smooth, coordinated fashion.

Step 3

Slowly carry the patient to the stretcher.

Step 4

Gently lower the patient onto the stretcher and secure with straps.

When lifting a patient by a sheet or blanket, center the patient on the sheet and tightly roll up the excess fabric on each side. This produces a cylindrical handle that provides a strong, secure way to grasp the fabric **Figure 8-19**. Though not routinely carried on an ambulance, you may also have access to sliding boards or other devices in the hospital or nursing homes that will assist you in sliding the patient from bed to stretcher or stretcher to bed with minimal effort.

Using a Scoop Stretcher

Another option when moving a patient is to use a scoop stretcher. With a scoop stretcher, the two halves of the device are inserted under each side of the patient, and the two sides are fastened together. Then the patient is lifted and carried to the nearby prepared stretcher. (Note that you can also log roll a patient onto a scoop stretcher that is already locked together.) To use a scoop stretcher, follow the steps in **Skill Drill 8-11**.

1. With the scoop stretcher separated, measure the length of the scoop and adjust to the proper length Step 1.
2. Position the stretcher, one side at a time. Lift the patient's side slightly by pulling on the far hip and upper arm, while your parnter slides the stretcher into place Step 2.
3. Lock the stretcher ends together by engaging their locking mechanisms one at a time and continue to lift the patient slightly as needed to avoid pinching Step 3.
4. Apply and tighten straps to secure the patient to the scoop stretcher before transferring to the stretcher Step 4.

Other Carries

Other carries are performed in the following manner:

- Place a backboard next to the patient, and, after using a log roll or slide to move the patient onto the backboard, secure the patient and lift and carry the backboard to the nearby prepared stretcher.
- Assist an able patient to the edge of the bed, and place the patient's legs over the side, helping the patient to sit up. Move the stretcher so that its foot end touches the bed near the patient. Help the patient to stand and rotate so that he or she can sit down on the center of the stretcher. Lift the patient's legs, and rotate them onto the stretcher while your partner lowers the patient's torso onto the stretcher.

To avoid the strain of unnecessary lifting and carrying, use the draw sheet method or assist an able patient to the stretcher whenever possible.

To move a patient from the ground or the floor onto the stretcher, use one of the following methods:

Figure 8-18 The draw sheet method. **A.** Log roll the patient onto a sheet or blanket. **B.** Place the stretcher parallel to the bed. Secure the stretcher. Gently pull the patient to the edge of the bed. **C.** Transfer the patient to the stretcher.

A, B, C: © Jones & Bartlett Learning. Courtesy of MIEMSS.

Figure 8-19 When lifting a patient by a bed sheet, center the patient on the sheet and tightly roll up the excess fabric on each side. This produces a cylindrical handle that provides a strong way to grasp the fabric.

- Lift and carry the patient to the nearby prepared stretcher using a direct body carry.
- Use a log roll or long-axis drag to place the patient onto a backboard, and then lift and carry the backboard to the stretcher. Place both the backboard and the patient onto the stretcher.
- Use a scoop stretcher.
- Log roll the patient onto a blanket, centering the patient on the blanket and rolling up the excess material on each side **Figure 8-20A**. Lift the patient by the blanket, and carry him or her to the nearby stretcher **Figure 8-20B**.

If a patient is sitting in a chair and cannot assist you, transfer the patient from the chair to a stair chair as described earlier in this chapter **Figure 8-21A** and **Figure 8-21B**.

Words of Wisdom

Ensure a thorough patient care report by including details of how you moved the patient. For example: "Moved patient to stretcher with draw sheet lift."

Geriatrics

Most patients transported by EMS are geriatric patients. For many older patients, the fear of illness and disability is ever present, and an emergency trip to the hospital can be a terrifying and disorienting experience. The possibility of never returning home is a real fear for many of these patients. In addition, there are physiologic changes that occur with aging that require special attention on your part as an EMT.

Skill Drill 8-11 Using a Scoop Stretcher

Step 1

Adjust the length of the stretcher.

Step 2

Lift the patient slightly and slide the stretcher into place, one side at a time.

Step 3

Lock the stretcher ends together, and avoid pinching both the patient and your fingers!.

Step 4

Secure the patient to the scoop stretcher, and transfer it to the stretcher.

1. **Skeletal changes:** Brittle bones (osteoporosis), rigidity, and spinal curvatures (kyphosis and spondylosis) Figure 8-22 present special challenges in packaging and moving older patients. Many patients cannot lie supine on a backboard or scoop stretcher without causing additional injury, such as fractures, pressure sores, and skin breakdown. Special care and creativity must be used in immobilizing such patients. For example, a patient with spinal curvature may have to be placed on his or her side and immobilized in place with towel and blanket rolls to prevent exacerbating his or her injuries. Be sure to consult your local protocols and medical director about geriatric-specific devices, such as a vacuum mattress (discussed later in this chapter), and alternative ways of immobilizing such patients.

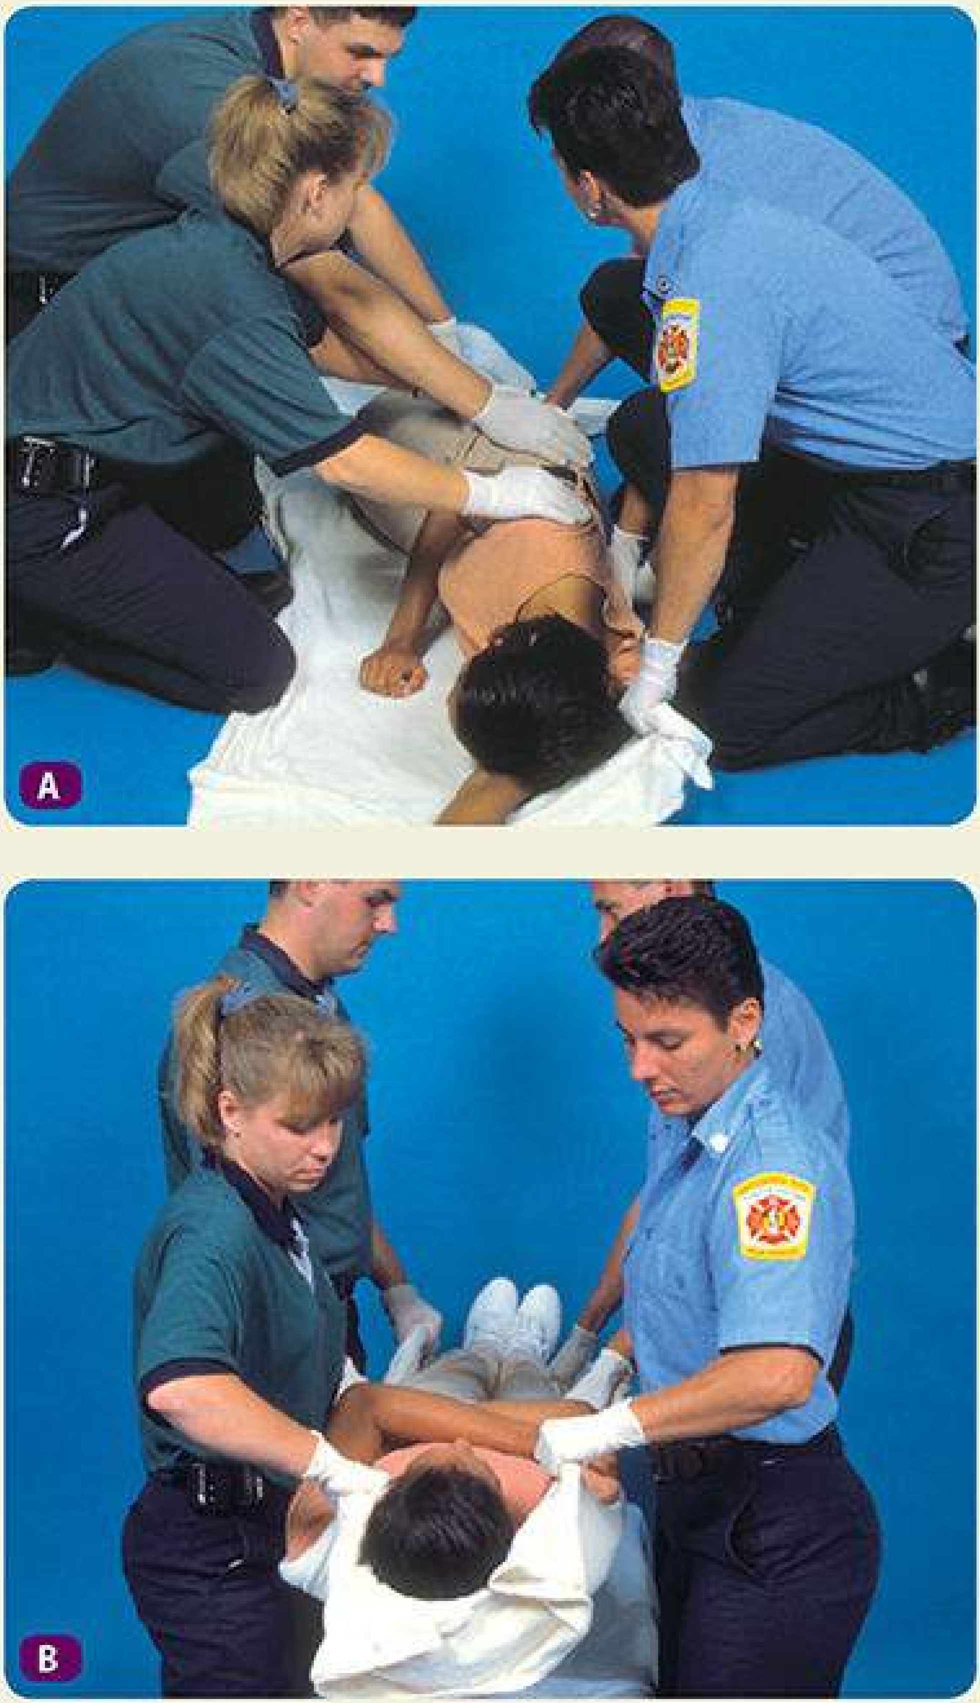

Figure 8-20 Log rolling a patient on the ground. **A.** Log roll the patient onto a blanket. **B.** Lift the blanket, and transfer the patient to the stretcher.

A, B: © Jones & Bartlett Learning. Courtesy of MIEMSS.

2. **Fear:** A sympathetic and compassionate approach can go a long way in lessening the natural fear many older patients experience when interacting with EMS. Slow down, explain, and anticipate: these actions can help you gain an older patient's cooperation and take some of the anxiety out of the process of packaging and transportation. Imagine how frightening it can be for a patient who lives in constant fear of falls and broken bones to be strapped to a stretcher and carried down a flight of stairs.

Figure 8-21 Moving a patient from a chair to a stair chair. **A.** If present, any removable side pieces on the chair should be removed or placed in a position so as to not interfere. Slide your arms through the patient's armpits, and grasp the patient's crossed forearms. Your partner grasps the patient's legs at the knees. **B.** Gently lift the patient into the locked stair chair.

Special Populations

Cover the older patient with a blanket to protect privacy and keep the patient warm. Cut clothes only when absolutely necessary. Many older patients live on a fixed income and cannot afford to replace damaged clothing.

Bariatrics

Over one-third of the adults in the United States (78.6 million people) are considered obese. The incidence of obesity is higher among adults aged 40 to 59 years (nearly 40%) than among adults aged 20 to 39 (30%) or older adults aged 61 years or older (35%). The numbers among children are also alarming; approximately 17% of all children and adolescents in the United States are classified in the obese category. The obesity rate has tripled compared to just one generation ago. In 2008, the estimated annual cost of medical care for obese patients in the United States was $147 billion, or approximately $1,429 higher per obese person than a person of normal weight. Obesity has reached epidemic proportions in the United States, and many programs are now aimed at teaching people from a young age the importance of exercise and a healthy diet.

Figure 8-22 Skeletal changes. **A.** Kyphosis. **B.** Spondylosis.

Obesity has become such a significant issue that a new field of medicine has emerged to provide specialty care for obese patients. **Bariatrics** is the branch of medicine concerned with the management (prevention or control) of obesity and allied diseases. It comes from the Greek words *baros*, weight, and *iatreia*, medical treatment. There is a direct correlation between the degree of obesity and the frequency and severity of health problems; therefore, the larger the patient, the more likely he or she is to need emergency treatment and transportation. This issue is taking an increasing toll on the health of EMTs because back injuries account for the largest number of missed days of work and both temporary and permanent disability.

Although manufacturers are producing equipment with ever higher capacities, this does not address the danger to the users of that equipment. European ambulance manufacturers regularly install mechanical lifts on their units; however, these features are not as common in the United States.

Additional Patient-Moving Equipment

Bariatric Stretchers

Because of the large girth of bariatric patients, they may not fit comfortably on the standard wheeled stretcher. As a result, a specialized type of wheeled stretcher has been developed, called the bariatric stretcher **Figure 8-23**. This type of stretcher is similar in design to the common wheeled stretcher; however, it has several differences. Bariatric stretchers typically have a wider patient surface area to allow for increased comfort, as well as increased dignity when transporting the patients. Bariatric stretchers also have a wider wheelbase, allowing for increased stability when rolling the patient over uneven terrain. Bariatric stretchers are sometimes equipped with optional features such as a tow package, which allows an ambulance-mounted winch to assist in loading the patient into the ambulance, decreasing the potential for EMT back injuries. Another optional feature is telescoping side lift handles, which allow for increased leverage when lifting with multiple providers. However, the most important feature of the bariatric stretcher is the increased weight-lifting capacity. Typical wheeled ambulance stretchers, depending on manufacturer ratings, are rated to a maximum weight of 650 lb (295 kg). Bariatric stretchers are usually rated between 850 and 900 lb (386 to 408 kg).

Figure 8-23 A bariatric stretcher.

Pneumatic and Electronic Powered Wheeled Stretchers

In an effort to decrease the potential for back injuries to EMS providers, manufacturers have developed pneumatic and electronic stretchers. Similar in appearance to conventional wheeled stretchers, electronic stretchers are battery operated and have electronic controls to facilitate raising and lowering of the undercarriage at the touch of a button **Figure 8-24**. A drawback to the powered wheeled stretcher is that by adding the electronic controls, as well as the associated equipment, the weight of the stretcher is increased, typically by 75 to 100 lb (34 to 45 kg). Coupled with the weight of the patient on the loaded stretcher, this creates a potential hazard when transporting the patient over uneven terrain or up and down steps.

YOU are the Provider PART 5

A cervical collar is applied and Patient 2 is secured to a Kendrick Extrication Device (KED). You are then able to remove her from the wreckage and onto a backboard. After loading her into the ambulance, you perform a complete assessment and transport her to the local trauma center for evaluation.

Recording Time: 27 Minutes	
Level of consciousness	Alert and oriented
Respirations	16 breaths/min; adequate depth
Pulse	110 beats/min; strong and regular
Skin	Pink, warm, and moist
Blood pressure	148/72 mm Hg
Spo_2	100% (on room air)

On arrival at the hospital, the patient tells you that she is still in pain, although it is not as severe and feels like “a pulled muscle.” After moving her from the wheeled stretcher to the hospital bed, you give your verbal report to the staff nurse and return to service.

11. How can you minimize the risk of injury while moving a patient on a wheeled ambulance stretcher?

Portable/Folding Stretchers

A **portable stretcher** is a stretcher with a strong, rectangular, tubular metal frame and rigid fabric stretched across it **Figure 8-25**. Portable stretchers do not have a second multipositioning frame or adjustable undercarriage. Some models have two wheels that fold down about 4 inches (10 cm) underneath the foot end of the frame and legs of a similar length that fold down from the head end at each side. The wheels make it easier to move the loaded stretcher. The legs should not be used as handles.

Some portable stretchers can be folded in half across the center of each side so that the stretcher is only half its usual length during storage. Many ambulances carry a portable stretcher to use if a patient is in an area that is difficult to reach with a wheeled ambulance stretcher or if a second patient must be transported on the squad bench of the ambulance.

Figure 8-24 An electronic stretcher.

Courtesy of Stryker Medical, a division of Stryker Corporation.

Figure 8-25 A portable stretcher.

© Steve Gorton/Getty.

A portable stretcher weighs much less than a wheeled stretcher and does not have a bulky undercarriage. However, because most models do not have wheels, you and your team must support all of the patient's weight and any equipment along with the weight of the stretcher.

Flexible Stretchers

Several types of flexible stretchers are available and can be rolled up across either the stretcher's width or length, so that the stretcher becomes a smaller, tubular package for storage and carrying **Figure 8-26**. When you must carry the equipment a considerable distance from the nearest place that the ambulance can be located, this is an important consideration. A **flexible**

stretcher forms a rigid stretcher that conforms around the patient's sides and does not extend beyond them. When these stretchers are extended, they are particularly useful when you must remove a patient from or through a confined space. Certain flexible stretchers can also be used if the patient must be belayed or rappelled by ropes.

Figure 8-26 A flexible stretcher.

The flexible stretcher is the most uncomfortable of all the various devices, but it provides excellent support and immobilization. When the stretcher is wrapped around the patient and the straps are secured, the patient is completely secured. The stretcher can then be lowered by rope or slid down a flight of stairs by resting it on the front edge of each step.

▶ Short Backboards

You can use a short backboard to immobilize the torso, head, and neck of a seated patient with a suspected spinal injury until you can immobilize the patient on a backboard. Short backboards are 3 to 4 feet long (approximately 1 m). However, the wooden short backboard has generally been replaced with a vest-type device, such as the Kendrick Extrication Device (KED), that is specifically designed to immobilize the patient until he or she is moved from a sitting position to a supine position on a backboard Figure 8-27. The vest-type devices are easier to use than the wooden short backboard.

Vacuum Mattresses

Another alternative to the backboard, especially for immobilizing geriatric and pediatric patients, is the vacuum mattress. With this device, the patient is placed on the mattress and the air is removed from the device, allowing it to mold around the patient. It fits snugly to the curvatures and contours of the body and limits pressure point tenderness. As the mattress molds to the body, it provides a high degree of immobilization and comfort. It also provides thermal insulation, thereby reducing the risk of hypothermia. Padding may be used for tender areas, but is not required for most patients.

Figure 8-27 The Kendrick Extrication Device (KED) is a vest-type immobilization device.

It is imperative to maintain spinal immobilization while placing the patient on the device and to secure the patient properly once he or she is placed on the mattress. The vacuum mattress cannot be used on patients weighing 350 lb (159 kg) or more. See Chapter 28, *Head and Spine Injuries*, for more information about the vacuum mattress.

Basket Stretchers

Use a rigid **basket stretcher**, also called a Stokes litter, to carry a patient across uneven terrain from a remote location that is inaccessible by ambulance or other vehicle Figure 8-28. If you suspect that the patient has a spinal injury, first secure him or her on a backboard and then place the backboard into the basket stretcher. Once you have reached the ambulance and wheeled ambulance stretcher, you can remove the patient secured to the backboard from the basket stretcher and place the patient on the stretcher.

Basket stretchers are made of plastic with an aluminum frame or have a full steel frame that is connected by a woven wire mesh. The wire basket is very uncomfortable for the patient unless the wire is padded. Either type can be used to carry a patient across fields, rough terrain, or trails or on a toboggan, boat, or all-terrain vehicle. Basket stretchers surround and support the patient, yet their design allows water to drain through holes in the bottom. Basket stretchers are also used for technical rope rescues and some water rescues. Not all basket stretchers are rated or appropriate for each of these specialized rescue uses. The types of basket stretchers that are acceptable for specialized rescue must be determined by providers with additional special training.

Figure 8-28 A basket stretcher.

Scoop Stretchers

The **scoop stretcher**, or orthopaedic stretcher, is designed to be split into two or four pieces **Figure 8-29**. These sections are fitted around a patient who is lying on the ground or another relatively flat surface. The parts are reconnected, and the patient is lifted and placed on a backboard or stretcher. A scoop stretcher may be used for patients who have been struck by a motor vehicle.

A scoop stretcher is efficient; however, both sides of the patient must be accessible. You must also pay special attention to the closure area beneath the patient so that clothing, skin, and other objects are not trapped or pinched. As with the backboard, you must fully immobilize and secure the patient before moving him or her; however, you cannot slip a scoop stretcher under the long axis of the patient's body. Scoop stretchers are narrow, well constructed, and compact and have excellent body support features but are not adequate when used alone for standard immobilization of a spinal injury. You and your team should practice often with a scoop stretcher to be ready for using it with a patient. It is important to remember that some scoop stretchers have internal supports running throughout their length; this feature prohibits hospitals from being able to obtain a radiograph while the patient is secured to it, often mandating another move to a standard backboard prior to obtaining the radiograph.

Figure 8-29 A scoop stretcher.

Neonatal Isolettes

When you need to transport a neonatal patient from one hospital to another, the common wheeled ambulance stretcher will not suffice. To safely transport a neonatal patient, the patient must be placed inside of an isolette, sometimes referred to as an incubator. The isolette keeps the neonatal patient warm with moistened air in a clean environment and helps to protect the infant from noise, drafts, infection, and excess handling. The specialized transport devices come in one of two forms: the isolette is placed directly on top of the wheeled stretcher and secured with seat belts, or a free-standing type of isolette is secured into the back of the ambulance, taking the place of the standard stretcher Figure 8-30.

Decontamination

It is essential that you decontaminate your equipment after use, for your own safety, the safety of the EMTs using the equipment after you, and the safety of your patients, to prevent the spread of disease. Just as you expect a hospital bed to be disinfected after the last patient, so too with your stretcher and other transport equipment. Know and follow your local standard operating procedures for disinfecting equipment after each call.

Figure 8-30 Neonatal isolette.

Patient Positioning

It is imperative while treating a patient that he or she be properly positioned based on the chief complaint. Certain patient conditions, such as head injury, shock, spinal injury, pregnancy, and obese patients, call for special lifting and moving techniques. While a patient with a potential spinal injury should be fully immobilized, a patient with no suspected injury reporting chest pain or respiratory distress should be placed in a position of comfort—typically a Fowler or semi-Fowler position—unless he or she is hypotensive. Patients who are in shock should be packaged and placed in a supine position. Patients in late stages of pregnancy should be positioned and transported on their left side if they are uncomfortable or hypotensive when supine. Place an unresponsive patient with no suspected spinal, hip, or pelvic injury into the recovery position by rolling the patient onto his or her side without twisting the body. Transport a patient who is nauseated or vomiting in a position of comfort, but ensure that you are positioned appropriately to manage and maintain a patent airway. Obese patients should be positioned the same as other patients with a similar condition; however, particular attention must be paid to ensure their dignity is maintained.

Medical Restraints

While not a common occurrence, there may be a time when you are called on to physically restrain a patient; for example, during a behavioral emergency. After evaluating the patient for correctible causes of combativeness, such as head injury, hypoxia, or hypoglycemia, you must decide whether to restrain your patient. There may be legal consequences for either applying the restraints (such as charges of assault and battery) or failing to restrain a patient who should have been restrained (such as a lawsuit). Contact law enforcement and consult local protocols prior to applying restraints; in some jurisdictions, medical control authorization is needed before an EMT can apply restraints. Chapter 22, *Psychiatric Emergencies*, discusses combative patients in more detail.

The decision to restrain a patient is not one to be taken lightly; however, if the patient poses a danger to you, your team members, himself or herself, or bystanders, the application of physical restraints needs to be considered. However, before you take action to restrain the patient, attempt to speak to the patient in a calming manner, while remaining firm in your requests. If de-escalation does not work and the patient continues to be combative, a plan needs to be developed and agreed upon by all personnel present as to who will do what, when it will happen, and how you will accomplish the restraint.

There should be a minimum of five personnel to assist in the restraint of a combative patient, one for each extremity and one for the head. One EMT should be established as the team leader, the one who will give commands. Be direct. State your intentions, what you expect of the patient, what you are doing, and maintain good eye contact.

When preparing to secure the patient on the stretcher, it is of the utmost importance to place the patient in the supine position. If the patient is placed in a prone position, positional asphyxia could develop. In prone positioning, the increased weight on the patient's lungs and his or her inability to fully expand the thoracic cavity could render the patient unable to breathe, creating a preventable, life-threatening emergency.

If a patient for whom use of medical restraints is indicated is in the supine position, some type of humane restraint should be applied to each extremity, such as triangle bandages, roller gauze, commercially available disposable restraints, or leather restraints. Preferably the patient should be restrained onto a backboard, which allows for easy movement should the patient begin to vomit. However, if it is impractical or inadvisable to secure the patient to the backboard, then secure the patient to the stretcher. Regardless of whether the patient is secured to a backboard or the stretcher, one arm should be secured above the patient's head and one arm should be secured at the patient's side. This technique will not give the patient the leverage to break free from the restraints. After the upper extremities are secured, each leg should be secured as well. Ensure that you will be able to quickly remove the restraints during transport if necessary. Patients should not be transported in handcuffs unless a police officer rides in the ambulance with you during transport.

After application of the restraints, it is imperative to assess the patient's ABCs, mental status, and distal circulation (pulse and motor and sensory function) frequently **Figure 8-31**. Document your findings on the patient care report. Include what types of restraints were used and why in the report, which is essential if the case is reviewed for medicolegal reasons.

Figure 8-31 After application of the restraints, it is imperative to assess the patient's distal circulation frequently.

Personnel Considerations

As an EMT, you will be required to assist in the movement of patients. In an effort to minimize injuries, prior to moving any patient, a complete plan needs to be developed and discussed among your team. Some questions to ask are the following:

Words of Wisdom

Restraints should never be punitive. Only apply restraints to patients who pose a threat to you, your team members, themselves, or bystanders, and follow local protocols for the use of restraints. If a restrained patient starts to spit, cover the patient's mouth with a simple face mask or surgical mask. Once restraints have been applied, never remove them until you arrive at the hospital and are requested to remove them by the hospital staff.

- Am I physically strong enough to lift and move this patient?
- Is there adequate room to get the proper stance to lift the patient?
- Do I need additional providers for lifting assistance?

The answers to these questions need to be evaluated prior to moving your patient. Remember that injured EMTs cannot help anyone.

YOU are the Provider SUMMARY

1. What immediate challenges do you face?

Your first concern is for the stability of the vehicle. Prior to attempting to physically access the patients, safety measures must be taken to stabilize the vehicle and prevent further rollover or collapse during the extrication process.

The next consideration is for the size of the patient. How much does the patient weigh? Does he or she weigh more than you and your partner can safely lift? There is also the consideration of working in an enclosed space that may not allow for additional providers to help.

Additionally, there are two patients and at least one is in critical condition. This further increases the stress on you and may lead to injury if the lift is not adequately planned. While your intention to help the patient is admirable, you must remember that you will be useless to the team and the patient if you are injured in the process.

2. Why is knowledge of body mechanics important when lifting and moving a patient?

Body mechanics describes the way you move your body. Posture is an important component in body mechanics. Good posture means the spine is in a neutral position. Knowing how your body moves will minimize the risk of a back injury when you are lifting or moving a patient. Always keep your back in a straight and upright position, and lift without twisting.

3. What other resources are needed?

You already know that Patient 1 is unresponsive and showing signs of dyspnea with cyanosis. You also know that both patients are entrapped in the overturned vehicle, and extrication will be required. Therefore, immediately call for paramedic backup and a rescue unit, as well as lifting assistance. There will be a delay in care as the patients are extricated. Having advanced units standing by will decrease the time to definitive care. If you are a long distance from a Level I trauma center, consider the use of air transport, if available.

Law enforcement should be dispatched for crowd control and to help with directing traffic around the scene to make it safe for everyone to work. Each agency has its own job to do, and the sooner each agency is dispatched, the quicker the patient will receive optimal care.

4. Do you consider Patient 1 to be in stable or unstable condition? Should you wait for further assistance or go ahead and gain access to him?

The condition of Patient 1 is unstable due to his altered level of consciousness and cyanosis. However, never enter a scene that is not safe. With the vehicle lying on its side in such a precarious position, any weight added could cause it to roll over and crush you or cause further injury to the patients. The vehicle must be stabilized prior to gaining access to the patients. Safety of the crew is paramount before any patient care is provided.

If Patient 2 is able to lift her arms and the tubing is long enough, it may be possible to toss a nonrebreathing mask into the vehicle and have Patient 2 place the mask over the face of Patient 1 to provide him with oxygen before further treatment begins. Any further care will have to be postponed until the vehicle has been stabilized.

5. Once you are able to gain access, what are your concerns for the use of proper body mechanics while removing these patients?

The overturned vehicle is a confined space that only allows for access by one EMT. This means that you must consider your lifting limits and think through what type of equipment may be utilized to place the least amount of physical stress on you. The patients may have to be moved in carefully planned stages. Try to use your legs to do the majority of the lifting, and try to keep your back as straight as possible with the limitations imposed.

6. Once Patient 1 is no longer entrapped, how will you attempt to remove him from the vehicle while maintaining cervical spine support?

Due to the mechanism of injury, cervical spine control for both patients is warranted. Patient 1 must be removed first. After gaining access, you will have to assess the situation and available space to see if a backboard can be introduced through the back door of the vehicle. If not, is there any other device that you may slide underneath the patient to assist with moving him? You can place an appropriately sized cervical collar on the patient, but remember that this does not provide stabilization unless someone is actually holding the head and neck in alignment. This is far from an ideal lifting situation, so you must proceed cautiously and try to manipulate his spine as little as possible. This is a situation where an urgent move is required and time is of the essence. Be as careful as possible while removing the patient.

7. What type of move is best for removing Patient 1?

Due to the unstable condition of the patient, it is necessary to move him as quickly and safely as possible. Unfortunately, with such a confined space there is no way to utilize additional help to maintain spinal alignment. If the rescue team is able to wedge a backboard through the open door of the vehicle, it will give you a platform to stand or kneel on, as well as something on which to move the patient. The best option for moving Patient 1 is to use a clothes drag (remember never to pull on pockets or belt loops, as they may break loose, causing the patient to fall down) or to grab underneath his arms and pull him upward if you are able to reach that far. If Patient 2 is able to use her arms, she may be able to help push upward from his hips to assist you in moving him. He will have to be pulled between the headrests because there is no other access. Make sure he is moved in small increments, using your arms to "curl" and repositioning often to protect your back. After his head and shoulders are pulled though the seats, a second provider can possibly reach through far enough to help pull him onto the backboard and then assist in removing him and the backboard from the vehicle.

8. What steps can you take to maximize safety while lifting a patient?

To safely lift and carry a patient, you and your team must anticipate and understand every move, and each move must be coordinated. To avoid confusion, which may result in one or more providers suddenly bearing an unexpected amount of weight, the team leader (typically the provider closest to the head of the patient) should call out all of the lifting commands.

The following general guidelines should be followed to maximize safety when lifting any patient:

- Keep your legs shoulder width apart.
- Keep your back in a straight, locked-in position.
- Keep the patient's weight as close to your body as possible.
- Bend at the knees, not the waist, when lifting.
- Avoid lifting and reaching at the same time.
- Avoid twisting your body as you are lifting.
- Lift with your palms facing up (power grip).
- Communicate with your partner (or team) at all times.

9. How is a patient's weight distributed when he or she is on a carrying device? Why is it important to know this?

To position your team accordingly, and thus minimize the potential for injury, it is important to know how a patient's weight is distributed when he or she is on a carrying device.

If a patient is supine on a backboard or a scoop stretcher or is in a semisitting position on an ambulance stretcher, his or her weight is not equally distributed between the two ends of the device. When a patient is in a horizontal position, between 68% and 78% of his or her weight is in the torso. Therefore, the strongest provider(s) should be positioned at the head end of the carrying device. However, you should still position the remaining providers so that each one—including the provider(s) at the patient's head—bears an equal amount of the patient's weight.

10. Considering her complaints and the fact that her condition is stable, what are your best options for removing Patient 2?

An urgent move is not required because the patient's condition is stable. Think through the possibilities while you provide reassurance to the patient. She has the potential for spinal injuries because of the mechanism of injury. She is also reporting back pain. The best way to move a stable patient reporting neck or back pain is to use a short vest device such as a KED. Apply a cervical collar to the patient and then position the KED behind the patient and have her thread the leg straps underneath her legs. Continuously remind the patient to hold her head still and try to move as little as possible because there is no room for another provider to hold cervical spine control. Once the device is positioned, you will have to lean through the seats to attach and secure the straps. Once secured, the patient can be moved as a unit. Pull her through the seats and onto the awaiting backboard where you will have additional assistance to remove her from the vehicle.

11. How can you minimize the risk of injury while moving a patient on a wheeled ambulance stretcher?

When you move a patient on a wheeled ambulance stretcher, make sure that it is elevated whenever possible, not lowered to the ground. If the stretcher is lowered to the ground, you will have to bend down and move the patient at the same time; this increases the potential for a back injury.

When the stretcher is elevated, the main frame and the patient are considerably higher than the wheels; this makes the stretcher top-heavy. Therefore, when you are moving a patient on an elevated stretcher, ensure that you hold the frame firmly between both of your hands at all times so that if the patient moves, the stretcher will not tip over.

If you are guiding the stretcher from the foot end, make sure your arms are held close to your body, and avoid reaching a great distance behind you or hyperextending your back. Your back should be locked, straight, and untwisted. To avoid hyperextending your elbows or injuring your shoulder, keep your elbows slightly flexed and use the muscles of your arms to pull.

If you are guiding the stretcher from the head end, push with your arms and bend your elbows so that your hands are about 12 to 15 inches (30 to 38 cm) in front of your torso. To protect your elbows from injury, avoid pushing the stretcher with your arms fully extended and your elbows locked. When you push with your elbows bent but firmly held from bending further, the strong muscles of your arms serve as a shock absorber if the wheels of the stretcher strike an obstacle, causing the stretcher to come to an abrupt stop.

EMS Patient Care Report (PCR)

Date: 09-20-16	**Incident No.:** 013409	**Nature of Call:** Motor vehicle crash		**Location:** 125 Parkview Place	
Dispatched: 0822	**En Route:** 0822	**At Scene:** 0828	**Transport:** 0938	**At Hospital:** 0947	**In Service:** 0955

Patient Information

Age: 82 **Sex:** F **Weight (in kg [lb]):** 69 kg (152 lb)	**Allergies:** Penicillin **Medications:** Ibuprofen, lisinopril **Past Medical History:** Chronic back pain, hypertension **Chief Complaint:** Back pain, right side pain

Narrative

Dispatched to the scene of a motor vehicle crash where a sedan-type vehicle was found lying on the passenger's side in ditch partially filled with water. Upon arrival secondary units were requested to stabilize vehicle and a paramedic unit was requested for backup. Both patients were unrestrained and the female patient was pinned underneath the male, who was unresponsive.

Once the vehicle was stabilized the male patient was removed and turned over to the awaiting paramedic team. The woman was then able to be accessed. 82-year-old female unrestrained passenger with a history of chronic back pain was reporting pain to her back and right side. She was alert and oriented with no significant injuries noted. A cervical collar was applied. In order to remove the patient from the vehicle, a Kendrick Extrication Device (KED) was placed behind the patient, and, with her help, the device was secured around her body and legs. Using the KED, the patient was pulled up over the seats and onto an awaiting backboard.

Once the patient was removed from the vehicle and secured to the backboard she was loaded into the ambulance. Vital signs were obtained and a secondary assessment was completed en route to the local trauma center. There were no significant injuries found and the patient remained stable during transport. Upon arrival at the trauma center patient report was given to the receiving nurse and the crew returned to service.**End of report**

Note: The responding paramedic team provided documentation for the care of the male patient turned over upon removal from the wreckage.

Prep Kit

Ready for Review

- The wheeled ambulance stretcher and the backboard are the most commonly used devices to move and transport patients.
- It is best to move a patient on a device that can be rolled. However, if a wheeled device is not available, you must understand and follow certain guidelines for carrying a patient on a stretcher or backboard.
- Whenever you move a patient, you must take special care to avoid injury to you, your team, and the patient.
- The safety of you, your team, and the patient depends on the use of proper lifting techniques and maintaining a proper hold when lifting or carrying a patient. You must practice each technique with your team often so that you are able to perform the move quickly, safely, and efficiently.
- The same basic body mechanics apply for safe reaching, pulling, lifting, and carrying.
- Good body mechanics are important to prevent injuries, but are not always sufficient. Special devices and technology should be used when possible to further decrease your risk of injury.
- The first key rule of lifting is to always keep your back in an upright position and lift without twisting. You can lift and carry significant weight without injury as long as your back is in the proper upright position.
- Do not hyperextend your back when reaching overhead.
- The power lift is the safest and most powerful way to lift.
- Pushing is better than pulling.
- If you do not have a proper hold, you will not be able to bear your share of the weight, or you may lose your grasp with one or both hands and possibly cause a low back injury to one or more providers.
- When you must carry a patient up or down a flight of stairs or other significant incline, use a stair chair. The exception to this is when the patient is in cardiac arrest, must be moved in a supine position, or must have his or her spine immobilized during transport, in which case the patient will be moved on the stairs on a backboard.
- If you must carry a loaded backboard or stretcher up or down stairs or other inclines, be sure that the patient is tightly secured to the device to prevent sliding.
- Be sure to carry the backboard or stretcher foot end first so that the patient's head is elevated higher than the feet.
- Directions and commands are important parts of safe lifting and carrying.
- You must constantly coordinate your movements with those of the other team members and communicate with them.
- You and your team must anticipate and understand every move and execute it in a coordinated manner.
- The team leader is responsible for coordinating the moves.
- Try to use four providers whenever resources allow.
- Know how much you can comfortably and safely lift and do not attempt to lift more than this amount.
- Rapidly summon additional help to lift and carry a weight that is greater than you are able to lift.
- Perform an urgent move if a patient has an altered level of consciousness or inadequate ventilation, is in shock, or during extreme weather conditions.
- You should normally move a patient with nonurgent moves, in an orderly, planned, and unhurried manner, selecting methods that involve the least amount of lifting and carrying.
- At times, you may have to use an emergency move to maneuver a patient before providing assessment and care.
- Other devices that are used to lift and carry patients include portable stretchers, flexible stretchers, backboards, basket stretchers (Stokes litters), and scoop stretchers.
- Training and practice are required to use all the equipment that is available to you.
- You will learn the technical skills of patient packaging and handling through practice and training.

Vital Vocabulary

backboard A long, flat board made of rigid, rectangular material that is used to provide support to a patient who is suspected of having a hip, pelvic, spinal, or lower extremity injury; also called a spine board, trauma board, and longboard.

bariatrics A branch of medicine concerned with the management (prevention or control) of obesity and allied diseases.

basket stretcher A rigid stretcher commonly used in technical and water rescues that surrounds and supports the patient yet allows water to drain through holes in the bottom; also called a Stokes litter.

body mechanics The relationship between the body's anatomical structures and the physical forces associated with lifting, moving and carrying; the ways in which the body moves to achieve a specific action.

diamond carry A carrying technique in which one provider is located at the head end of the stretcher or backboard, one at the foot end, and one at each side of the patient; each of the two providers at the sides uses one hand to support the stretcher or backboard so that all are able to face forward as they walk.

direct ground lift A lifting technique that is used for patients who are found lying supine on the ground with no suspected spinal injury.

emergency move A move in which the patient is dragged or pulled from a dangerous scene before assessment and care are provided.

extremity lift A lifting technique that is used for patients who are supine or in a sitting position with no suspected extremity or spinal injuries.

flexible stretcher A stretcher that is a rigid carrying device when secured around a patient but can be folded or rolled when not in use.

portable stretcher A stretcher with a strong, rectangular, tubular metal frame and rigid fabric stretched across it.

power grip A technique in which the stretcher or backboard is gripped by inserting each hand under the handle with the palm facing up and the thumb extended, fully supporting the underside of the handle on the curved palm with the fingers and thumb.

power lift A lifting technique in which the EMT's back is held upright, with legs bent, and the patient is lifted when the EMT straightens the legs to raise the upper body and arms.

rapid extrication technique A technique to move a patient from a sitting position inside a vehicle to supine on a backboard in less than 1 minute when conditions do not allow for standard immobilization.

scoop stretcher A stretcher that is designed to be split into two or four sections that can be fitted around a patient who is lying on the ground or other relatively flat surface; also called an orthopedic stretcher.

stair chair A lightweight folding device that is used to carry a conscious, seated patient up or down stairs.

wheeled ambulance stretcher A specially designed stretcher that can be rolled along the ground. A collapsible undercarriage allows it to be loaded into the ambulance; also called an ambulance stretcher.

Assessment *in Action*

A call comes in for an injured person in a wooded area. Dispatch tells you that the patient, a 42-year-old man, was cutting down a tree when it fell on him. Upon arrival you are led to an area about 200 yards from where you have to leave the ambulance outside the tree line. When you reach the patient he is lying supine with a large tree trunk across his upper legs and pelvic region. Bystanders who were working with him are using a jack to try to lift up the tree high enough to get him out. The patient is alert and reports tremendous pain in his right hip and upper thigh.

1. What is the best way to remove the patient once the tree is lifted?

   A. Power lift
   B. Clothes drag
   C. Extremity lift
   D. Direct lift

2. When freeing the patient, it is imperative to use which proper body mechanics?

   A. Keep your back straight.
   B. Keep your feet close together.
   C. Bend as far forward at the hips as possible.
   D. Keep your back curved.

3. Should you consider spinal immobilization for this patient?

   A. Yes, every patient should be immobilized.
   B. Yes, there is a significant MOI.
   C. No, he is not reporting neck or back pain.
   D. No, there is no significant MOI.

4. Once the patient is free, how should he be moved to the backboard?

   A. Extremity lift
   B. Direct ground lift

C. Scoop stretcher
D. Log roll with attention to cervical spine

5. When you use a body drag to move a patient, your back should be locked and straight and:

A. your feet should be close together.
B. your arms should be fully extended with elbows locked.
C. your elbows should only extend just beyond the anterior torso.
D. you should bend from the waist with your feet 12 inches (30 cm) apart.

6. When lifting a backboard, you should use the:

A. lateral lift.
B. diamond carry.
C. power grip.
D. power lift.

7. The scoop stretcher is also known as a(n):

A. orthopaedic stretcher.
B. flexible litter.
C. basket litter.
D. ambulance stretcher.

8. Because you are unable to bring the stretcher to the patient, the best way to carry him to the stretcher is using the:

A. diamond carry.
B. firefighter's carry.
C. direct carry.
D. emergency carry.

9. Describe how constant communication between team members can avoid provider injury.

10. What are three questions you should ask yourself before lifting a patient?

9 Patient Assessment

CHAPTER 9

Patient Assessment

National EMS Education Standard Competencies

Assessment

Applies scene information and patient assessment findings (scene size-up, primary and secondary assessment, patient history, and reassessment) to guide emergency management.

Scene Size-up

› Scene safety (pp 317–318)

› Scene management

- Impact of the environment on patient care (pp 317–318)
- Addressing hazards (p 318)
- Violence (p 318)
- Need for additional or specialized resources (p 321)
- Standard precautions (pp 319–320)
- Multiple patient situations (pp 320–321)

Primary Assessment

› Primary assessment for all patient situations (pp 323–336)

- Level of consciousness (pp 324–325)
- ABCs (pp 326–332)
- Identifying life threats (pp 325–326, 332–335)
- Assessment of vital functions (pp 323–325, 329–330)
- Initial general impression (pp 323–324)

› Begin interventions needed to preserve life (pp 325–326, 332)

› Integration of treatment/procedures needed to preserve life (pp 335–336)

History Taking

› Determining the chief complaint (pp 338–339)

› Mechanism of injury/nature of illness (pp 318–319)
› Associated signs and symptoms (pp 338–340)
› Investigation of the chief complaint (pp 338–339)
› Past medical history (pp 338–340)
› Pertinent negatives (p 340)

Secondary Assessment

› Performing a rapid full-body scan (pp 348–353)
› Focused assessment of pain (pp 348, 353–372)
› Assessment of vital signs (pp 354–363, 370–372)
› Techniques of physical examination
- Respiratory system (pp 353–356)
  - Presence of breath sounds (pp 355–356)
- Cardiovascular system (pp 356–363)
- Neurologic system (pp 363–368)
- Musculoskeletal system (pp 369–370)
- All anatomic regions (pp 366, 368–370)

Monitoring Devices

› Obtaining and using information from patient monitoring devices including (but not limited to)
- Pulse oximetry (p 371)
- Noninvasive blood pressure (p 372)

Reassessment

› How and when to reassess patients (p 375)
› How and when to perform a reassessment for all patient situations (p 375)

Knowledge Objectives

1. Identify the components of the patient assessment process. (p 315)
2. Explain how the different causes and presentations of emergencies will affect how EMTs perform each step of the patient assessment process. (p 315)
3. Discuss some of the possible environmental, chemical, and biologic hazards that may be present at an emergency scene, ways to recognize them, and precautions to protect personal safety. (pp 317–318)
4. Discuss the steps EMTs should take to survey a scene for signs of violence and protect themselves and bystanders from real or potential danger. (pp 317–318)
5. Describe how to determine the mechanism of injury (MOI) or nature of illness (NOI) at an emergency and the importance of differentiating trauma patients from medical patients. (pp 318–319)
6. List the minimum standard precautions that should be followed and personal protective equipment (PPE) that should be worn at an emergency scene, including examples of when additional precautions would be appropriate. (pp 319–320)
7. Explain why it is important for EMTs to identify the total number of patients at an emergency scene and how this evaluation relates to determining the need for additional or specialized resources, implementation of the incident command system (ICS), and triage. (pp 320–321)
8. Describe the principal goals of the primary assessment process, including how to identify and treat life threats and determine if immediate transport is required. (p 323)
9. Explain the process of forming a general impression of a patient as part of primary assessment and the reasons why this step is critical to patient management. (pp 323–324)
10. Explain the importance of assessing a patient's level of consciousness (LOC) to determine altered mental status and include examples of different methods used to assess alertness, responsiveness, and orientation. (pp 324–325)
11. Describe the assessment of airway status in patients who are both responsive and unresponsive, including examples of possible signs and causes of airway obstruction in each case as well as the appropriate EMT response. (pp 326–327)
12. Describe the assessment of a patient's breathing status, including the key information EMTs must obtain during this process and the care required for patients who have both adequate and inadequate breathing. (pp 327–328)
13. List the signs of respiratory distress and respiratory failure. (p 329)
14. Describe the assessment of a patient's circulatory status, including the different methods for obtaining a pulse and

appropriate management depending on the patient's status. (pp 329–330)
15. Explain the variations required to obtain a pulse in infant and child patients compared with adult patients. (pp 329–330)
16. Describe the assessment of a patient's skin color, temperature, and condition, including examples of both normal and abnormal findings and the information this provides related to the patient's status. (pp 330–331)
17. Discuss the process of assessing and methods for controlling external bleeding. (p 332)
18. Discuss the steps used to identify and subsequently treat life-threatening conditions that endanger a patient during an emergency. (pp 332–333)
19. List the steps EMTs should follow during the primary assessment of a trauma patient, including examples of abnormal signs and appropriate related actions. (pp 334–335)
20. Explain the process for determining the priority of patient care and transport at an emergency scene and include examples of conditions that necessitate immediate transport. (pp 335–336)
21. Discuss the importance of protecting a trauma patient's spine and identifying fractured extremities during patient packaging for transport. (pp 335–336)
22. Discuss the process of taking a focused history, its key components, and its relationship to the primary assessment process. (p 338)
23. Describe examples of different techniques EMTs may use to obtain information from patients during the history-taking process. (pp 340–346)
24. Discuss different challenges EMTs may face when taking a patient history on sensitive topics and strategies that can be used to facilitate each situation. (pp 341–343)
25. Describe the purpose of a secondary assessment and a physical exam; include how to determine which aspects of the physical exam to use, and the steps. (pp 348–353)
26. Explain situations in which patients may receive a focused assessment, including examples by body system of what each focused assessment should include based on a patient's chief complaint. (pp 353–373)
27. List normal blood pressure ranges for adults, children, and infants. (p 364)
28. Explain the importance of performing a reassessment of the patient and the steps in this process. (p 375)

Skills Objectives

1. Demonstrate how to use the AVPU scale to test for patient responsiveness. (p 324)
2. Demonstrate how to evaluate a patient's orientation and document his or her status correctly. (p 325)
3. Demonstrate the techniques for assessing a patient's airway and correctly obtain information related to respiratory rate, rhythm, quality, and character of breathing, and depth of breathing. (pp 326–328)
4. Demonstrate how to assess a radial pulse in a responsive patient and an unresponsive patient. (pp 329–330)
5. Demonstrate how to assess a carotid pulse in an unresponsive patient. (pp 329–330)
6. Demonstrate how to palpate a brachial pulse in a child who is younger than 1 year (or a manikin). (pp 329–330)
7. Demonstrate how to obtain a pulse rate in a patient. (pp 329–330)
8. Demonstrate how to assess capillary refill in an adult or child older than 6 years. (p 332)
9. Demonstrate how to assess capillary refill in an infant or child younger than 6 years; include variations that would be required when assessing a newborn. (p 332)
10. Demonstrate how to perform a rapid exam during primary assessment of a patient. (pp 334–335, Skill Drill 9-1)
11. Demonstrate how to perform a secondary assessment. (pp 349–353, Skill Drill 9-2)
12. Demonstrate how to measure blood pressure by auscultation. (pp 360–361, Skill Drill 9-3)
13. Demonstrate how to measure blood pressure by palpation. (pp 362–363, Skill Drill 9-4)
14. Demonstrate how to test pupil reaction in response to light in a patient and document his or her status correctly. (pp 364–365)
15. Demonstrate the assessment of neurovascular status. (pp 366–368, Skill Drill 9-5)
16. Demonstrate the use of a pulse oximetry device to evaluate the effectiveness of oxygenation in the patient. (pp 370–372)
17. Demonstrate the use of electronic devices to assist in determining the patient's blood pressure in the field. (p 372)
18. Demonstrate how to assess a patient's blood glucose level. (p 373, Skill Drill 9-6)

Patient Assessment

Scene Size-up

Ensure scene safety
Determine mechanism of injury/nature of illness
Take standard precautions
Determine number of patients
Consider additional/specialized resources

Primary Assessment

Form a general impression
Assess level of consciousness
Assess the airway: identify and treat life threats
Assess breathing: identify and treat life threats
Assess circulation: identify and treat life threats
Perform primary assessment
Determine priority of patient care and transport

History Taking

Investigate the chief complaint (history of present illness)
Obtain SAMPLE history

Secondary Assessment: Medical

Systematically assess the patient
- Secondary assessment and/or focused assessment

Assess vital signs using the appropriate monitoring device

Secondary Assessment: Trauma

Systematically assess the patient
- Secondary assessment and/or focused assessment

Assess vital signs using the appropriate monitoring device

Reassessment

Repeat the primary assessment
Reassess vital signs
Reassess the chief complaint
Recheck interventions
Identify and treat changes in the patient's condition
Reassess the patient
- Unstable patients: every 5 minutes
- Stable patients: every 15 minutes

Introduction

One of the most important skills that you can develop as an EMT is the ability to assess your patients. This skill is used in every patient encounter and is the basis for all treatment you will provide as an EMT. This chapter provides the framework and information necessary for you to be able to understand and conduct the patient assessment. The assessment process is divided into five main parts:

1. Scene size-up
2. Primary assessment
3. History taking
4. Secondary assessment
5. Reassessment

Although these steps represent a logical approach to patient assessment, the order in which they are performed may vary depending on the patient's condition and the environment in which you find him or her. For example, the same components of patient assessment used to evaluate a medical patient are used to assess a trauma patient; however, it may be necessary to change the order of some steps after scene size-up based on your findings and the need to prioritize the care of certain conditions. Regardless of the patient's complaint or the environment in which you find yourself, the key to effective patient assessment is to remain organized.

Rarely does one sign or symptom show you the patient's status or underlying problem. Rather, it is the combination of many signs and symptoms that will direct the care that you provide for your patient. A **symptom** is a subjective condition that the patient feels and tells you about. A **sign** is an objective condition that you can observe or measure. Therefore, it is essential to have a basic understanding of the causes and presentations of commonly encountered emergencies so that you know what to look for.

For example, a man with chest pain may be having a heart attack. Or, he may have a lung infection, a pulmonary embolism, or a simple strained muscle in the chest. He may also have sustained chest trauma. He describes the pain as crushing, radiating down the left arm and up into the jaw; he is pale and soaked in sweat; the episode began while he was shoveling snow; he has a history of coronary bypass surgery; and has nitroglycerin in his pocket. On the basis of this information, it seems likely the patient is experiencing, and should be treated for, a myocardial infarction.

As an EMT, the treatment you will provide for patients is based on symptoms, not an exact diagnosis. Many conditions may have similar signs and symptoms. As your career in EMS progresses, you may begin to formulate a list of potential conditions or injuries a patient may be experiencing as you treat them. Remember, it is essential to collect all pertinent information and be able to interpret how it fits together.

The patient assessment process is the foundation upon which all levels of EMT education are built and is the starting point for all patient care. EMS providers cannot effectively treat their patients if they cannot correctly assess them. Strong assessment skills will assist you in the process of saving lives.

Words of Wisdom

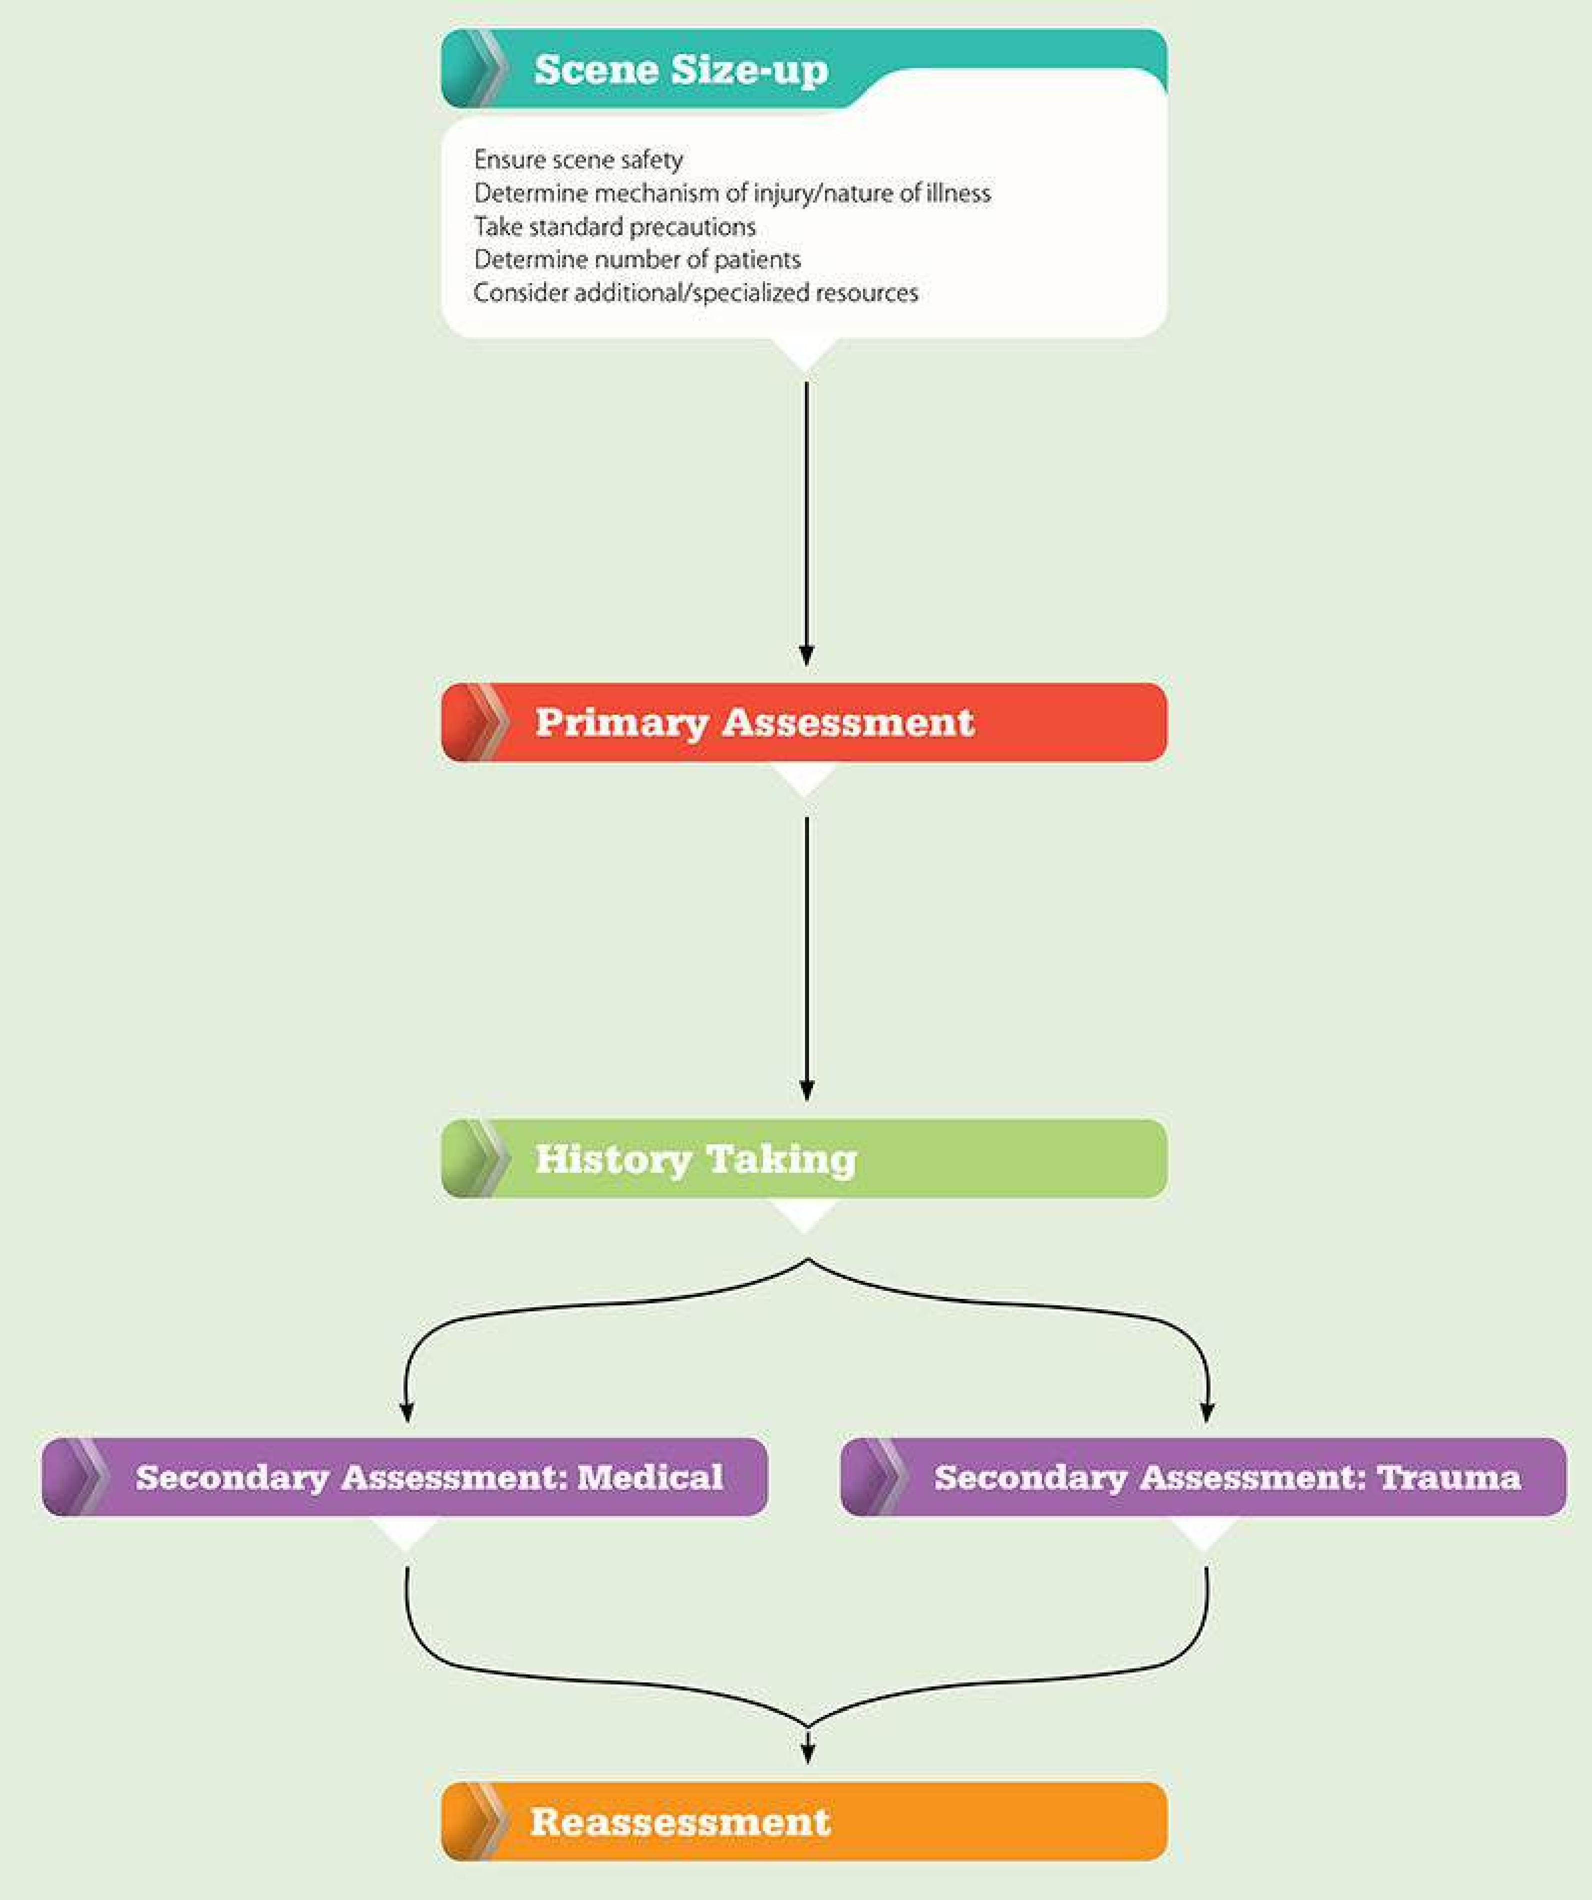
Although the steps of patient assessment represent a logical approach to the evaluation of a patient, the order in which they are performed is dictated by the patient's condition.

YOU are the Provider — PART 1

At 1815 hours, you are dispatched to an apartment complex at 1326 South Main Street for a "man down." The dispatcher has no additional information to provide, and law enforcement officers have been dispatched. The weather is overcast and rainy, the temperature is 62°F (16.7°C), and the traffic is light. Your response time to the scene is approximately 4 minutes.

1. What are the components of patient assessment?
2. Will your assessment of the patient differ if he is injured versus ill? If so, how?

Patient Assessment



Scene Size-up

Scene size-up refers to your evaluation of the conditions in which you will be operating. While this will be the focus of your attention when you first arrive on scene, continuous **situational awareness** is necessary throughout the entire call to ensure safety. Situational awareness is paying attention to the conditions and people around you at all times and the potential risks those conditions or people pose.

For example, before you know the specific location of the incident, consider how the weather, time of day, currently available resources, and other incidents in the same response district may affect your ability to operate safely and effectively. Scene size-up is listed at the top of the assessment algorithm because it is the first thing you must consider, but it does not end when you move through the rest of the assessment process.

When you are alerted for an emergency call, your dispatcher will provide you with some basic information about the request for your assistance. From the moment you are called into action until you reach your patient, you will consider a variety of things that will have an impact on how you operate on scene and provide patient care. These include road and traffic hazards that will affect where you park your vehicle, incident hazards such as fire, hazardous materials, or scenes of violence that may affect how and if you approach the scene, and more. Your scene size-up must combine an understanding of your situation and conditions prior to responding, the information the dispatcher gave you, and an observation of the scene itself to help you ensure safe and effective operations.

Ensure Scene Safety

Issues that you may encounter in the prehospital setting can range from minor difficulties to major dangers. Even scenes that first appear relatively safe and secure can turn unsafe with little notice. Look for possible difficulties and dangers as you approach the scene. Ask yourself, "Is it safe for my team and me to enter the scene and approach and manage the patient?" If the answer to this question is, "No, the scene is not yet safe to approach and manage the patient," then do what you can to make it safe or call for additional resources. These may include firefighters, utility workers, hazardous materials technicians, or law enforcement personnel, depending on the condition that is making the scene unsafe.

Before you step out of your response vehicle, observe for issues such as uneven or unstable surfaces, water, mud, and ice on the ground. Remember, you have to gain access to a patient to provide care, typically while carrying gear and a stretcher with you. In addition, when you leave, you will be moving up to a 100-pound (45 kg) stretcher, if it is motorized, and possibly a patient weighing 200 pounds (90 kg) or more, as well as patient care equipment and the patient's personal belongings. If your footing was compromised going in, you are going to have an even more difficult time coming out.

If you must exit your vehicle or approach the patient on a working roadway, you must consider traffic safety issues as well as other physical hazards. When operating in the area of an active roadway, you must wear, at a minimum, a high-visibility Class 2 or 3 safety vest approved by the American National Standards Institute. This vest helps make you visible to others on the roadway while minimizing interference with other clothes and equipment. A variety of other traffic-incident management techniques may be appropriate, including the use of personnel and traffic markers such as cones, flares, and signs to divert traffic around the area, and the strategic positioning of emergency vehicles to protect the area.

Consider environmental conditions that may present hazards at the scene. Is it cold, snowing, raining, hot, or humid? The weather may present a difficulty by itself, but consider how it may affect the physical terrain you may encounter, such as wooded areas, hills, mountains, gorges, rivers, lakes, streams, and islands. Even relatively minor weather conditions may present a significant hazard if responders and patients may be exposed to them for a significant amount of time; for example, during a long approach to, or while carrying out, a patient across difficult terrain **Figure 9-1**.

Figure 9-1 At times you may need to carry patients out of areas with difficult terrain.

Courtesy of James Tourtellote/US Customs and Border Protection.

Working in unfavorable conditions and on unstable surfaces is a large part of prehospital care. Without knowing the infinite number of situations you may become involved in, a good rule to use when faced with a wide variety of possibilities is that any actions you may take to protect yourself (eg, heavy coats, rain gear, life jackets, air conditioned or heated vehicles) should also be considered for the patient. If you are putting on equipment to address environmental hazards and can safely do so, provide the patient with the same or similar equipment. If you move away from the scene to take cover from an environmental hazard, move the patient with you when possible. Taking your time to stay focused on what you are doing will go a long way in preventing injuries to yourself and your patients.

If appropriate, help protect bystanders from becoming patients as well. Many bystanders attempt to help during an emergency; always remember that they are not trained to handle complicated EMS equipment, illnesses, or injuries.

Hazards come in many different forms, shapes, and sizes. You may encounter environmental hazards; physical hazards (such as sharp metal and broken glass, or slip-and-fall hazards from leaking fluids at a motor vehicle biohazards (such as blood and body fluids); chemical hazards (such as the release of a hazardous material); electrical hazards (such as downed power lines); water hazards; fires; explosions; and the threat of physical violence, to name a few. **Figure 9-2**.

You must be aware of scenes that have the potential for violence due to violent patients, distraught family members, angry bystanders, gangs, or unruly crowds. When you enter the home of a patient, look around the immediate area. Are there weapons visible in the area to which a patient or others may have access? Weapons need not be typical like a knife or gun; they can also be items such as a screwdriver, hammer, or simple things sitting on the kitchen table or nightstand by the bed. Always be observant for such objects, and if they are not secured, make sure that you place yourself between the patient and the potential danger, thus preventing possible access to the object. Request the assistance of law enforcement personnel if the scene is unsafe with the potential for violence **Figure 9-3**.

An emergency scene is a dynamically changing environment and simply checking the safety of the scene once at the beginning of the call is not enough. As an EMT, you must remain aware of changes in your surroundings that may present safety hazards to you, your EMS team, the patient, or bystanders. Regardless of when the hazards present themselves, it is up to you to either make the scene safe if you have the education and equipment to safely do so, or call for additional resources and move to a safe location.

Figure 9-2 Evaluate the scene for hazards as soon as you arrive.

Figure 9-3 If the scene is unsafe, request law enforcement support.

Determine Mechanism of Injury/Nature of Illness

Virtually all calls for assistance to which you may respond can be categorized as medical conditions, traumatic injuries, or both. Some emergency calls may involve a medical problem that leads to a traumatic injury, such as a patient who becomes weak and dizzy from a low blood glucose level, causing her to stumble, fall, and break her ankle. As an EMT, you will need to be able to identify the general classification and underlying issue(s) of the emergency to which you respond.

Traumatic injuries are the result of physical forces applied to the outside of the body, usually from an object striking the body or a body striking an object. These are generally classified according to the type or amount of force, how long it was applied, and where it was applied to the body. This is described as the **mechanism of injury (MOI)**. The MOI can be used as a guide to help you focus your assessment.

Certain parts of the body are more easily injured than others. The brain and the spinal cord are very fragile and easy to injure. Fortunately, they are protected by the skull, the vertebrae, and several layers of soft tissues. The eyes are also easily injured. Even small forces on the eye may result in serious injury. The bones and certain organs are stronger and can absorb small forces without resulting injury. A good understanding of anatomy and physiology will help you identify times when a mechanism of injury may lead to injury to parts of the body not directly impacted. For example, consider a patient who has fallen off a roof, landing feetfirst. This patient's MOI would direct attention to possible injury to the feet. But significant energy likely transferred to other body areas and may have caused further injury in the patient's legs, pelvis, and even his or her spine.

Terms commonly associated with MOI include blunt trauma and penetrating trauma. With blunt trauma, the force of the injury occurs over a broad area, and the skin is sometimes not broken. However, the tissues and organs underneath the area of impact may be damaged. With penetrating trauma, the force of the injury occurs at the specific point of contact between the skin and the object. The object pierces the skin and creates an open wound that carries a higher potential for infection.

As an EMT, you will also care for patients who require EMS attention because of illnesses or conditions not caused by an outside force. For these patients with medical problems, you must examine the general type of illness the patient is experiencing, or the **nature of illness (NOI)**. An example of this would be a patient who tells you that he feels like he cannot get enough air. This patient's NOI would be difficulty breathing and, like the MOI, would help direct both your assessment and your care.

There are similarities between the MOI and the NOI. Both require you to search for clues regarding how the incident occurred. You must make an effort to determine the general type of illness, which is often best described by the patient's **chief complaint**, the most serious thing the patient is concerned about and the reason EMS was called. To quickly determine the NOI, talk with the patient, family, or bystanders about the problem. At the same time, use your senses to check the scene for clues as to the possible problem. You may see open or spilled medication containers, poisonous substances, or unsanitary living conditions. You may smell an unusual or strong odor, such as the odor of fresh paint in a closed room. You may hear a hissing sound, such as a leak from a home oxygen system. Keep these observations of the scene in mind as you begin to assess a medical patient.

Be aware of scenes with multiple patients who are exhibiting similar signs or symptoms. An example would be an older couple experiencing flulike symptoms, headache, nausea, and vomiting. These symptoms may be indicative of carbon monoxide poisoning, which would also indicate an unsafe scene for you and your partner.

The Importance of the MOI and NOI

Considering the MOI or NOI early can be of value in preparing to care for your patient. For example, when you begin to gather equipment from the unit, what would you take to treat a patient reporting chest pain? How would that equipment differ from the equipment used for a pedestrian struck by a vehicle? The appearance of the scene may also guide your preparation. Other MOIs may include falls, motor vehicle crashes, assaults, and industrial accidents. Examples of NOIs include seizures, heart attacks, diabetic problems, and poisonings. Family members, bystanders, or even law enforcement personnel may also provide important trauma or medical information to help you assist the patient.

You may be tempted to categorize your patient immediately as a trauma or medical patient. Remember, the fundamentals of a good patient assessment are the same despite the unique aspects of trauma and medical care. If an unconscious patient is found at the bottom of a ladder, did he fall off the ladder, strike his head, and become unconscious? Or did he experience a medical problem that caused him to have a loss of consciousness and then fall off the ladder? Early in the assessment, it can be difficult to identify with absolute certainty whether the problem is of a traumatic or medical origin. Although further assessment is needed to come to a conclusion, considering the MOI or NOI early will help you begin your assessment.

Take Standard Precautions

Standard precautions and **personal protective equipment (PPE)** need to be considered and adapted to the prehospital task at hand. Personal protective equipment includes clothing or specialized equipment that protects the wearer. The type of PPE used depends on the specific job duties required during a patient care interaction. For example, rescue personnel may wear PPE such as helmets, eye protection, boots, gloves, and turnout gear designed to protect them from injury when working to extricate a patient trapped in a damaged motor vehicle. Hazardous materials technicians may don a protective suit designed to prevent contamination by potentially lethal hazardous materials.

Standard precautions are protective measures that have traditionally been recommended by the Centers for Disease Control and Prevention (CDC) for use in dealing with objects, blood, body fluids, and other potential exposure risks of communicable disease. If you have a primary responsibility for patient care, you will need to follow standard precautions when assessing and treating the patient. They are required in each and every patient encounter. These measures may not provide absolute protection from exposure to infectious diseases or bloodborne pathogens, but they are the most effective way to reduce your risk of exposure. The concept of standard precautions assumes that all blood, body fluids, nonintact skin, and mucous membranes may pose a substantial risk of infection. This includes blood and other potentially infectious materials that are dried, because some diseases such as hepatitis can live for days outside the body.

Take standard precautions before actual patient contact, often before you step out of your response vehicle **Figure 9-4**. After you make contact with a patient, it may be too late to think about what precautions should have been considered. The use of standard precautions in EMS, including but not limited to consistent handwashing (with soap and water or with alcohol-based hand cleansers) before and after care, gloves, eye protection, a mask, and a gown, may be dictated by local standards or protocols. At a minimum, gloves must be in place before any patient contact. Remember that after contact with a patient, gloves may be contaminated by infectious materials, so avoid handling EMS equipment with the same gloves used during patient contact. The use of eye protection may be necessary during patient interactions. Standard eyeglasses may not offer enough protection because most are not designed with side splash guards. For that reason, eyewear should protect you from potential exposures from many different directions. Blood and body fluids that contain potentially infectious materials may become airborne; consider wearing a mask if there is a risk of splash or spray. A mask will provide protection from some airborne diseases, but its level of protection will depend on the type of mask, a proper fit, and your ability to apply and wear it properly.

You must be appropriately educated in the use of standard precautions, which should include training in the many types of PPE used in different situations. If you are not trained in the application of PPE, you should not approach a scene or make patient contact but should call for additional help. After making contact with the patient, if you discover a condition that warrants a higher level of PPE than you are using, do not hesitate to regroup and upgrade your protection. For example, if you discover in your primary assessment that a patient has a productive cough and a history of tuberculosis (TB), and you are not wearing an N95 mask, you and your crew should immediately don appropriate respiratory protection. If you suspect you have been exposed to a communicable disease without the protection of proper PPE, follow your local agency’s protocols for postexposure reporting, testing, and prophylaxis.

Figure 9-4 Proper protective equipment is vital when you are called to a scene in which you may be exposed to blood or other body fluids.

Determine Number of Patients

As part of the scene size-up, it is essential that you accurately identify the total number of patients. This evaluation is critical in determining your need for additional resources, such as firefighters, a specialized rescue group, a hazardous materials team, or additional ambulances. When there are multiple patients, use the **incident command system**, identify the number of patients, and then begin triage **Figure 9-5**. The incident command system is a flexible system implemented to manage a variety of emergency scenes. Emergency responders work in groups according to their function or assigned area, with the leader of each group reporting to the person in charge of the incident, the incident commander. **Triage** is the process of sorting patients based on the severity of their condition. Once all patients have been triaged, treatment and transport of these patients can begin. Usually the most experienced EMT is assigned to perform triage. This process helps allocate personnel, equipment, and resources to provide the most effective care to everyone. When a large number of patients are present or there are more patients than the responding unit can effectively handle, put your mass-casualty plan into action, utilizing the incident command system and your local protocols. These topics are covered in Chapter 39, *Incident Management*.

Figure 9-5 With multiple patients, use the incident command system, call for additional resources, and then begin triage.

Consider Additional/Specialized Resources

Some trauma or medical situations may require more ambulances, whereas others may have a need for specialized resources. Basic life support units may be all that are needed for some patients; however, advanced life support (ALS) should be requested for patients with severe injuries or complex medical problems depending on available resources and local protocols. ALS care may be provided by AEMTs or paramedics, depending on how your EMS system is set up. Air medical support may be another resource for ALS in your area. Follow your local protocols in requesting ALS resources.

In addition to EMS and fire suppression, many resources such as hazardous materials management, technical rescue services including complex extrication from motor vehicle crashes, wilderness search and rescue, high-angle rope rescue, and water rescue are typically available through the fire department **Figure 9-6**.

Figure 9-6

Scenes involving toxic substances may require specially trained rescuers with extra protective equipment.

Courtesy of Tempe Fire Department.

Law enforcement personnel may be needed to assist with traffic or scene control and should be the first to enter crime scenes and hostile environments.

If any situation presents itself as a danger to you, your partner, or your patient, you must retreat to a safe area. Be aware of the potential for danger at all times and understand when additional or specialized resources are required.

To determine if you require additional resources, ask yourself the following questions:

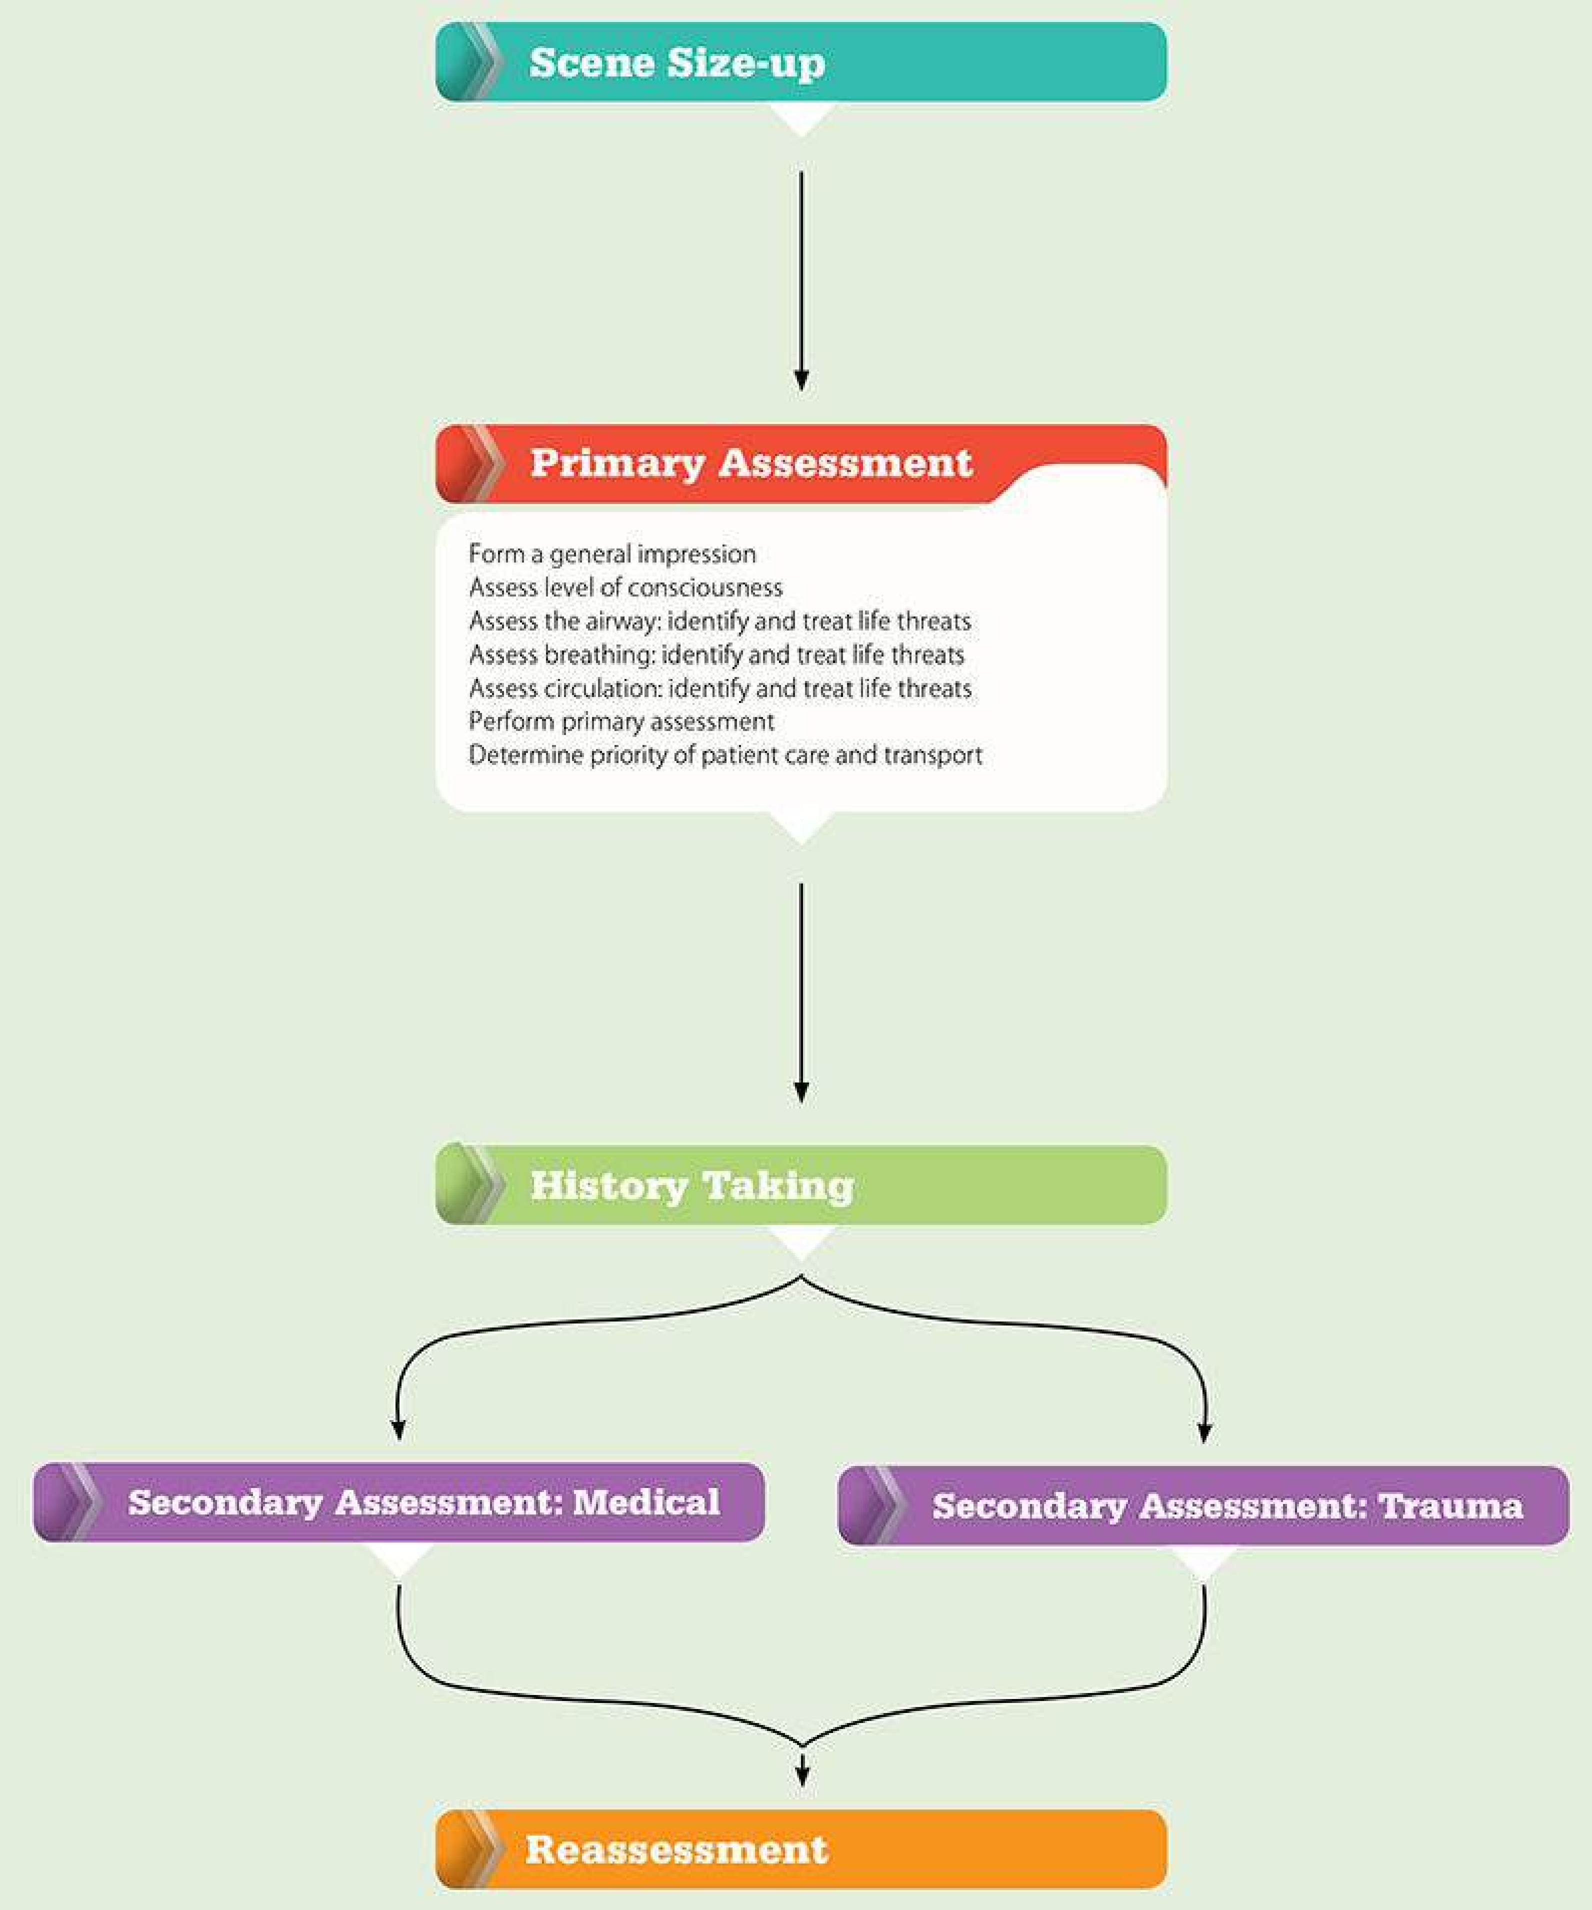
- Does the scene pose a threat to you, your patient, or others?
- How many patients are there?
- Do we have the resources to respond to their conditions?

Knowing how your EMS system is organized will help you determine the additional resources that may be required. The sooner these resources are identified, the sooner they can be requested.

Words of Wisdom

Keep in mind that standard precautions are the infection prevention practices intended to reduce the risk of transmission of bloodborne and other pathogens from both identified and unrecognized sources of infection. These precautions include hand hygiene; use of personal protective equipment such as gloves, gowns, and masks; safe injection practices; safe handling of potentially contaminated equipment and surfaces; and respiratory hygiene/ cough etiquette. The term *standard precautions* has replaced terms for similar concepts, such as *body substance isolation*, and is promoted by both the Centers for Disease Control and Prevention (CDC) and World Health Organization (WHO).

Patient Assessment



Primary Assessment

During the scene size-up, you evaluated potential or actual scene hazards and threats, protected yourself and your team, and decided whether you needed additional resources. You also evaluated the dispatch information, the environment into which you are responding, and your initial view of the patient setting to begin to understand what happened and what action you should take. It is critical for these steps to be accomplished before you make direct contact and begin to focus on the patient. Nevertheless, the heart of patient assessment begins when you first greet the patient and begin the **primary assessment**.

The primary assessment has a single, all-important goal: to identify and begin treatment of immediate or imminent life threats. To do this, you must physically examine the patient and assess level of consciousness (LOC) and airway, breathing, and circulation (ABCs); however, this is not an in-depth physical exam or assessment of **vital signs**. These will be addressed later in the secondary assessment. During the primary assessment, you must identify signs of life threats and immediately work to correct them **Figure 9-7**. From here you will be able to determine the priority of patient care and transport.

Form a General Impression

Any time you meet someone new, you form an initial general impression about that person. Forming the **general impression** of a patient is a similar process, but the focus is on rapid identification of potentially life-threatening problems. The general impression is formed to determine the priority of care and is the first part of your primary assessment. This includes noting things such as the person's age, sex, race, level of distress, and overall appearance, which may lead you to anticipate different problems. A woman reporting abdominal pain, for example, may have more serious implications than a man with the same complaint because of the complexity of the female reproductive system.

Think of your general impression as an overall visual assessment, gathering information as you approach the patient. Make sure that the patient sees you coming to avoid surprising the patient or causing the patient to turn to see you, possibly making any injuries worse. Note the patient's position and whether the patient is moving or still.

Avoid standing over the patient, if possible, especially if he or she is seated or lying down. This helps to show respect for the patient and helps the patient feel comfortable and less threatened as you begin your assessment. Refer to the patient by name. The initial general impression continues during your introduction **Figure 9-8**. Introduce yourself to the patient by stating, "Hi, I am Sam, an EMT with the fire department, and I am here to help you." After you introduce yourself, ask the patient about the chief complaint. Is the patient able to respond to your greeting easily and appropriately? The patient's response can give you insight into the level of consciousness, airway patency, respiratory status, and overall circulatory status before you begin your examination. Sometimes life-threatening conditions are obvious even during the general impression. If a life-threatening condition is found, treat it immediately.

Figure 9-7 A survey of the patient's airway, breathing, and circulatory status is used to establish whether the patient has a life-threatening condition(s) and what you should do about it.

Figure 9-8 As you approach the patient, form a general impression of his or her overall condition.

You will define your patient's condition as stable, stable but potentially unstable, or unstable to direct further assessment and treatment. This determination must be made so that prehospital care providers can work together with an appropriate sense of urgency. However, you must constantly be aware of changes in the patient's condition.

Assess Level of Consciousness

Early in your assessment, you will need to evaluate the patient's level of consciousness. This will help you rapidly determine if the patient has a life-threatening injury and to what extent the patient will be able to provide reliable information about his or her own condition as well as follow your directions. The patient's level of consciousness can tell you a great deal about his or her neurologic and physiologic status. The brain requires a constant supply of oxygen and glucose to function properly. In the primary assessment, you need to ascertain only the gross LOC by determining which of the following categories best fits your patient:

- Unconscious
- Conscious with an altered LOC
- Conscious with an unaltered LOC

Focus your initial assessment of a patient who is unconscious on problems with airway, breathing, and circulation, which are critical life threats. Sustained unconsciousness should warn you that a critical respiratory, circulatory, or central nervous system problem or deficit may exist, and you should presume that the patient has a critical injury or life-threatening condition until proven otherwise.

An altered LOC in a conscious patient can be caused by medications, drugs, alcohol, or poisoning. It may indicate that inadequate perfusion is adversely affecting the brain and its ability to function. **Perfusion** is the circulation of blood within an organ or tissue to provide necessary oxygen and nutrients and to remove waste. Further assessment will be required for any patient with an altered LOC.

Often, the same system that you use to perform the assessment will help you relay your findings in a clear and concise way to other medical providers either verbally or through documentation. This is the case with the AVPU scale used to assess a patient's level of consciousness depending on how well he or she responds to external stimuli, including verbal stimuli (sound) and painful stimuli (such as pinching the patient's ear lobe). The **AVPU scale** tests a patient's **responsiveness** based on the following criteria:

- **Awake and Alert.** The patient's eyes open spontaneously as you approach, and the patient appears to be aware of you and responsive to the environment. The patient is awake, appears to follow commands, and the eyes visually track people and objects.
- **Responsive to Verbal Stimuli.** The patient is not alert and awake. The patient's eyes do not open spontaneously. However, the patient's eyes do open when you speak to him or her, or the patient is able to respond in some meaningful way when spoken to; for example, by moaning, speaking, or moving. A patient who does not respond to your normal speaking voice but who responds when you speak loudly is responding to loud verbal stimuli.
- **Responsive to Pain.** The patient does not respond to your questions but moves or cries out in response to painful stimulus. There are appropriate and inappropriate methods of applying a painful stimulus **Figure 9-9**. Be aware that some methods may not give an accurate result if a spinal cord injury is present.
- **Unresponsive.** The patient does not respond spontaneously or to a verbal or painful stimulus. Unresponsive patients usually have no cough or gag reflex and lack the ability to protect their airway. If you are in doubt about whether a patient is truly unresponsive, assume the worst and treat appropriately.

To determine whether a patient who does not respond to verbal stimuli will respond to a painful stimulus, gently but firmly pinch the patient's skin. Areas where this technique works best are on the patient's ear, back of the upper arm (triceps), or the trapezius area (the muscle above the collar bone). Another effective technique is to apply upward pressure along the ridge of the orbital rim along the underside of the eyebrow. A patient who moans or withdraws is responding to the painful stimulus. Be sure to note the type and location of the stimulus and how the patient responded. Remember that the point is not to cause as much pain as possible, but to see if the patient responds to or withdraws from the sensation of pain where you have caused it.

Words of Wisdom

When using the AVPU scale, be sure to note how the patient responded. Tap a patient who is hard of hearing with your fingers repeatedly. If the patient responds, note that the patient is hard of hearing but responds to being tapped.

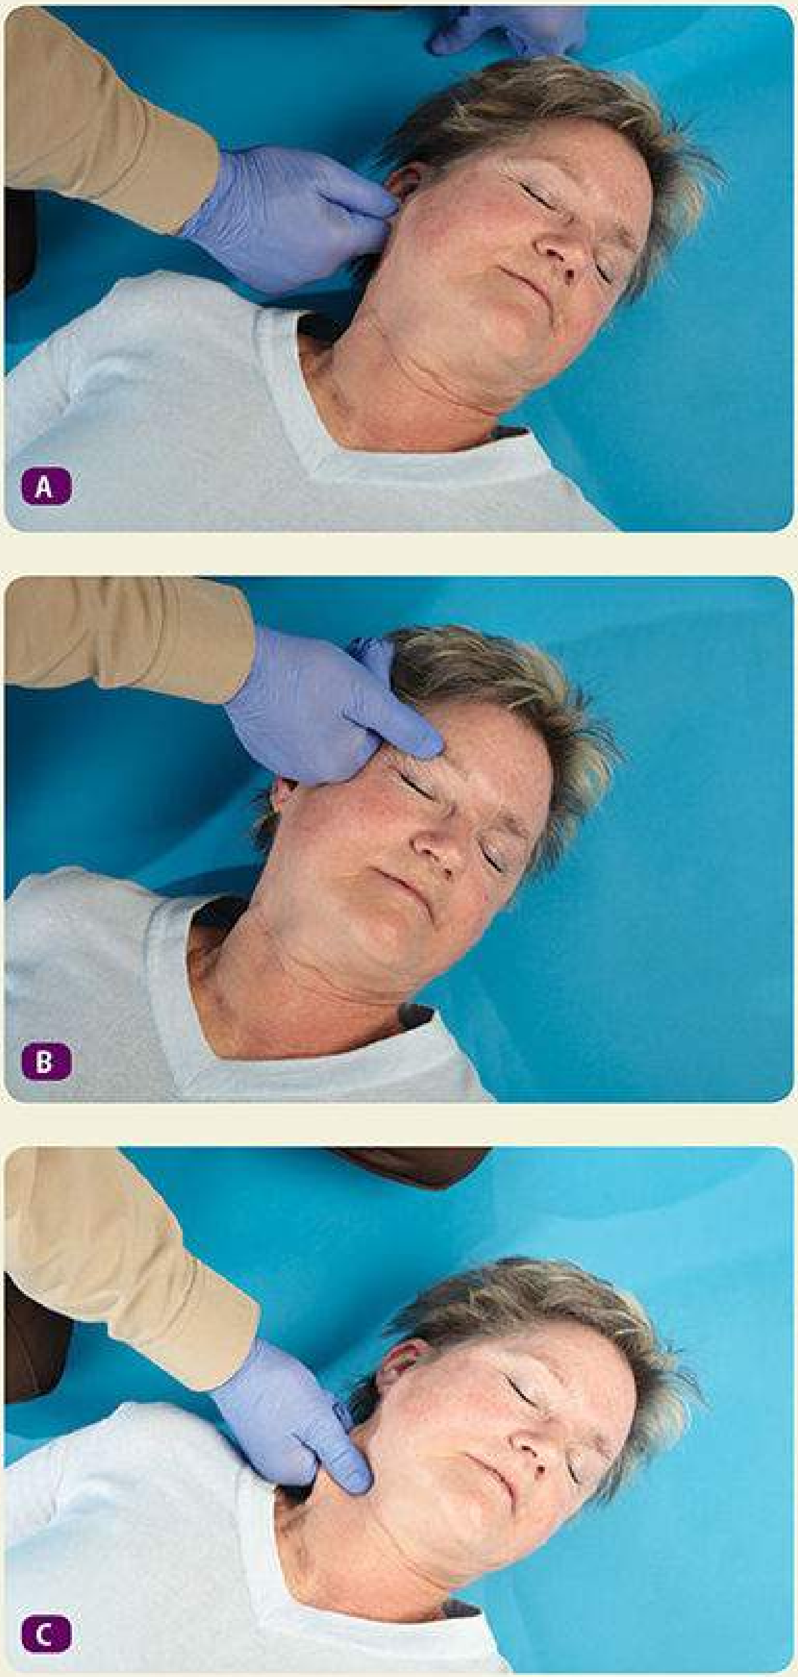


Figure 9-9 Methods of gauging a patient's responsiveness to painful stimuli. **A.** Gently but firmly pinch the patient's ear lobe. **B.** Press on the bone above the eye. **C.** Gently but firmly pinch the muscles of the neck.

If the patient does not respond to a painful stimulus on one side, try to elicit a response on the other side. Note that a patient who remains flaccid and does not move or make a sound is considered unresponsive.

For a patient who is alert or responsive to verbal stimuli, next evaluate orientation. **Orientation** tests a patient's mental status by checking his or her memory and thinking ability. The most common test evaluates a patient's ability to remember four things:

- **Person.** The patient is able to remember his or her name.
- **Place.** The patient is able to identify his or her current location.
- **Time.** The patient is able to tell you the current year, month, and approximate date.
- **Event.** The patient is able to describe what happened (the MOI or NOI).

These questions were not selected at random. They evaluate long-term memory (person and place), intermediate memory (place and time when asking year or month), and short-term memory (time when asking approximate date and event). If the patient knows these facts, the patient is said to be "alert and fully oriented," "alert and oriented to person, place, time, and event," or "alert and oriented × 4." It is important to determine, if possible, the patient's normal mental status. A number of circumstances, including ongoing illness, history of stroke, traumatic brain injury, developmental delay, Alzheimer disease, and more, may cause a patient to have a baseline of not being fully alert and oriented. Any deviation from alert and oriented to person, place, time, and event, or from a patient's normal baseline is considered an **altered mental status**.

If you determine that the patient has any of the indicators for spinal immobilization listed in **Table 9-1**, ensure that the patient's cervical spine (c-spine) is manually stabilized by either you or another provider. If it is not possible to both manually stabilize the patient's c-spine and continue your assessment to identify and correct life threats, do your best to ensure that the patient's spine remains in a stable position while you continue your primary assessment.

Identify and Treat Life Threats

Your role as an EMT is to determine if a life threat is present and, if so, to quickly address it. A life-threatening condition can quickly lead to death; the rapid process may begin with the absence or loss of meaningful communication between you and the patient. A severely sick or injured person becomes less aware of his or her surroundings and stops being able to communicate. Unless an intervention occurs, loss of consciousness may follow. The patient will become totally unresponsive to external stimuli. The muscles become slack, among them the muscles of the jaw, thus permitting the tongue to sag against the posterior part of the throat, obstructing the airway. When air can no longer enter the lungs, the patient stops breathing, cutting off the intake of oxygen and the release of carbon dioxide. The heart cannot continue to function without oxygen, and it will soon stop beating. Starved of oxygen, brain cells begin to die within a few minutes, leading to irreversible brain damage.

Table 9-1	Indications for Spinal Immobilization
Either blunt or penetrating trauma with any of the following:	▪ Pain or tenderness on palpation of the neck or spine ▪ Patient report of pain in neck or back ▪ Paralysis or neurologic complaint (numbness, tingling, partial paralysis of the legs or arms) ▪ Priapism (male patients)
Blunt trauma with any of the following:	▪ Altered mental status ▪ Intoxication (alcohol or drugs) ▪ Difficulty or inability to communicate
Distracting injury (Any injury that distracts the patient's attention from other injuries he or she may have, even severe injuries. An example is a painful femur or tibia fracture that prevents the patient from noticing back or neck pain.)	
Adapted From: National Association of Emergency Medical Technicians, American College of Surgeons. *PHTLS: Prehospital Trauma Life Support, Eighth Edition.* Jones & Bartlett Learning, pg. 298–301.	

Words of Wisdom

Distracting injuries may prevent patients from reliably identifying neck or back pain associated with an unstable fracture. Therefore, all patients with a long bone fracture and a significant mechanism of injury warrant spinal immobilization.

There are only a few general conditions that cause sudden death: airway obstruction, respiratory failure, respiratory arrest, shock, severe bleeding, and primary cardiac arrest. Often these conditions are manageable or even reversible, but to address them you have to be able to recognize them quickly and take immediate steps to correct them. This is the purpose of the primary assessment.

Lifesaving assessments and interventions include identifying airway obstructions and clearing and then maintaining an open airway. Assess the patient's breathing, and initiate ventilations in patients who have inadequate respirations or no respirations at all. Assess the skin color, temperature, and condition, and the pulse. If these appear to be inadequate, consider treating for shock (Chapter 12, *Shock*, covers the treatment for shock in detail). If the cause of shock is identifiable, attempt to correct the problem. A common example of a life-threatening cause of shock is severe bleeding. If life-threatening bleeding is found, immediately control the bleeding using direct pressure and tourniquets. If you determine that a patient is unresponsive, not breathing, and does not have a pulse, begin cardiopulmonary resuscitation (CPR), starting with high-quality chest compressions. Chapter 13, *BLS Resuscitation*, covers CPR in more detail.

In most cases, identifying and correcting life-threatening issues begins with the airway, followed by breathing and circulation (ABC). However, when a patient is in cardiac arrest, the ABCs should be assessed simultaneously in the interest of minimizing the time to first compression. Also, when a patient has life-threatening bleeding, it is more appropriate to address life threats to circulation first, following a sequence of circulation, airway, and breathing (CAB). In these cases, controlling life-threatening bleeding takes priority over airway and breathing concerns.

Assess the Airway

An airway obstruction can result in partial or complete blockage of air movement into and out of the lungs and therefore inadequate perfusion of the entire body. As you move through the steps of the primary assessment, stay alert for signs of airway obstruction. To prevent death or permanent disability to your patient, ensure that the airway remains open (patent) and adequate.

Responsive Patients

Patients of any age who are talking or crying have an open airway. However, watching and listening to how patients speak, particularly patients with respiratory problems, may provide important clues about the adequacy of their airway and the status of their breathing. A conscious patient who cannot speak or cry most likely has a severe airway obstruction.

If you identify an airway problem, stop the assessment process and work to clear the patient's airway. This may be as simple as positioning the patient so the air moves in and out, suctioning liquids from the airway, or removing an obvious foreign body from the patient's mouth; it may be as complex as abdominal thrusts or chest compressions to remove a foreign body from the airway. Although airway and breathing problems are not the same, their signs and symptoms often overlap. If your patient has signs of difficulty breathing or is not breathing, immediately take corrective actions using appropriate airway management techniques.

Unresponsive Patients

With an unresponsive patient or a patient with a decreased LOC, immediately assess the patency of the airway. Unresponsive patients may have experienced a traumatic event. If there is a potential for trauma, use the jaw-thrust maneuver to open the airway. If you cannot obtain a patent airway using the jaw-thrust maneuver or if it can be confirmed that the patient did not experience a traumatic event, use the head tilt–chin lift maneuver to open and maintain a patent airway. This maneuver is described in Chapter 10, *Airway Management*. Another cause of airway obstruction in an unconscious patient could be relaxation of the tongue muscles, allowing the tongue to fall to the back of the throat. Address this first by positioning the airway, followed by placing an oral or nasal airway. Dentures, blood clots, vomitus, mucus, food, and other foreign objects may also create an obstruction. These can be cleared with manual techniques and suctioning. These techniques are also described in Chapter 10, *Airway Management*. Once you have confirmed that the airway is clear, you can continue your assessment.

Signs of airway obstruction in an unconscious patient include the following:

- Obvious trauma, blood, or other obstruction
- Noisy breathing, such as snoring, bubbling, gurgling, crowing, stridor, or other abnormal sounds (normal breathing is quiet)
- Extremely shallow or absent breathing (Airway obstructions may impair breathing.)

If any of the aforementioned conditions exist, the airway is considered inadequate and you should open the airway using the head tilt–chin lift maneuver, suction as necessary, and use an airway adjunct as necessary. If the patient's airway is not managed quickly and efficiently, the body will not be able to receive the oxygen needed to survive.

Assess Breathing

A patient's breathing status is directly related to the adequacy of his or her airway. Once you have made sure the patient's airway is open, make sure the patient's breathing is present and adequate. A patient who is breathing without assistance is said to have **spontaneous respirations** or spontaneous breathing.

As you assess the patient's breathing, ask yourself the following questions:

- Is the patient breathing?
- Is the patient breathing adequately?
- Is the patient hypoxic?

YOU are the Provider — PART 2

When you arrive on scene, a police officer directs you to a poorly kept apartment on the second floor. The scene is safe. You find the patient, a young man, lying in a prone position on the floor in the kitchen. He was found by his neighbor, who became concerned when he did not answer the door. You carefully roll the patient to a supine position and begin your assessment. An engine company arrives to provide assistance.

Recording Time: 0 Minutes	
Appearance	Pale; blood draining from the side of the mouth
Level of consciousness	Responsive to pain
Airway	Bloody secretions and vomitus in the mouth
Breathing	Slow, shallow, and gurgling
Circulation	Radial pulse, slow and weak; skin, cool and pale

3. Is spinal immobilization indicated? Why or why not?
4. Which of these assessment findings requires your *most* immediate attention?

Positive pressure ventilations should be performed for patients who are not breathing or whose breathing is too slow or too shallow. If the patient is breathing adequately but remains hypoxic, administer oxygen. The goal for oxygenation for most patients is an oxygen saturation of approximately 94% to 99%.

If a patient seems to develop difficulty breathing after your primary assessment, immediately reevaluate the airway. When respirations exceed 28 breaths/ min or are fewer than 8 breaths/min, or are too shallow to provide adequate air exchange, consider providing positive pressure ventilations with an airway adjunct. Remember that air exchange is the critical issue, not the number of breaths. Normal breathing is an effortless process that does not affect a patient's speech, posture, or positioning. Speech is a good indicator of whether a conscious patient is having difficulty breathing. A patient who can speak smoothly without unusual extra pauses is breathing normally. However, a patient who can speak only one word at a time, or must stop every two to three words to catch his or her breath, is having significant difficulty breathing. Normal respirations are not usually shallow or excessively deep. **Shallow respirations** can be identified by little movement of the chest wall (reduced tidal volume) or poor chest excursion. Deep respirations cause a significant rise and fall of the chest. Document when the patient's respirations are shallow or deep.

Observe how much effort is required for the patient to breathe. The presence of **retractions** (indentation above the clavicles and in the spaces between the ribs) or the use of **accessory muscles** of respiration is a sign of inadequate breathing. Accessory muscles include the neck muscles (sternocleidomastoid), the chest pectoralis major muscles, and the abdominal muscles. **Nasal flaring** and seesaw breathing in pediatric patients indicate inadequate breathing. A patient who can speak only two or three words without pausing to take a breath, a condition known as **two- to three-word dyspnea**, has a serious breathing problem.

Patients who are having marked difficulty breathing will instinctively assume a posture in which it is easier for them to breathe. There are two common postures that indicate the patient is trying to increase air flow. The first position is called the **tripod position**. In this position, a patient is sitting and leaning forward on outstretched arms with the head and chin thrust slightly forward; significant conscious effort is required for breathing. The second position is most commonly seen in children—the **sniffing position**. The patient sits upright with the head and chin thrust slightly forward, and the patient appears to be sniffing **Figure 9-10**.

Figure 9-10 A patient in the sniffing position sits upright with the head and chin thrust slightly forward.

Courtesy of Health Resources and Services Administration, Maternal and Child Health Bureau, Emergency Medical Service for Children Program.

Breathing that becomes progressively more difficult requires progressively more effort. When you can see that effort, the patient's breathing is described as **labored breathing**. Initially, labored breathing is characterized by the patient's position, concentration on breathing, and the increased effort and depth of each breath. As breathing becomes more labored, accessory muscles in the chest and neck are used, and the patient may make grunting sounds with each breath. In infants and small children, nasal flaring and supraclavicular and intercostal retractions are commonly associated with labored breathing. Sometimes the patient may be gasping.

Infants and small children may have labored breathing for a sustained period, will then often become exhausted, and finally will no longer have the strength to maintain the necessary energy to breathe. In infants and small children, cardiac arrest is generally caused by respiratory arrest.

Respiratory distress occurs when a person, particularly a child, has difficulty breathing; therefore, the work of breathing is increased. Typically a person in respiratory distress has an increase in respiratory effort and rate. Respiratory failure occurs when the blood is inadequately oxygenated or ventilation is inadequate to meet the oxygen demands of the body. Respiratory arrest is the ultimate result of respiratory failure if it is not corrected Table 9-2.

Table 9-2 Signs of Respiratory Distress and Failure

Respiratory Distress	Respiratory Failure
Agitation, anxiety, restlessness	Lethargy, difficult to rouse
Stridor, wheezing	Tachypnea with periods of bradypnea or agonal respirations
Accessory muscle use; intercostal retractions, neck muscle use (sternomastoid)	Inadequate chest rise/ poor excursion
Tachypnea	Inadequate respiratory rate or effort
Mild tachycardia	Bradycardia
Nasal flaring, seesaw breathing, head bobbing	Diminished muscle tone

Assess Circulation

Assessing circulation helps you to evaluate how well blood is circulating to the major organs, including the brain, lungs, heart, kidneys, and the rest of the body. A variety of problems can impair circulation, including blood loss, shock, and conditions that affect the heart and major blood vessels. Circulation is evaluated by assessing the patient's mental status, pulse, and skin condition. You will also need to search for, identify, and control severe external bleeding.

Assess Pulse

With each heartbeat, the ventricles contract, forcefully ejecting blood from the heart and propelling it into the arteries. Often referred to as a heartbeat, the pulse is the pressure wave that occurs as each heartbeat causes a surge in the blood circulating through the arteries. The pulse is most easily felt at a pulse point where a major artery lies near the surface and can be pressed gently against a bone or solid organ.

Your first consideration when taking a pulse is to determine whether the patient has one. To determine if a pulse is present, you will need to **palpate** (feel) the pulse. Hold together your index and long fingers and place their tips over a pulse point. Press gently against the artery until you feel intermittent pulsations. In responsive patients who are older than 1 year, palpate the radial pulse at the wrist **Figure 9-11A**. In unresponsive patients older than 1 year, palpate the carotid pulse in the neck **Figure 9-11B**. When palpating the carotid pulse, place the fingertips of your index and long fingers in the center of the throat on the wind-pipe and then slide your fingers toward you into the groove between the trachea and the neck muscle. This positions your fingers directly over the carotid artery. Always palpate the carotid pulse on the same side of the patient that you are on. Use caution when palpating the carotid pulse in a responsive patient, especially an older patient. Only gentle pressure on one side of the neck should be used. Never press on the carotid arteries on both sides of the neck at the same time. Doing so can reduce circulation to the brain.

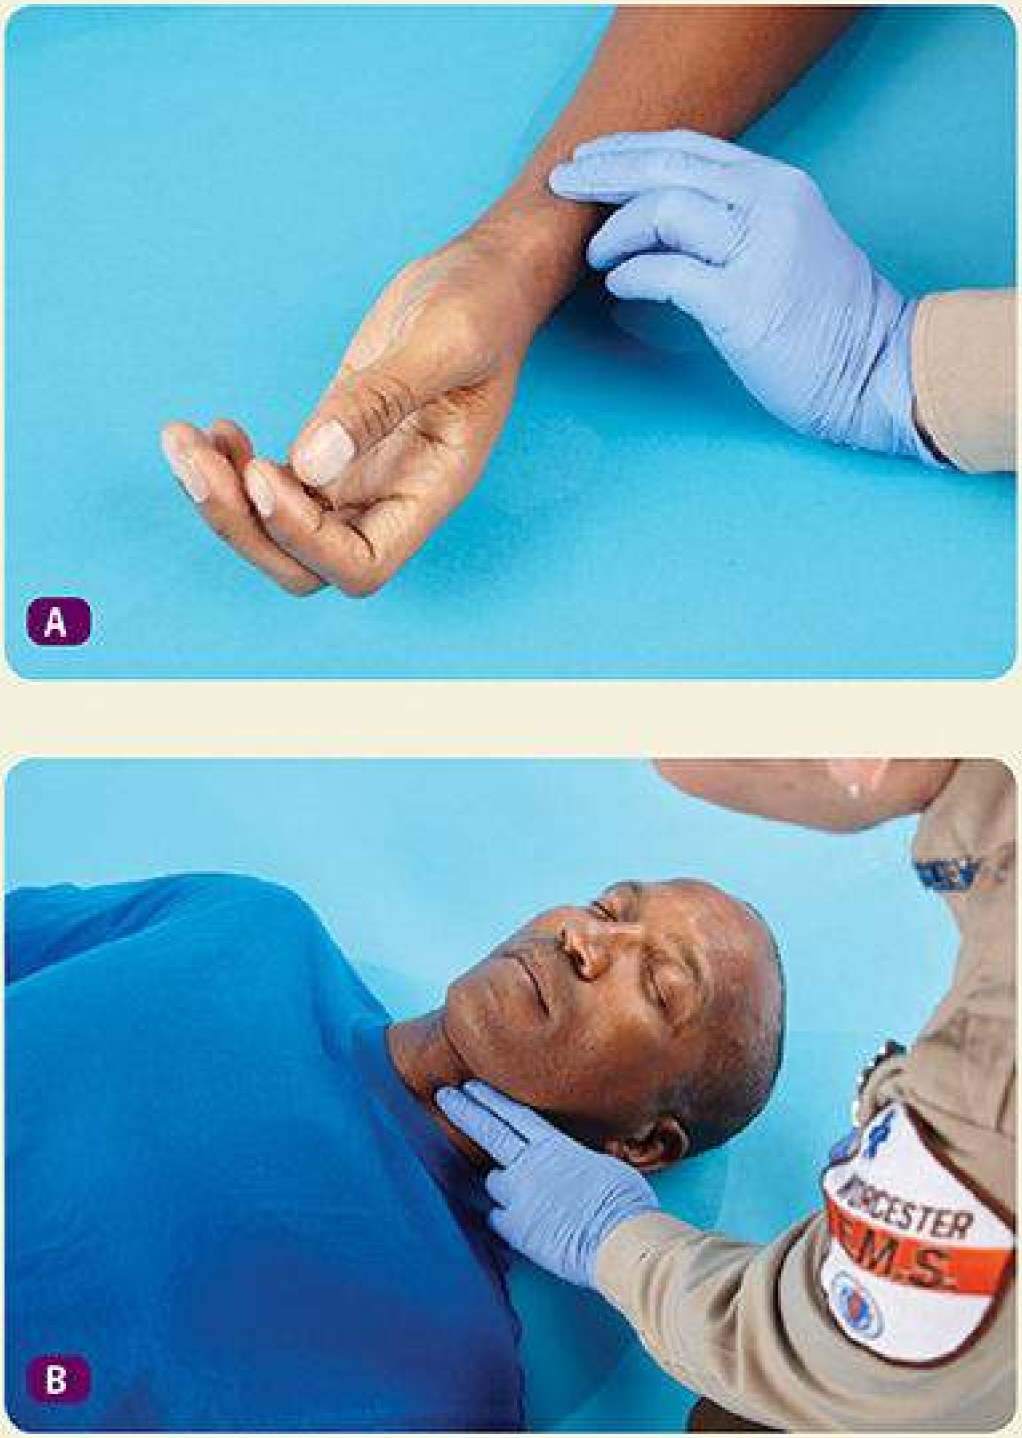

Figure 9-11 **A.** To palpate the radial pulse, place the tips of your index and long fingers over the radial artery, pressing gently until you feel intermittent pulsations. **B.** To palpate the carotid pulse, place the tips of your index and long fingers over the carotid artery, pressing gently until you feel intermittent pulsations.

Sometimes, you may have to slide your fingertips a little to each side and press again until you feel a pulse. When palpating a pulse, do not allow your thumb to touch the patient. If you do so, you may mistake the strong pulsing circulation in your thumb for the patient's pulse.

Special Populations

In infants, the radial and carotid pulses are difficult to locate.

Palpate the brachial pulse, located at the medial area (inside) of the upper arm, in children younger than 1 year **Figure 9-12**. With the infant lying supine, you can access the brachial pulse by elevating the arm over the infant's head. Because most infants have chubby arms, you need to press your adjacent fingertips firmly along the brachial artery, which lies parallel to the long axis of the upper arm, to be able to palpate the pulse.

If you cannot palpate a pulse in an unresponsive patient, begin CPR. If an automated external defibrillator (AED) is available, turn it on and follow the voice prompts, following your local protocol. An AED is indicated for use on patients who have been assessed to be unresponsive and pulseless. An AED with special pediatric pads and a dose-attenuating system should be used on pediatric patients younger than 8 years; if these are not available, an adult AED should be used. In infants (1 month to 1 year), it is preferable to perform manual defibrillation or use a dose-attenuating system; if these are not available, an adult AED should be used. More information about this is available in Chapter 13, *BLS Resuscitation*.

Figure 9-12 To palpate the brachial pulse in an infant, press firmly along the brachial artery on the inside of the upper arm.

If the patient has a pulse but is not breathing, provide ventilations at a rate of 10 to 12 breaths/min for adults and 12 to 20 breaths/min for an infant or a child. Continue to monitor the pulse to evaluate the effectiveness of your ventilations. If the patient becomes pulseless, start CPR and apply the AED. The apparent absence of a palpable pulse in a responsive patient is not caused by cardiac arrest. Therefore, never begin CPR or use an AED on a responsive patient.

With practice, you will be able to assess whether the pulse is too slow, too fast, or irregular without actually counting the pulsations. This will help to speed up your assessment of the ABCs and allow you to focus on finding other potentially life-threatening problems. A pulse rate that is too slow or too fast may change decisions related to transporting your patient. The pulse should be easily felt at the radial or carotid artery and have a regular rhythm. If it is difficult to feel or is irregular, the patient may have problems with his or her circulatory system that may need further evaluation later in your assessment.

Skin Condition

The skin has many functions. It acts as insulation and protection from infection, helps maintain the water content of the body, and has a role in regulating body temperature by changing the amount of blood circulating through the surface of skin.

Assessing the skin is one of the most important and most readily accessible ways of evaluating circulation and perfusion, blood oxygen level, and body temperature. Perfusion is assessed by evaluating a patient's skin color, temperature, moisture, and capillary refill. A normally functioning circulatory system perfuses the skin with oxygenated blood, allowing it to maintain a normal color, temperature, and moisture for the environment. Inadequate blood flow to the skin will result in abnormal findings such as pale, cool skin. This may be associated with hypoperfusion to the brain, lungs, heart, and kidneys. In most situations, hypoperfusion is caused by shock. The degree of hypoperfusion and how long it lasts will determine if a patient will sustain permanent injuries.

Skin Color. Many blood vessels lie near the surface of the skin. The skin's color is determined by the blood circulating through these vessels and the amount and type of pigment that is present in the skin. Blood is red when it is adequately saturated with oxygen. As a result, skin in lightly pigmented people is pink. The pigmentation in most people will not hide changes in the skin's underlying color, regardless of the person's race. In patients with deeply pigmented skin, changes in color may be apparent only in certain areas, such as the fingernail beds, the mucous membranes in the mouth, the lips, the underside of the arm and palm (which are usually less pigmented), and the conjunctiva of the eyes. The **conjunctiva** is the delicate membrane lining the eyelids, and it covers the exposed surface of the eye. In addition, the palms of the hands and soles of the feet should be assessed in infants and children.

Poor peripheral circulation will cause the skin to appear pale, white, ashen, or gray, possibly with a waxy translucent appearance like a white candle. Abnormally cold or frozen skin may also appear this way. When the blood is not properly saturated with oxygen, it appears blue. Therefore, in a patient with insufficient air exchange and low levels of oxygen in the blood, the blood and vessels become blue, and the lips, mucous membranes, nail beds, and skin over the blood vessels appear blue or gray. This condition is called **cyanosis** Figure 9-13.

High blood pressure may cause the skin to be abnormally flushed and red. A patient with a significant fever, heat stroke, sunburn, mild thermal burns, or other conditions in which the body is unable to properly dissipate heat will also appear to have red skin.

Changes in skin color may also result from chronic illness. Liver disease or dysfunction may cause **jaundice**, resulting in the patient's skin and sclera turning yellow. The **sclera** is the normally white portion of the eye and may show color changes even before skin color change is visible.

Skin Temperature. Normal skin temperature will be warm to the touch; normal body temperature is 98.6°F (37°C). Abnormal skin temperatures are hot, cool, cold, and clam-my (moist). When the patient has a significant fever, sunburn, or hyperthermia, the skin feels hot to the touch. The skin will feel cool when the patient is in early shock, has mild hypothermia, or has inadequate perfusion. With poor perfusion, the body pulls blood away from the surface of the skin and diverts it to the core of the body. The result is cool, pale, clammy skin; in your primary assessment, this is a good indication of hypoperfusion and shock. The skin will feel cold when the patient is in profound shock, has hypothermia, or has frostbite.

Figure 9-13

Cyanosis occurs when the patient has low levels of oxygen in the blood.

In most cases it will be adequate to assess the patient's skin temperature by feeling the patient's forehead with the back of your hand to see if it is excessively elevated or decreased. A more accurate temperature obtained with a thermometer will help in patient assessment of some cases such as environmental hypothermia or hyperthermia, infection, and septic shock. Although a wide variety of devices to measure temperature are available for use by EMS, you must operate the device exactly as the manufacturer specifies to obtain an accurate measurement.

Skin Moisture. Dry skin is normal. Skin that is moist or wet from sweat, or excessively dry and hot suggests a problem. In the early stages of shock, the skin will become slightly moist. Skin that is only slightly moist but not covered excessively with sweat is described as clammy, damp, or moist. When the skin is bathed in sweat, such as after strenuous exercise or when the patient is in shock, the skin is described as wet or **diaphoretic**.

Because the skin's color, temperature, and moisture are often related signs, you should consider them together. When recording or reporting your assessment of the skin, first describe the color, then the temperature, and last, whether the skin is dry, moist (clammy), or wet. For example, you could say or write, "Skin: pale, cool, and clammy."

Again, these characteristics are important findings in your primary assessment because hypoperfusion can lead to serious consequences if treatment is delayed or ignored.

Words of Wisdom

Remember to assess:

- Skin color
- Skin temperature
- Skin moisture

Capillary Refill. **Capillary refill** is often evaluated in pediatric patients to assess the ability of the circulatory system to perfuse the capillary system in the fingers and toes. When evaluated in an uninjured limb, capillary refill time (CRT) may provide an indication of the pediatric patient's level of perfusion. It should be kept in mind, however, that especially in an adult patient, capillary refill can be affected by the patient's position, age, history as a smoker, history of medical problems such as diabetes, medications the patient is currently taking, and exposure to a cold environment (**hypothermia**) including frozen tissue (**frostbite**) and **vasoconstriction** (narrowing of a blood vessel). Injuries to bones and muscles of the extremities may cause local circulatory compromise, resulting in hypoperfusion of an extremity rather than hypoperfusion of the body in general.

To test capillary refill, place your thumb on the patient's fingernail with your fingers on the under-side of the patient's finger and gently compress **Figure 9-14A**. The blood will be forced from the capillaries in the nail bed. Remove the pressure applied against the tip of the patient's finger. The nail bed will remain blanched (white) for a brief period. As the underlying capillaries refill with blood, the nail bed will return to its normal pink color.

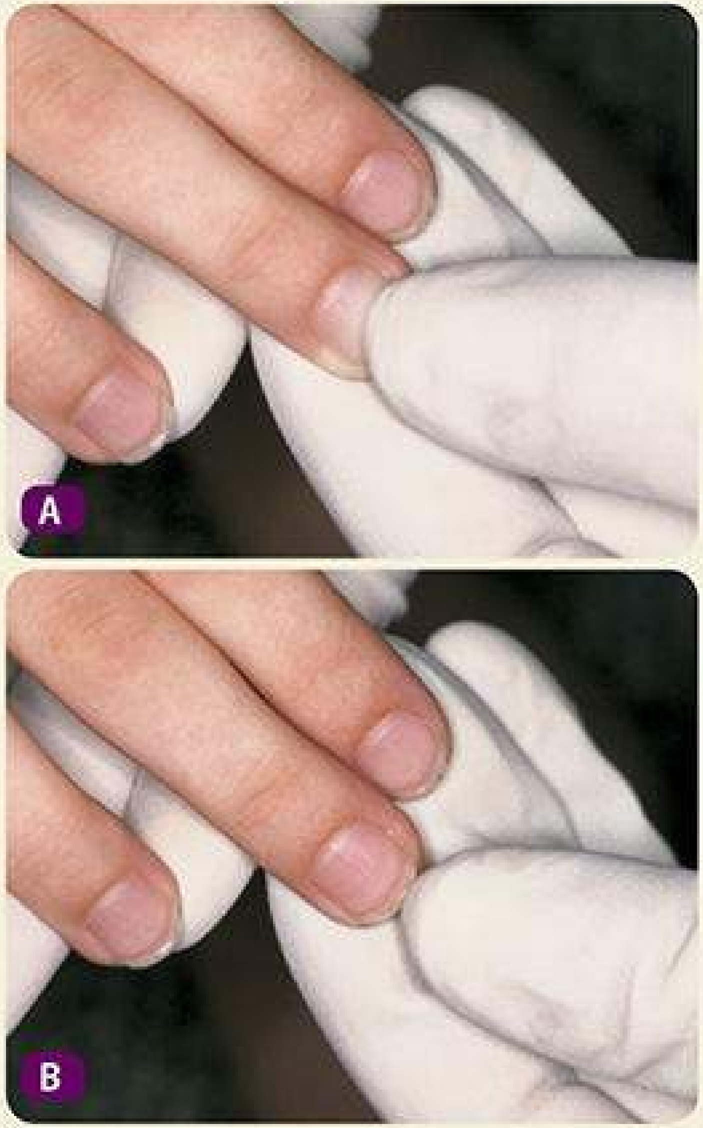

Figure 9-14 **A.** To test capillary refill, gently compress the fingertip until it blanches. **B.** Release the fingertip, and count until it returns to its normal pink color.

A, B: © Jones & Bartlett Learning. Courtesy of MIEMSS.

To assess capillary refill in newborns and young infants, press on the forehead, chin, or sternum.

With adequate perfusion, the color in the infant's or child's nail bed should be restored to its normal pink color within 2 seconds, or about the time it takes to say "capillary refill" at a normal rate of speech **Figure 9-14B**. Report and document the CRT as normal (2 seconds or less). Suspect poor peripheral circulation when capillary refill takes more than 2 seconds or the nail bed remains blanched. In this case, report and document the CRT as "delayed" or "CRT > 2." Again, delayed capillary refill is not considered an accurate indication of poor perfusion in adult patients.

Consider the capillary refill test invalid if the patient is in or has been exposed to a cold environment or if the patient is older. In both situations, delayed capillary refill may be normal, and thus, capillary refill assessment becomes unreliable.

Assess and Control External Bleeding

In trauma patients, identify and immediately control major external bleeding. This step should occur before addressing airway or breathing concerns. In some cases, blood loss can be very rapid and can quickly result in shock or even death.

Signs of blood loss include active bleeding from wounds and/or evidence of bleeding such as blood on the clothes or near the patient. Serious bleeding from a large vein may be characterized by steady blood flow. Bleeding from an artery is characterized by a spurting flow of blood. When you evaluate an unconscious patient, do a sweep for blood by quickly and lightly running your gloved hands from head to toe, pausing periodically to see if your gloves are bloody.

Controlling external bleeding is often very simple. Initially, direct pressure with your gloved hand and soon thereafter a sterile bandage over the wound will control bleeding in most cases. Direct pressure stops the bleeding and helps the blood to **coagulate**, or clot, naturally. Most minor bleeding can be adequately controlled by using direct pressure. When direct pressure is not quickly successful or whenever you encounter obvious arterial hemorrhage of an extremity, apply a tourniquet. More information about applying a tourniquet is found in Chapter 25, *Bleeding*.

Performing a Rapid Exam to Identify Life Threats

It takes about 60 to 90 seconds to perform a rapid exam of the patient's body to identify other injuries that must be managed and/or protected before the patient is transported. This is *not* a systematic or focused physical examination. That will be performed during the secondary assessment.

To perform a rapid exam of the patient to identify life treats, follow the steps in Skill Drill 9-1. Remember, this should take no longer than 60 to 90 seconds!

1. Assess the head, looking and feeling for **DCAP-BTLS** (mnemonic to help you remember Deformities, Contusions, Abrasions, Punctures, Burns, Tenderness, Lacerations, and Swelling) Step 1.
2. Assess the neck, looking and feeling for DCAP-BTLS, jugular venous distention, deviation of the trachea from midline in the neck, and **crepitus**, the sound or feeling of fractured bone ends rubbing or grinding together Step 2. In trauma patients, you should now apply a properly sized cervical collar Step 3. It is particularly important to assess the neck before covering it with a cervical collar.
3. Assess the chest, looking and feeling for DCAP-BTLS, paradoxical motion, subcutaneous emphysema, and crepitus. Listen to breath sounds on both sides of the patient's chest Step 4.
4. Assess the abdomen, looking and feeling for DCAP-BTLS, rigidity (firm or soft), and distention Step 5.
5. Assess the pelvis, looking for DCAP-BTLS. If there is no pain, gently compress the pelvis downward and inward to look for tenderness and instability Step 6.
6. Assess all four extremities, looking and feeling for DCAP-BTLS. Also assess bilaterally for distal pulses and motor and sensory function Step 7.
7. Assess the back and buttocks, looking and feeling for DCAP-BTLS. In all trauma patients, maintain in-line stabilization of the spine while rolling the patient on his or her side in one motion Step 8. It is particularly important that you check the patient's back before you log roll the patient and before you place him or her onto a backboard.

YOU are the Provider — PART 3

Your partner begins assisting the patient's ventilations with high-flow oxygen while an EMT from the engine company obtains his vital signs. You ask the police officer to inspect the patient's apartment for anything suspicious. The officer on the engine tells you that the neighbor has no knowledge of the patient's medical history. The patient's blood glucose level is assessed and reads 108 mg/dL.

Recording Time: 5 Minutes	
Respirations	8 breaths/min and shallow (baseline); ventilations are being assisted
Pulse	42 beats/min; weak and regular
Skin	Cool and pale
Blood pressure	76/58 mm Hg
Oxygen saturation (Spo_2)	95% (with assisted ventilation)

Your primary assessment of the patient reveals no obvious signs of trauma, medical alert tags, or anything else that might explain his condition. The police officer did not find any pill bottles, drug paraphernalia, or anything else suspicious. His driver's license shows that he is 25 years old. You hear on the radio that a paramedic unit has just cleared a scene and is approximately 18 minutes away.

5. Does the patient require further treatment at the scene? If so, what?
6. Should you remain at the scene and wait for the paramedic unit? Why or why not?

Skill Drill 9-1 Performing a Rapid Exam to Identify Life Threats

Step 1

Assess the head. Have your partner maintain in-line spinal stabilization if indicated.

Step 2

Assess the neck.

Step 3

Apply a cervical collar if indicated.

Step 4

Assess the chest. Listen to breath sounds on both sides of the chest.

Step 5

Assess the abdomen.

Step 6

Assess the pelvis. If there is no pain, gently compress the pelvis downward and inward to look for tenderness and instability.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 7

Assess all four extremities. Assess the pulse and motor and sensory function.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 8

Assess the patient's back. If spinal immobilization is indicated, do so with minimal movement to the patient's spine by log rolling the patient in one motion.

Determine Priority of Patient Care and Transport

The primary assessment will assist you in determining transport priority **Figure 9-15**. If you do not identify any injuries that require treatment or rapid transport when completing your assessment of the ABCs, you may find indications for rapid transport during your primary assessment of the patient's body. For example, you may identify an internal hemorrhage by the presence of a distended or firm abdomen or bilateral femoral fractures. These types of conditions are indications for rapid transport.

Would you consider your patient a high, medium, or low priority for transport? Priority designation is used to determine if a patient needs immediate transport or will tolerate a few more minutes on scene. Patients with any of the following conditions are examples of high-priority patients and should be transported immediately:

- Unresponsive
- Poor general impression
- Difficulty breathing
- Uncontrolled bleeding
- Responsive but unable to follow commands
- Severe chest pain
- Pale skin or other signs of poor perfusion
- Complicated childbirth
- Severe pain in any area of the body

Protecting the patient's spine as needed and identifying fractured extremities are integral parts of packaging for transport. If a spinal injury is suspected or found on assessment, consider spinal immobilization. If you are unsure if spinal immobilization is necessary, err on the side of caution and provide immobilization. Spinal injuries can be made worse if you neglect to assess and treat them before moving the patient.

Figure 9-15 Identifying priority patients.

Recognizing the need to transport serious trauma patients is of such importance that you may hear colleagues refer to the **Golden Hour**, also called the Golden Period. This refers to the time from injury to definitive care, during which treatment of shock and traumatic injuries should occur because survival potential is best **Figure 9-16**. Over time the body has increasing difficulty in compensating for shock and traumatic injuries. For this reason, you should spend as little time as possible on scene with patients who have sustained significant or severe trauma. Aim to assess, stabilize, package, and begin transport to the appropriate facility within 10 minutes (often referred to as the "Platinum 10") after arrival on scene whenever possible (a difficult or complex extrication may make this time goal difficult to achieve).

Words of Wisdom

The "Golden Hour" is occasionally referred to as the "Golden Period". Because many injured patients require definitive care in less than an hour, the term "Golden Period" is sometimes substituted. Regardless, the concept is that initial care must be delivered as expeditiously as possible.

Some patients may benefit from remaining on scene and receiving continuing care. For example, an older patient with chest pain may be better served on scene by being administered nitroglycerin and waiting for an ALS vehicle than by immediate transport. Support from ALS should be called for if a unit is not already en route to the scene. If ALS is delayed or farther away, coordinating a rendezvous may be a better decision for a high-priority patient. Your decision to stay on scene or transport immediately will be based on your patient's condition, the availability of more advanced help, the distance you must transport, and your local protocols.

Correct identification of high-priority patients is an essential aspect of the primary assessment and helps to improve patient outcome. While initial treatment is important, it is essential to remember that immediate transport is one of the keys to the survival of any high-priority patient. Transport should be initiated as soon as practical and possible.

Remember, the goal of your primary assessment is to identify and treat life threats, including management of airway, breathing, and circulation problems, as quickly as possible. Measure vital signs precisely during the secondary assessment (discussed later), once time and life threats are less of an issue.

If the patient's condition is stable, reassess vital signs every 15 minutes until you reach the emergency department (ED). If the patient's condition is unstable, reassess vital signs every 5 minutes, or as often as the situation permits, looking for trends in the patient's condition.

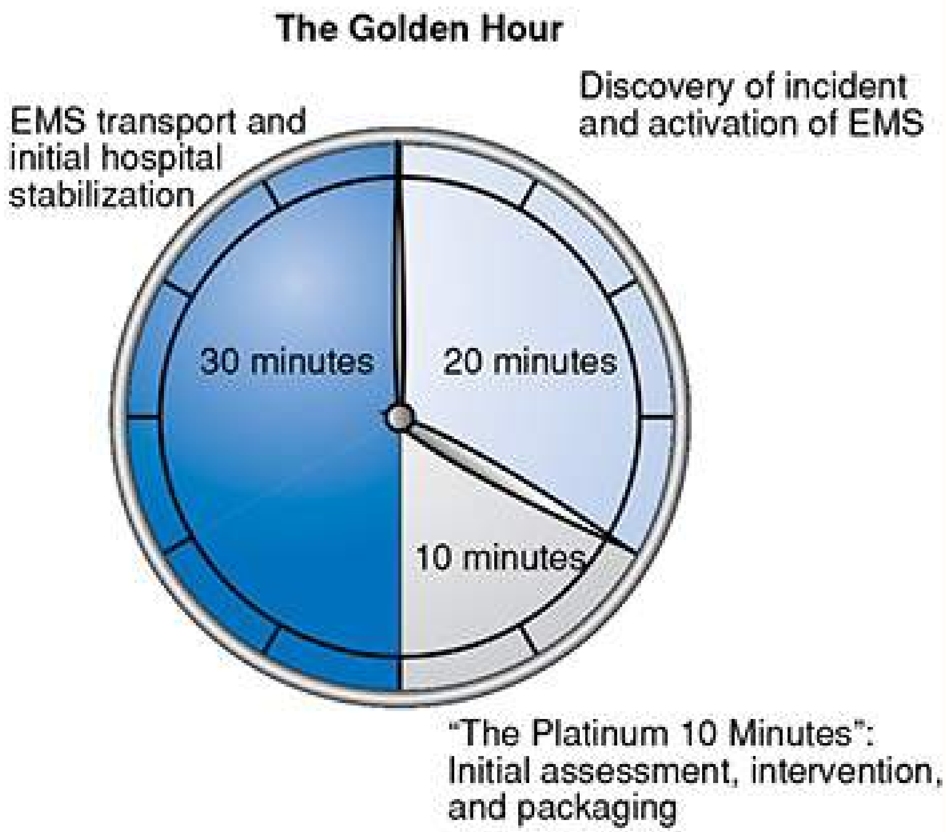

Figure 9-16 The Golden Hour, also called the Golden Period, is the time during which treatment of shock or traumatic injuries is most critical and the potential for survival is best.

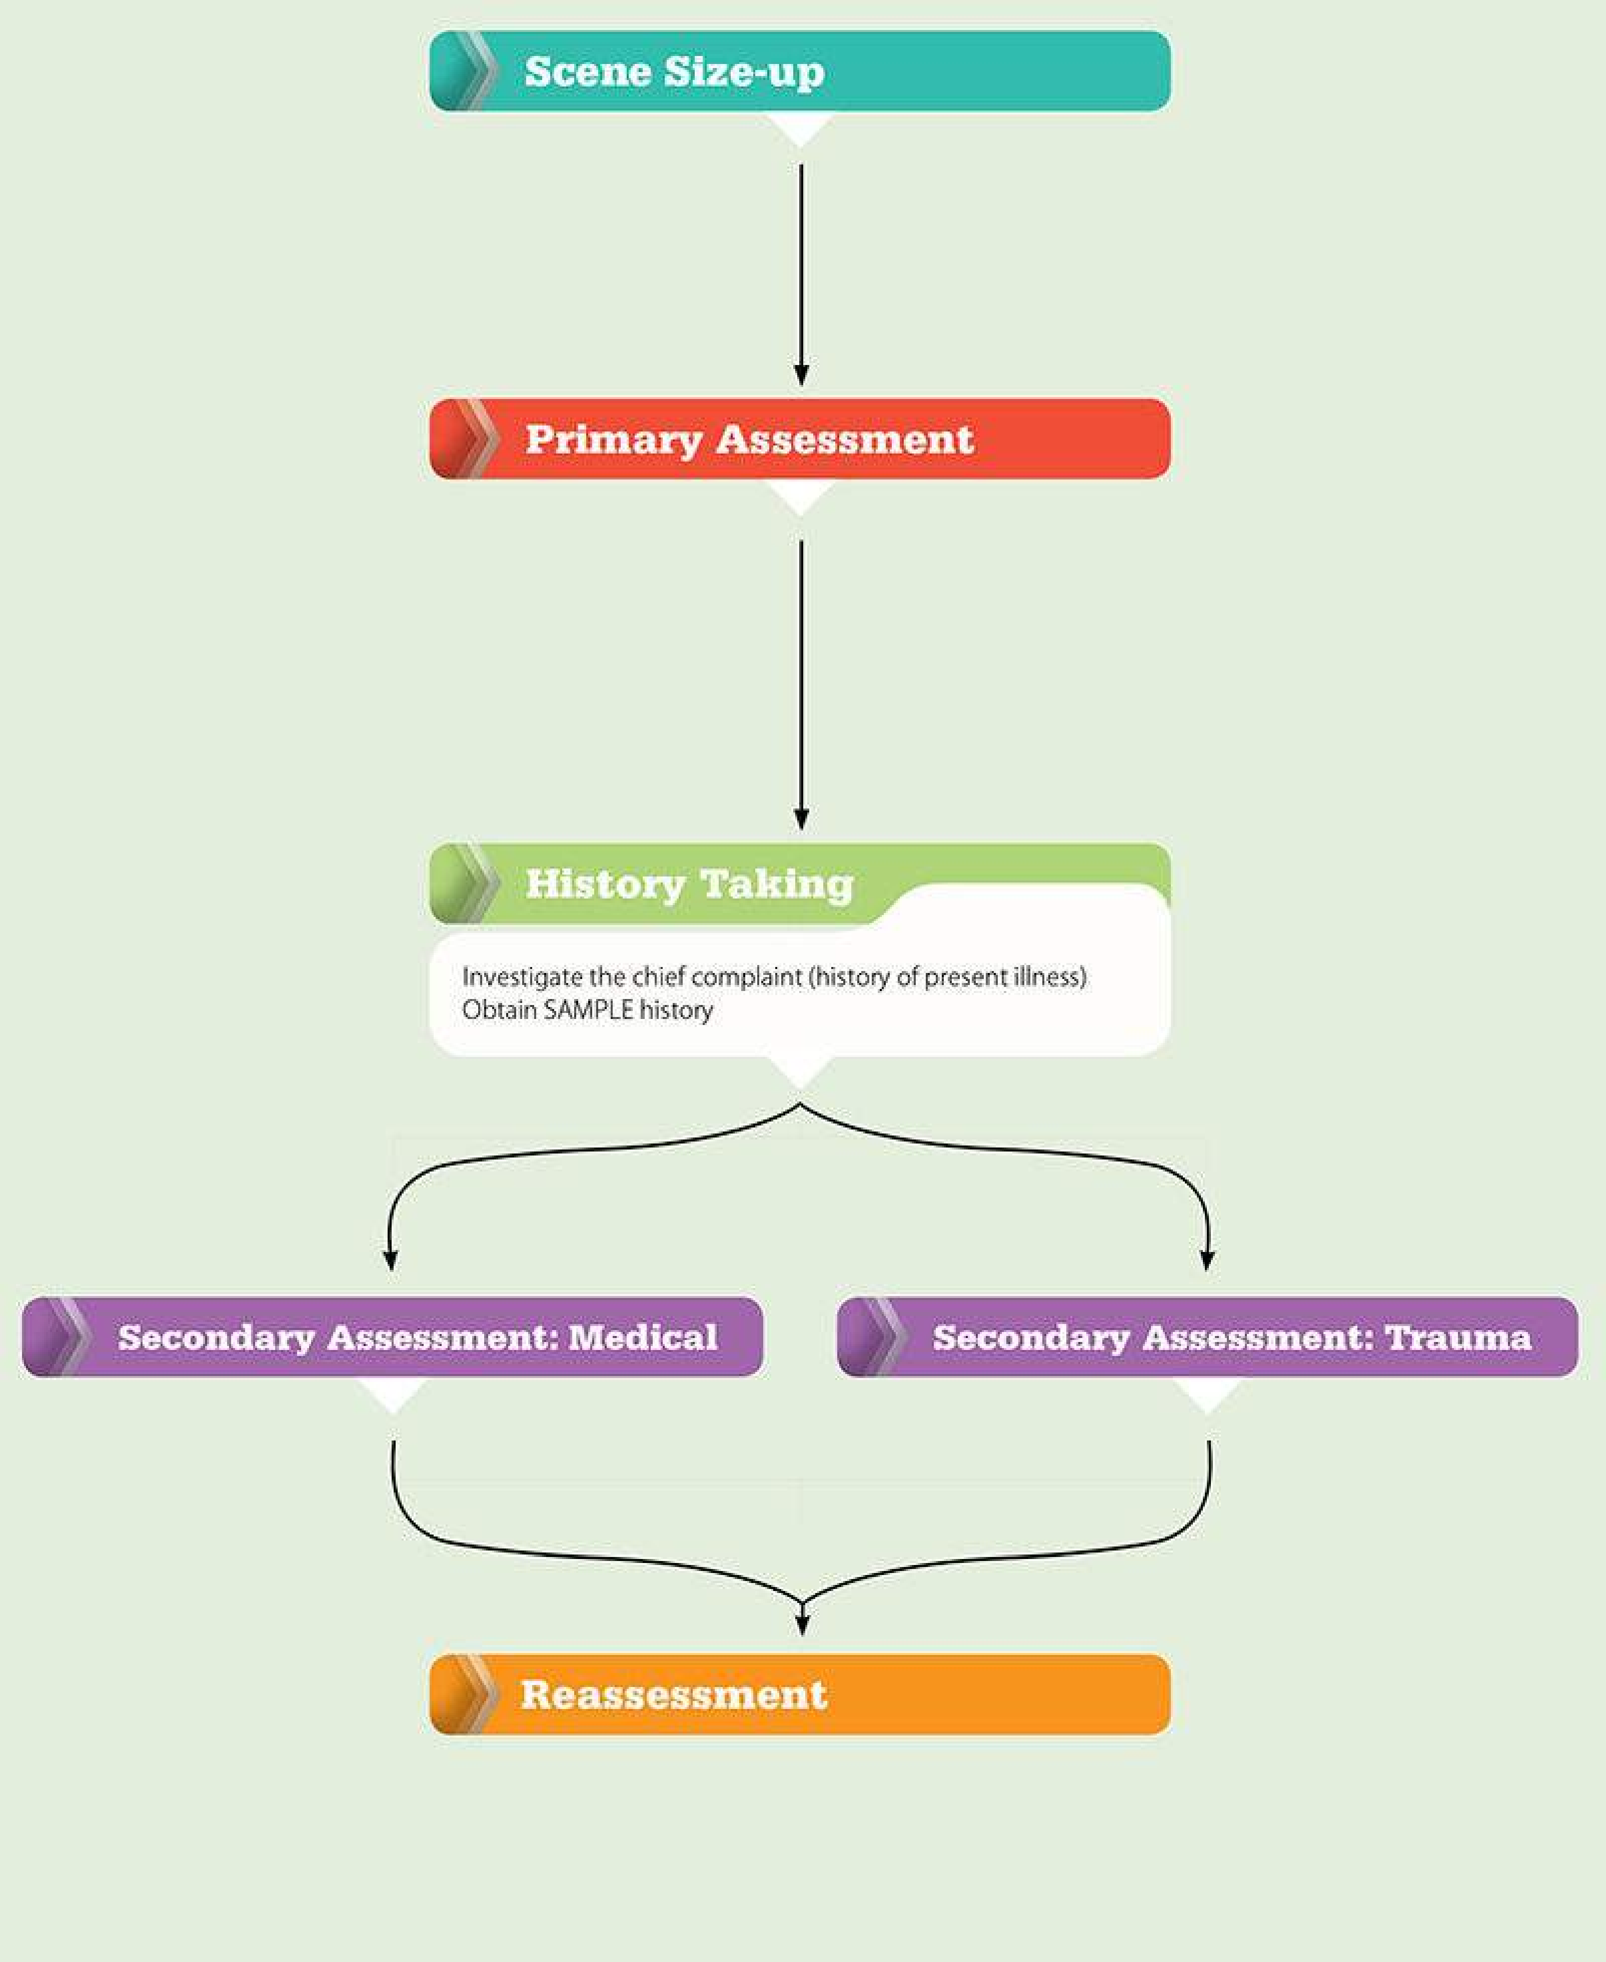
Do not be falsely reassured by apparently normal vital signs. The body has amazing abilities to compensate for severe injury or illness, especially in children and young adults. Even patients who have experienced severe medical or traumatic conditions may initially exhibit fairly normal vital signs. However, the body's ability to compensate eventually decreases (decompensated shock), and the vital signs may deteriorate rapidly, especially in children. In fact, this tendency for the vital signs to fall rapidly as the patient decompensates is the reason that it is important to frequently recheck and record vital signs. Treating a patient for shock before obvious signs of shock increases your patient's potential to survive.

Words of Wisdom

Reassess vital signs often, watching for trends that may indicate a patient is unable to compensate for his or her illness or injury. Suspect shock in any patient exhibiting tachycardia and pale, cool, clammy skin, and transport immediately.

Patient Assessment



History Taking

Although history taking is listed after the primary assessment, it is an integral part of the assessment and should be initiated on scene simultaneously with other tasks, if possible. You may work with another responder, allowing one of you to ask questions of people in the vicinity, while the other initiates patient assessment. It is important to gather as much history as possible on scene from family, friends, and bystanders because this information may be lost forever if not retrieved at this time. Also check for medical identification tags and paperwork to gain essential information concerning events leading up to the incident. If the patient is able to answer questions or a family member is transported in the ambulance with the patient, history taking can be expanded while en route. Sometimes the history may be essential to determining patient treatment; however, transport should not be delayed in patients who are in unstable condition. **History taking** provides details about the patient's chief complaint and an account of the patient's signs and symptoms. It is important to document all of the information gathered during this phase of the assessment process. This includes demographic information, past medical history, and current health status of the patient. Be sure to document the following information:

- Date of the incident
- Patient's age
- Patient's gender
- Patient's race
- Past medical history, including any pertinent information about the patient's condition, such as medical problems, traumatic injuries, and surgical procedures
- Patient's current health status, including diet, medications, drug use, living environment and hazards, physician visits, and family history

Investigate the Chief Complaint (History of Present Illness)

The patient's chief complaint is the most serious thing the patient is concerned about **Figure 9-17** and is usually the reason EMS was dispatched. To investigate the chief complaint, begin by making introductions. Make the patient feel comfortable, and obtain permission to treat. Then ask a few simple and direct questions. Refer to the patient as Mr., Ms., or Mrs., using the patient's last name. Open-ended questions such as, "What seems to be the matter?" or "What is bothering you the most today?" will help determine the chief complaint. These questions and others can help to elicit a response that may determine the patient's highest concern. The response is usually expressed in the patient's own words with simple answers like, "My chest hurts," or "I have been feeling weak." This is a good time to gather further information about the chief complaint and identify if there are any associated complaints. For a patient with a chief complaint of chest pain, ask more questions about the patient's chest pain as well as other symptoms and signs commonly related to chest pain such as shortness of breath, sweating, nausea, and weakness. Use eye contact to encourage the patient to continue speaking, and repeat statements back to the patient to show that you understand the situation. Do not interrupt, and be empathetic of the patient's situation. As discussed previously, the problems or feelings the patient reports to you are the symptoms. Symptoms cannot be felt or observed by others. Signs are objective conditions that can be seen, heard, felt, smelled, or measured by you or others **Figure 9-18**.

Figure 9-17 The patient's initial response to the question "What's wrong?" is the chief complaint.

You must consider the wide range of age groups that you will interact with. Information from infants and children may come from a parent or caregiver. Older patients may be slow to respond or have multiple complaints. Over time, every EMT develops his or her own particular technique or style to obtain a patient's chief complaint.

You will also gather information about the chief complaint from observable clues and information received from the original dispatch. If the patient is unresponsive, information about the patient, pertinent past medical history, and clues about the immediate incident may be obtained from family members present, a person who may have witnessed the situation, bystanders, medical alert jewelry, or other patient medical history documentation **Figure 9-19**. Observable signs may include things such as the patient not being able to respond using full sentences and appearing to have some respiratory distress. These clues may indicate the patient's chief complaint is "difficulty breathing," or the clues may be part of a bigger problem that has to do with a lengthy history of cardiac problems.

Figure 9-18 **A.** A symptom is a subjective condition that the patient feels and tells you about. **B.** A sign is an objective finding that you can detect by observing or examining the patient.

A, B: © Jones & Bartlett Learning. Courtesy of MIEMSS.

For example, you are called to the home of an older man who fell. This information was provided by the dispatcher, and you can use it to help process all of the clues that may be presented in what appears to be a simple fall. You find the patient lying at the bottom of the stairs. How many stairs are there, are they carpeted, and is the floor concrete, wood, or tile? Additional observable clues are used to determine a chief complaint. You note that the patient has an obvious deformity to his right arm, and your initial general impression is a possible fracture. Is this the patient's chief complaint, or is this the result of another problem? The patient states he did fall, which is how the injury occurred, and he reports pain in the right arm. However, was the fall the result of tripping on a step, or was it associated with a medical problem such as dizziness, vertigo, or a syncopal episode, all of which may have caused the fall? It is your responsibility to look at the possibilities and ask the appropriate questions to determine the patient's primary complaint.

Figure 9-19 If the patient is unresponsive, try to obtain a pertinent history or patient information from family or bystanders.

Patient interaction sometimes occurs during the worst possible time in the patient's life. These are emergency situations in which patients are afraid and confused. Some patients assume this could be the end of their lives. Sorting through the clues from the emergency scene itself, from the patient's complaints, and from the patient's signs and symptoms and past medical history will assist you in understanding the cause of your patient's problem and enable you to make appropriate, timely decisions about your patient's care.

OPQRST

You may find it helpful to use the **OPQRST** mnemonic for gathering additional information about a patient's history of present illness and current symptoms. While OPQRST can be used most easily for questions about pain, it can be adapted to quantify other symptoms such as dizziness, nausea, or shortness of breath.

O *Onset.* What were you doing when the symptoms began?
P *Provocation/palliation.* Does anything make the symptoms better or worse? How are you most comfortable?
Q *Quality.* What does the symptom feel like? Is it sharp, dull, crushing, tearing? Does it come in waves? Ask the patient to describe the symptom.
R *Region/radiation.* Where do you feel the symptom? Does it move anywhere?
S *Severity.* On a scale of 0 to 10, with 0 being "nothing at all" and 10 being "the worst you can imagine," how would you rate your symptom?
T *Timing.* Has the symptom been constant or does it come and go? How long have you had the symptom? When did it start?

Special Populations

Assessment of pain is important. According to studies by the American Academy of Pediatrics and the Society for Academic Emergency Medicine, a pain scale such as the Wong-Baker scale (discussed in Chapter 34, *Pediatric Emergencies*) may be helpful in assessing a patient's pain, especially in children and patients with a developmental delay.

Identify Pertinent Negatives

The process of gathering a patient's past medical history, history of present illness, and signs and symptoms is important, but sometimes just as important are the signs and symptoms that the patient does not have. These important negative findings are referred to as **pertinent negatives**. Often, a patient's complaint would be expected to be associated with a number of related findings. Examples include chest pain with shortness of breath, palpitations, and sweating or a severe allergic reaction with itching, hives, and trouble breathing. The absence of these findings is relevant, and should be reported and documented. Pertinent negatives are often helpful in identifying a patient's problem and choosing an appropriate treatment.

Obtain SAMPLE History

As discussed previously, the problems or feelings the patient reports to you are the symptoms. Symptoms are complaints that cannot be felt or observed by others. Signs are objective conditions that can be seen, heard, felt, smelled, or measured by you or others. As you obtain a patient history from medical and trauma patients, you will need to know some of the standard techniques for questioning patients. By obtaining a **SAMPLE history**, you will be able to gather important information from the patient. Use the mnemonic SAMPLE to obtain the following information:

S *Signs and symptoms.* What signs and symptoms occurred at the onset of the incident? Does the patient report pain?

A *Allergies.* Is the patient allergic to any medication, food, or other substance? What reactions did the patient have to any of them? If the patient has no known allergies, you should note this on the run report as "No known allergies" or "NKA."

M *Medications.* What medication is the patient prescribed? What dosage is prescribed? How often does the patient take the medication? What prescription, over-the-counter, and herbal medications has the patient taken in the last 12 hours? This includes medications taken for birth control or erectile dysfunction. How much was taken and when? Does the patient take recreational drugs?

P *Pertinent past medical history.* Does the patient have any history of medical, surgical, or trauma occurrences? Has the patient had a recent illness or injury, fall, or blow to the head? Is there important family history that should be known?

L *Last oral intake.* When did the patient last eat or drink? What did the patient eat or drink, and how much was consumed? Did the patient take any drugs or drink alcohol? Has there been any other oral intake in the last 4 hours?

E *Events leading up to the injury or illness.* What are the key events that led up to this incident? What occurred between the onset of the incident and your arrival? What was the patient doing when this illness started? What was the patient doing when this injury happened?

Critical Thinking in Assessment

Assessment is the logical and ordered process of identifying problems and setting priorities to provide treatment, but it is important that this is not done robotically "by the book." When providers do this, it is referred to as *cookbook medicine*—the process of going through steps in a process without considering other options.

Cookbook medicine does not work in emergency medical services because EMS work occurs in a dynamically changing and often chaotic environment. To provide quality patient care in this environment, you must become an expert in gathering, evaluating, and synthesizing information. This is called critical thinking; without it you will find yourself confused and unable to manage any incident that does not appear exactly the same as described in the textbook.

Gathering. The first step in gathering information involves seeking facts to help your clinical decision making and scene management. Gathering information is often a straightforward process of observing the scene and questioning the patient and bystanders. However, you may experience challenges in gathering information, such as patients who are uncooperative, are unconscious, or have communication barriers. Consider a scenario where you receive a call for a patient with a headache and flu-like symptoms. The call occurs during cold weather flu season so it is possible that this patient simply has a cold or flu. As you gather more information on scene, you learn that the patient believes that he got sick from his family and they are all experiencing the same signs and symptoms. The patient also tells you that the heater in their home is not working properly, leaving them with chills, and that he has been happy on the days that he has been able to make it into work because he feels much better there.

Evaluating. The next step is to consider what the information gathered means. In the previous example, while it is possible this is simply a case of cold or flu moving from person to person within a household, you must use critical thinking skills and consider other conditions that would produce the same signs and symptoms. In this case, the same signs and symptoms might be caused by carbon monoxide. Several other elements of information that you have gathered point in that direction as well, including a malfunctioning heater, everyone in the house experiencing the same signs and symptoms, and that the patient feels better when out of the house.

Synthesizing. The final step in critical thinking is putting together the information that you have gathered and validated, and synthesizing it into a plan to manage the scene and/or care for the patient. In the previous example, you may choose to continue your primary assessment of the patient while you direct your partner to reassure the bystanders and try to gather any additional information. You may also recommend the evacuation and evaluation of all occupants of the house, as well as calling for the fire department to meter the house for carbon monoxide.

Taking History on Sensitive Topics

Alcohol and Drugs. The signs and symptoms a patient may have while under the influence of alcohol or drugs may be confusing, hidden, or disguised. Many patients who abuse alcohol and/or drugs may deny having any problems. Families, friends, and coworkers may be unaware that a patient has any drug or alcohol troubles because patients often hide their dependency from these same people. The reasons patients deny using alcohol or drugs can vary greatly. It may be out of fear of losing their employment or driver's license, worry about what friends may think about them, and embarrassment or insecurity about their dependency.

The history that you gather from a chemically dependent patient may be unreliable Figure 9-20. If patients are not telling the people closest to them that they have a problem, you, as an outsider, may have even less success in obtaining information about a patient's current dependency. The signs and symptoms of alcohol or drug use may be masked by the patient's presentation. Use all of your senses when dealing with patient care.

Establish a strong rapport with your patients. Do not judge a patient who may have a chemical dependency, and be professional in your approach. Be honest and open. Above all, impress on the patient that information received will be kept in confidence. Then and only then, a patient may open up to you and provide information that can be valuable in his or her assessment and treatment.

Figure 9-20 Many vehicle crashes involve alcohol. In these cases, the patient history may not be reliable.

Physical Abuse or Violence. All cases of suspected physical abuse or domestic violence must be reported to the appropriate authorities. Follow your state laws and local protocols when dealing with such cases. If you suspect a patient is a victim of physical abuse or domestic violence, do not accuse any person of being responsible for the situation. Instead, immediately involve law enforcement.

Because abuse and physical violence are very sensitive situations, look for hidden clues that such a situation exists.

Information gathered at the scene, during the assessment process, and while transporting a patient may indicate violence or abuse.

What should you look for? When gathering a history, determine if the information provided by the patient and others present at the scene is inconsistent. Do you observe multiple injuries in various stages of healing? Are some bruises red, black, brown, or even green? In some cases, a victim of abuse or violence will not tell you what happened because of fear of further violence when EMS is not present. Victims may not answer your questions because the physical aggressor is still present and is answering questions for the patient. In these cases, separate the people present and interview both parties about the situation.

In cases of domestic violence, involvement can be extremely dangerous. If you determine that the emergency response is part of a domestic abuse situation, call law enforcement personnel immediately **Figure 9-21**.

When involved with cases of physical abuse, be very observant and open-minded, have a high index of suspicion, and be nonjudgmental. Documentation will be very important in cases of abuse and domestic violence. Your documentation should be an objective report of the facts. Avoid subjective, judgmental statements, and include any pertinent statements made by the patient or others present using quotation marks. Remember, these prehospital situations will most likely involve some type of legal process later on. You may be summoned several years later to provide testimony regarding what may have happened, which makes accurate and thorough documentation very important.

Sexual History. Obtaining information about a patient's sexual history may be limited because a number of factors may influence the details a patient may reveal. Religious beliefs, cultural stereotypes, and society's expectations may have a major role in patients not revealing a very personal side of their life, including practices considered by some people to be bizarre or exotic. In addition, some patients find sharing information regarding their sexual history with others very uncomfortable.

Figure 9-21 Do not handle potentially violent calls alone. Summon law enforcement personnel.

When would information about a patient's sexual history become important? As an EMT, you will be involved in the care of female patients reporting lower abdominal pain. You should consider all women of childbearing years who are reporting lower abdominal pain to be pregnant unless ruled out by history or other information. There are a number of questions to ask when faced with this prehospital scenario:

- When was your last menstrual period?
- Are your periods normal? (Is there any vaginal discharge or bleeding not associated with a menstrual period?)
- *If the patient is bleeding:* How many sanitary pads or tampons have you used?
- Do you have urinary frequency or burning?
- What is the severity of cramping, and are there any foul odors?
- Are you sexually active?
- Is there a possibility you may be pregnant?
- Are you taking birth control pills?

When dealing with a male patient, you must inquire about urinary symptoms:

- Is there pain associated with urination?
- Do you have any discharge, sores, or an increase in urination?
- Do you have burning or difficulty voiding?
- Has there been any trauma?
- Have you had recent sexual encounters?

When appropriate, ask about the potential for sexually transmitted diseases. Gathering this information may be difficult and uncomfortable for the patient. Never be judgmental once this information is gathered. All patients should be, and expect to be, treated with compassion and respect. All information gathered from a patient for the purpose of determining a treatment plan is strictly confidential and should not be shared with others unless necessary in the process of treating a patient's medical or traumatic condition.

Special Challenges in Obtaining Patient History

Dealing with patient care, you will be faced with a number of challenges, many of them new and difficult. Each and every patient interaction should be viewed as a new experience and handled as an educational opportunity as well.

Silence. Dealing with patients who say very little or say nothing at all can be difficult and frustrating. Patience is extremely important when dealing with patients and their emergency crises. Patients may be thinking about how to answer you, getting the facts straight, or assessing your crew to determine if they feel comfortable answering you. Using a close-ended question that requires a simple yes or no answer may work best. Consider whether the silence is a clue to the patient's chief complaint.

Always look for visual signs in the patient's environment that may indicate why a patient is not communicating. In addition, look for nonverbal clues, including facial expressions that may show pain or fear. Is the patient distressed or intimidated by your presence? How is the patient sitting or standing? Is there a communication problem? Is there a language problem? There are many reasons a patient may be silent during the prehospital encounter. A good EMT will continue to assess the situation and determine a way to communicate with the patient.

Overly Talkative. On the other end of the spectrum is the patient or bystander who is extremely talkative. Some people just talk a lot, and gathering details about their medical condition may be difficult if they talk around your question or you have a difficult time refocusing the patient's conversation. Some possible causes as to why a patient may be overly talkative could include excessive caffeine consumption; nervousness; ingestion of cocaine, crack, or methamphetamines; or some underlying psychologic issue.

YOU are the Provider — PART 4

As you are packaging the patient and preparing to move him from his apartment, the paramedic unit is dispatched to another call. There are no other paramedic units in your district. You move the patient from his apartment and load him into the ambulance. With an EMT from the engine company assisting you in the back with the patient, you depart the scene and reassess the patient. The closest appropriate hospital is 25 minutes away.

Recording Time: 12 Minutes	
Level of consciousness	Unconscious and unresponsive
Respirations	6 breaths/min (baseline); ventilations are being assisted
Pulse	44 beats/min; weak and regular
Skin	Pale and cool; cyanosis noted around mouth

Blood pressure	78/54 mm Hg
Spo_2	88% (with assisted ventilation)

7. How has your patient's condition changed from the previous assessments?
8. What should you do in response to the patient's change in condition?

Once you have allowed a talkative patient a chance to express himself or herself, you must keep the patient focused on the questions presented. Have the patient stick to the facts, and clarify statements for the purpose of making sure the information you are gathering is correct. Remember that there is no such thing as too much information.

Multiple Symptoms. Some patients present with multiple symptoms. This is often true of older patients. Prioritize the patient's complaints as you would in triage; start with the most serious and end with the least serious. Always ask for additional information to determine why EMS was called.

Keep an open mind, and do not focus on just one complaint or detail to determine a treatment plan. Always remember there may be a number of possible medical or traumatic causes for a patient's chief complaint.

Anxiety. When a person is involved in an emergency situation, it is natural for that person to appear excited or anxious. Many people have not been faced with a true emergency during their lifetime and part of your job as an EMT will be to help provide calm to the situation. It is important to also consider the context of the situation and recognize that the anxiety you are observing may be a sign of a serious underlying medical condition. Your patient or bystander may be nervous, pacing, vocal, panicked, or, in some extreme cases, experiencing complete hysteria. It is your responsibility to deal not only with the emergency crisis at hand, but also with the people present who are having difficulties coping with the situation. Frequently, anxious patients can be observed in emergency scenes that involve a large number of patients, such as during a disaster. Anxiety also can be observed or encountered during a routine EMS call when family members or patients cannot cope.

Some anxious patients exhibit signs of psychologic shock, such as pallor, diaphoresis, shortness of breath, numbness in the hands and feet, dizziness or light-headedness, and even loss of consciousness. They may have no real medical complaint but may be hiding or concealing something, such as trying to keep a family member, friend, or employer from discovering their dependency on alcohol or drugs. Or, the patient may have been involved in a physical abuse or domestic situation that he or she wants to keep quiet. In any situation involving an anxious patient, be aware of verbal and nonverbal clues. Is the patient making sense during a verbal conversation? Anxiety can also be an early indicator of low blood glucose level, shock, or hypoxia. Perform the appropriate examination to rule out these potentially life-threatening causes early in your assessment.

During a crisis situation, reassure the patient that any nervous or anxious response is normal and can be overcome. It may be possible for you to control an anxious patient by simply smiling or using a delicate touch. Be confident in your approach, and have a positive demeanor. In many patient care interactions, your presence may be all that is required to calm the patient.

As in every response, safety is a paramount concern. Be aware that emergency responses involving anxious and possibly hysterical patients can turn violent. A confident but cautious EMT can prevent a bad situation from getting worse and professionally calm and control anxious patients, friends, and family members.

Anger and Hostility. Every patient encounter has the potential for verbal hostility and physical violence, from a situation involving a 9-year-old boy who was hit by a vehicle to a 90-year-old grandmother experiencing chest pain. Emergency calls have a high potential for sudden violence because friends, family, or bystanders may direct their anger and rage toward you. Do not to take this anger and frustration personally. More important, do not become angry yourself because "anger feeds anger."

When handling potentially violent situations, remain calm, reassuring, and gentle. Always be observant. Be aware of nonverbal clues, such as posture, position, and facial expressions. Look at the patient, and be aware of how the patient is positioned. Is the patient stiff, with hands clenched and feet wide apart? Is his or her body weight all on one leg? This may indicate the patient has assumed a position to allow him or her to kick.

If the scene is not safe or secured, retreat until it is secured. Never let a potentially violent or hostile patient leave the room alone. Understand that everything in reach of a patient has the potential to be used as a weapon.

Intoxication. The number of EMS calls dealing with an intoxicated patient has increased over the years. When you attempt to gather a history for an intoxicated patient, be aware the information may not only be difficult to get, but could also be unreliable. An intoxicated patient may become very impatient with you when he or she is trying to provide you with information. As the patient's impatience increases, so does his or her anger level. Do not put an intoxicated patient in a position where he or she feels threatened and has no way out. As in other emergency cases, the potential for violence and a physical confrontation is high when a patient is intoxicated.

During the assessment and treatment of a patient who has consumed alcohol, be accepting, diplomatic, objective, and nonjudgmental. Because of the intoxication, the patient may not be telling you everything about how he or she feels. Alcohol dulls a patient's senses, which will make it difficult for an intoxicated patient to inform you that something feels painful. Treat the patient with dignity and respect despite the intoxication. Never presume that the patient's condition is the result of alcohol consumption when there may be an underlying medical or traumatic cause for the patient's presentation.

Crying. A crying patient is a breathing patient. A patient who cries may be sad, in pain, or emotionally overwhelmed. No matter the reason for crying, you need to be calm, patient, reassuring, confident, and maintain a soft voice.

Your presence may make a crying patient feel more secure. In some extreme cases, additional verbal intervention will help the patient. As with all patients, treat a crying patient with respect and dignity.

Depression. Depression is a common reason patients call EMS. In fact, according to the WHO, depression is among the leading causes of disability worldwide. Some of the symptoms a patient with depression will have include sadness, a feeling of hopelessness, restlessness, and irritability. The patient may also have sleeping and eating disorders and a decreased energy level. Depression is a normal human response, but it can lead to harmful behavior. In the treatment of depression, be nonjudgmental and compassionate toward the patient's feelings. The most effective treatment in handling a patient's depression is being a good listener. Oftentimes, the patient just needs someone to talk to and someone to listen.

Confusing Behavior or History. Patients sometimes provide more or additional history information to hospital personnel because they are embarrassed or frightened about telling the EMTs and they may feel more comfortable talking with hospital staff. Whatever the situation may be, there are medical causes that you must be aware of that can cause a patient to report a confusing history. Conditions such as hypoxia, stroke, diabetes, trauma, medications, and other drugs could alter a patient's explanation of events. One of the most common causes of confusion is hypoxia. It is not uncommon to encounter an older patient who has dementia, delirium, or Alzheimer disease. It is important to verify the normal mental status of each patient. Do not assume that because a patient is older he or she has one of these conditions.

Confused behavior is not a normal response. After you have properly assessed and treated any life threats, attempt to ask the patient again about the chief complaint or ask someone close to the patient, such as family members or friends, to provide additional details.

Limited Cognitive Abilities. Cognitive disabilities can range from those that are barely recognizable to those that are very severe. You should develop a method for dealing with a patient who has limited cognitive abilities. First, assume you can get an adequate history. Keep your questions simple, and limit the use of medical terms. Be alert for partial answers, and keep asking questions. In cases of patients with severely limited cognitive function, rely on family, caregivers, and friends to supply answers to your questions.

Cultural Challenges. As an EMT, you are likely to provide care for patients from a variety of different backgrounds and cultures. Cross-cultural communication is an important skill for you to develop to provide proper medical care to all patients equally. Just as you may experience physical challenges to providing good field care, you might also need to overcome cultural and literacy barriers to provide proper prehospital services.

For example, you may obtain only a limited patient history if you ask questions using health care terminology. The patient may have limited understanding of medical language and have difficulty answering your questions. Or, you may encounter a patient from a culture that prefers to speak only with health care providers of the same gender.

Strategies for overcoming cultural challenges include gaining an understanding of the cultures and patient backgrounds you might encounter on emergency calls; gaining the assistance of the patient's friends or family members; and enlisting the help of health care providers of the same culture or background.

Language Barriers. We live in a country that is a melting pot of people with diverse nationalities. Not everyone speaks English. For example, you respond to a call for an older woman who fell at a nursing home. The emergency response seems pretty straightforward until you ask the patient what happened and she answers in French. If you don't speak the language, how will you ask the patient to describe what happened and what hurts? Keep in mind that some patients may have disabilities that make it difficult to understand them in any language.

To overcome language barriers, consider using interpreters, translation resources, and related mobile device apps.. The best answer is to find an interpreter, but it is not always that simple. First, determine whether the patient speaks or understands any English by asking the patient or others who may be present. Start by introducing yourself by using your name. Determine whether the patient understands who you are. If the patient is able to respond by giving you his or her name, the patient has the ability to understand some English. Remember that increasing the volume of your questions will not increase the patient's understanding of what you are asking him or her. Keep questions straightforward and brief. Simple is best in these patient situations. Use of hand gestures may be helpful.

Be aware of the language diversity in your community. Some dispatch centers and most hospitals have set up programs within the institution that identify various employees who can speak different languages. Provide the hospital with advance notice that a non–English-speaking patient will be arriving. This will allow the hospital the opportunity to make arrangements for an interpreter.

Family and friends on the scene may temporarily interpret for you in an emergency. Using an untrained interpreter increases the risk of misunderstanding, but often cannot be avoided on 9-1-1 calls. When asking questions through an interpreter, continue to look at the patient. Avoid using children to interpret except when there is no other option.

Hearing Problems. Hearing disabilities in patients range from very slight to total deafness. Hearing problems can make the process of obtaining an in-depth history difficult. When you are treating a patient who has a hearing loss, ask questions slowly and clearly. You may want to use a stethoscope to function like a hearing aid; have the patient place the stethoscope in his or her ears while you speak into the stethoscope bell, which will amplify the sound. Changing the pitch of your voice may also help the patient to hear you.

Oftentimes, a patient who has had a hearing disability for some time will have mastered the technique of reading lips. If the patient has a hearing aid, ask the patient to use it. Speak slowly and face-to-face with the patient. Some deaf patients will attempt to use sign language for communication, which can be difficult for others to understand. Learning simple sign language will help you in the communication process. Probably the simplest way to communicate with a patient who has a hearing deficit is to use a pencil and paper. Write uncomplicated questions that require simple yes or no answers. If the patient cannot see clearly and has glasses, ask the patient to put them on.

Special Populations

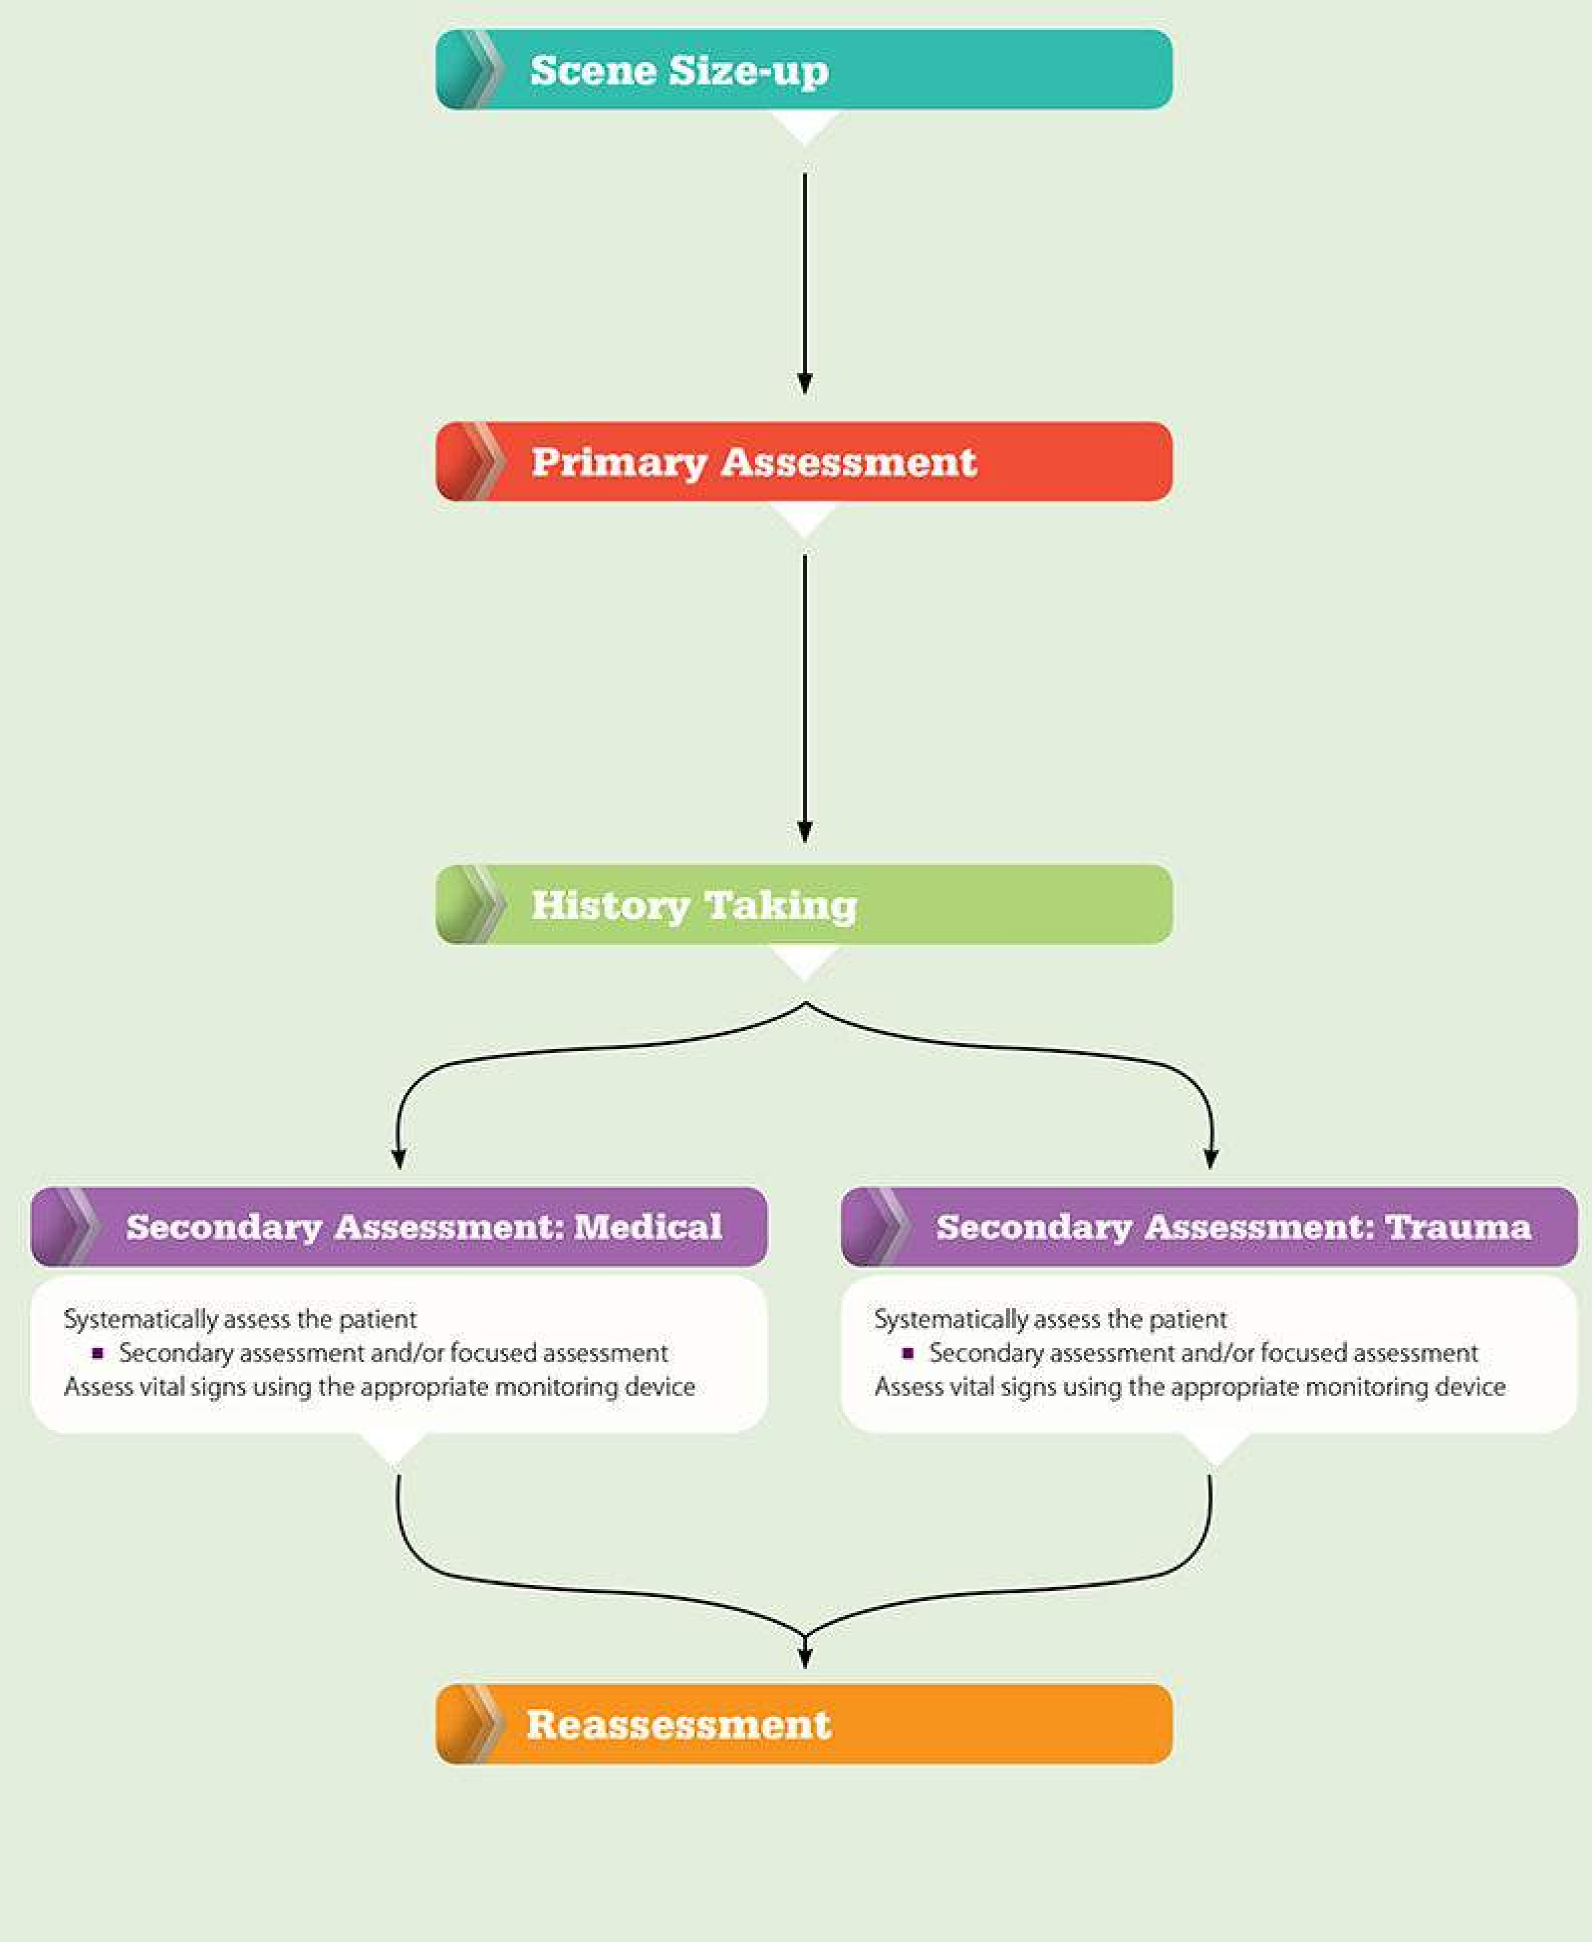
There are many mobile device apps available to help you communicate with patients who are deaf or who speak another language.

Visual Impairments. Identify yourself verbally when you enter the home of a visually impaired patient who has called for help. Announcing yourself when entering a residence lets a patient know that help has arrived. Any response from the patient may help you safely locate the patient's whereabouts.

During the assessment and subsequent treatment of a patient who is visually impaired, it is important that you put any items that have been moved back into their previous position. Many visually impaired patients can move freely about their homes because they know exactly where everything is placed.

During the assessment and history-taking process, explain each step in your vital signs assessment. Notify the patient when you prepare to lift and move him or her on the stretcher. Remember, you are a stranger to the patient, and an EMS vehicle is a foreign environment. A little communication can ease uncertainty in a visually impaired patient. If the patient is not able to provide you with all of the necessary information, try to find someone else who can.

Patient Assessment



Secondary Assessment

If the patient is in stable condition and has an isolated complaint, you may choose to perform the secondary assessment at the scene. If the secondary assessment is not performed at the scene, it is performed in the back of the ambulance en route to the hospital. However, you may not have time to perform a secondary assessment if you have to continually manage life threats that were identified during the primary assessment.

The purpose of the **secondary assessment** is to perform a systematic physical examination of the patient. The physical examination may be a systematic head-to-toe secondary assessment or an assessment that focuses on a certain area or system of the body, often determined by the chief complaint (a focused assessment). Circumstances will dictate which aspects of the physical examination will be used.

Words of Wisdom

Patients may feel vulnerable and exposed during a physical examination. Display compassion during this difficult time. It is also important to cover the patient as much as possible during your assessment to maintain the patient's modesty and body temperature.

The following are guidelines on how and what to assess during a physical examination:

- **Inspection.** Inspection is simply looking at your patient for abnormalities. This is done by looking for anything that may indicate a problem. For example, swelling in a lower extremity may indicate an acute injury or a chronic illness.
- **Palpation.** Palpation describes the process of touching or feeling the patient for abnormalities. Palpation may be gentle or firmer to help you identify where the patient has pain. Your fingertips are best suited for detecting texture and consistency, while the back of your hand is best suited for noting temperature.
- **Auscultation.** Auscultation is the process of listening to sounds the body makes by using a stethoscope. For example, when measuring a patient's blood pressure, you listen (**auscultate**) with a stethoscope to the sound of the flow of blood against the brachial artery as you release the pressure in a blood pressure cuff. This is auscultation of a blood pressure. When auscultating, make sure the earpieces of the stethoscope are facing forward when placed in your ears.

The mnemonic DCAP-BTLS will help remind you what kinds of abnormal findings to look for when inspecting and palpating various body regions.

An integral part of your physical examination is to compare findings on one side of the body with the other side when possible. For example, if a patient reports a grating or grinding sensation in his or her arm or you note air bubbles under the skin that produce a crackling sound, check the other arm before determining that the sensation or noise is caused by fractured bone ends or joints rubbing together (crepitus). If one ankle appears swollen, look at the other. If one shoulder feels "out of joint," feel the other one to compare. When listening to breath sounds, listen to both sides of the chest. If possible, find out what conditions are new and which ones the patient has been experiencing for some time. Do not assume that just because a patient has a condition that is causing discomfort, it just happened. As you assess, ask what, if anything, has changed about the condition.

On some occasions, it may even be helpful to note odors during an examination. Odors can indicate anything from infections, to certain medical conditions, to scene safety threats.

Systematically Assess the Patient—Secondary Assessment

The goal of the secondary assessment is to identify hidden injuries or identify causes that may not have been identified during the 60- to 90-second exam that took place during the primary assessment. Any patient who has sustained a significant MOI, is unconscious, or is in critical condition should receive this type of examination. An unconscious patient is unable to tell you what is wrong; therefore, this type of examination may give you clues to identify the problem.

To perform a secondary assessment of a patient with no suspected spinal injuries, follow the steps in Skill Drill 9-2:

1. Look at the face for obvious lacerations, bruises, and deformities Step 1.
2. Inspect the area around the eyes and eyelids Step 2.
3. Examine the eyes for redness and for contact lenses. Assess the pupils using a penlight Step 3.
4. Look behind the patient's ears to assess for bruising (Battle sign) Step 4.
5. Use the penlight to look for drainage of spinal fluid or blood in the ears Step 5.
6. Look for bruising and lacerations about the head. Palpate for tenderness, depressions of the skull, and deformities Step 6.

7. Palpate the zygomas for tenderness or instability Step 7.
8. Palpate the maxillae Step 8.
9. Check the nose for blood and drainage Step 9.
10. Palpate the mandible Step 10.
11. Assess the mouth and nose for cyanosis, foreign bodies (including loose teeth or dentures), bleeding, lacerations, and deformities Step 11.
12. Check for unusual odors on the patient's breath Step 12.
13. Look at the neck for obvious lacerations, bruises, and deformities. Observe for jugular vein distention Step 13.
14. Palpate the front and back of the neck for tenderness and deformity Step 14.
15. Look at the chest for obvious signs of injury before you begin palpation. Be sure to watch for movement of the chest with respirations Step 15.
16. Gently palpate over the ribs to elicit tenderness. Avoid pressing over obvious bruises and fractures Step 16.
17. Listen for breath sounds over the midaxillary and midclavicular lines Step 17.
18. Listen also at the bases and apices of the lungs Step 18.
19. Look at the abdomen and pelvis for obvious lacerations, bruises, and deformities. Gently palpate the abdomen for tenderness. If the abdomen is unusually tense, describe the abdomen as rigid Step 19.
20. Gently compress the pelvis from the sides to assess for tenderness Step 20.
21. Gently press the iliac crests to elicit instability, tenderness, and/or crepitus Step 21.
22. Inspect all four extremities for lacerations, bruises, swelling, deformities, and medical alert anklets or bracelets. Also assess distal pulses and motor and sensory function in all extremities Step 22.
23. Assess the back for tenderness and deformities. Remember, if you suspect a spinal injury, provide manual spinal stabilization as you log roll the patient Step 23.

Skill Drill 9-2 Performing the Secondary Assessment*

Step 1

Observe the face.

Step 2

Inspect the area around the eyes and eyelids.

Step 3

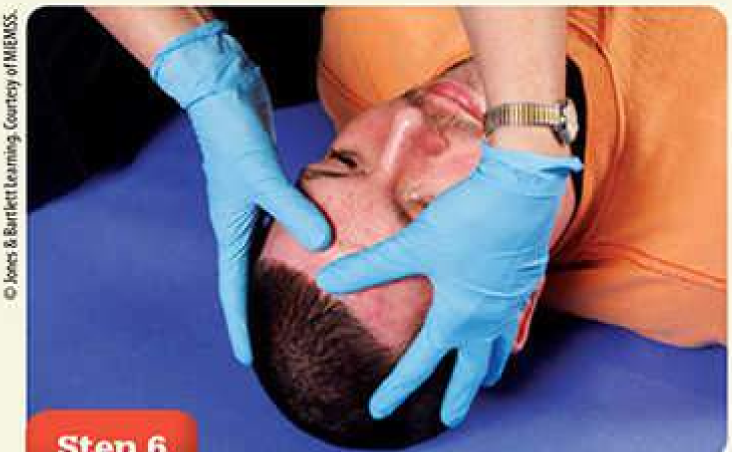
Examine the eyes for redness and contact lenses. Check pupil function.

Step 4

Look behind the ears for Battle sign.

Step 5

Check the ears for drainage or blood.



Step 6

Observe and palpate the head.

Step 7

Palpate the zygomas.

Step 8

Palpate the maxillae.

Step 9

Check the nose for blood and drainage.

Step 10

Palpate the mandible.

Step 11

Assess the mouth and nose.

Step 12

Check for unusual breath odors.

Step 13

Inspect the neck. Observe for jugular vein distention.

Step 14

Palpate the front and back of the neck.

Step 15

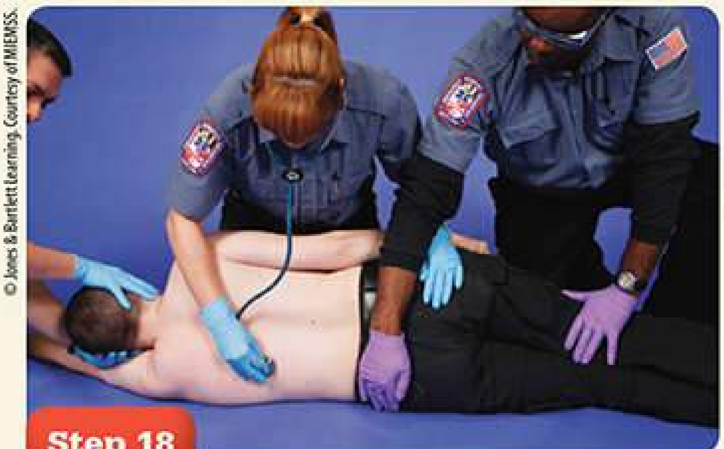
Inspect the chest, and observe breathing motion.

Step 16

Gently palpate over the ribs.

Step 17

Listen to anterior breath sounds (midaxillary, midclavicular).



Step 18

Listen to posterior breath sounds (bases, apices).

Step 19

Observe and then palpate the abdomen and pelvis.

Step 20

Gently compress the pelvis from the sides.

Step 21

Gently press the iliac crests.

Step 22

Inspect the extremities; assess distal circulation and motor and sensory function.

Step 23

Log roll the patient, and inspect the back.

*When performing a secondary assessment on a patient who has sustained significant trauma, provide manual spinal stabilization.

Systematically Assess the Patient—Focused Assessment

A **focused assessment** is generally performed on patients who have sustained nonsignificant MOIs or on responsive medical patients. This type of examination is typically based on the chief complaint. Your assessment can focus on a particular body part that has been affected, such as abrasions to the elbow, or to a particular body system that has been affected such as the cardiovascular, respiratory, neurologic, musculoskeletal, integumentary, or genitourinary system. For example, a person with a laceration to the arm may need to only have that arm evaluated. For a person reporting a headache, carefully and systematically assess the head and/or the neurologic system. The goal of a focused assessment is to focus your attention on the body part or systems affected by the priority problem(s).

Respiratory System

When the patient's chief complaint is focused on the respiratory system, you should have identified and managed life threats during the primary assessment. During the secondary assessment, you will perform an examination directed at obtaining clues that will help determine which treatment to perform and protocols to follow.

Expose the patient's chest. Look again for signs of airway obstruction, as well as trauma to the neck and/or chest. Inspect the chest for overall symmetry. Does the right side of the chest look like the left side? Listen carefully to breath sounds, noting abnormalities. Measure the respiratory rate, chest rise and fall (for tidal volume), and effort. Look for retractions. Is the patient using accessory muscles to help with breathing, and is there increased work of breathing?

For example, sounds of **stridor**, a brassy crowing sound prominent on inspiration, suggest a mildly occluded airway caused by swelling. High-pitched crowing sounds may indicate a mild airway obstruction from a foreign body.

Each complete breath includes two distinct phases: inspiration and expiration. During inspiration (inhalation), the diaphragm and intercostal muscles contract and the chest rises up and out, drawing oxygenated air into the lungs. During expiration (exhalation), the muscles relax and the chest returns to its original position, releasing air with an increased carbon dioxide level out of the lungs. Inhalation and exhalation times occur in a 1:3 ratio; the active inhalation phase lasts one-third the amount of time of the passive exhalation phase.

Breathing is a continuous process in which each breath regularly follows the last with no notable interruption. Breathing is normally a spontaneous, automatic process that should occur without conscious thought, visible effort, marked sounds, or pain. You will assess breathing by watching the patient's chest rise and fall, listening to **breath sounds** with a stethoscope over each lung and, if the patient is unconscious, feeling for air through the mouth and nose during exhalation. Chest rise and breath sounds should be equal on both sides of the chest.

When assessing breathing, you must obtain the following information:

- Respiratory rate
- Rhythm, regular or irregular
- Quality or character of breathing
- Depth of breathing

Respiratory Rate

A normal respiratory rate varies widely in adults, ranging from approximately 12 to 20 breaths/min. Children breathe at even faster rates. With practice, you will be able to estimate the rate and note whether it is too fast or too slow. At times it may be important to actually count the number of respirations during your primary assessment either by listening to breaths, observing the patient for chest rise, or gently placing a hand on the patient's chest and feeling for chest rise.

Respirations are determined by counting the number of breaths the patient takes in 30 seconds and multiplying by two. The result is the number of breaths per minute. For accuracy, count each breath at the same point in its cycle. This is most easily done by counting each peak chest rise. Although you can see peak chest rise, it is easier to place your hand on the patient's chest and feel it. However, be aware that a conscious patient who knows that you are evaluating his or her breathing will often override the automatic rate and depth by breathing more slowly and deeply. To prevent this from happening, check respirations in a conscious, alert patient without making the patient aware of what you are evaluating. This can be easily done by first taking a radial pulse and then, without releasing the wrist or otherwise suggesting a change, counting the chest rise that you see or feel as the patient's forearm rises and falls with the movement of the chest **Figure 9-22**. If the patient coughs, yawns, sighs, or talks during the 30-second period, wait a few seconds and start again. **Table 9-3** shows the normal range of respiratory rates of patients who are at rest.

Respiratory Rhythm. While counting the patient's respirations, also note the rhythm. If the time from one peak chest rise to the next is fairly consistent, respirations are considered regular. If the respirations vary or the rate changes frequently, the respirations are considered irregular. When you document the vital signs, be sure to note whether the patient's respirations were regular or irregular.

Figure 9-22 Assess respirations in a conscious patient by first taking a radial pulse and then, without releasing the patient's wrist, counting the chest rise and fall for 30 seconds.

Table 9-3 Normal Ranges for Respirations

Age	Range (breaths/min)
Adults	12 to 20
Adolescents (13 to 18 years)	12 to 16
School-Aged Children (6 to 12 years)	18 to 30
Preschoolers (4 to 5 years)	22 to 34
Toddlers (1 to 3 years)	24 to 40
Infants	30 to 60

Note: Adult respiratory ranges are per the NHTSA 2009 EMT National EMS Education Standards. Pediatric ranges are modified from Pediatric Advanced Life Support, 2012, the American Heart Association. Ranges presented in other sources may vary.

Quality of Breathing

It may be helpful to listen to breath sounds on each side of your patient’s chest early in the primary assessment. This can help identify the quality of air movement in both lungs. Decreased or absent breath sounds on one side of the chest and decreased movement in the rise and fall on one side indicate inadequate breathing.

Normal breathing is almost silent. In a very quiet environment you may hear only the sounds of air movement at the mouth and nose. Through a stethoscope, normal breath sounds include just the sound of air movement through the bronchi accompanied by a soft, low-pitched murmur. Breathing accompanied by other sounds may indicate a significant respiratory problem. A snoring sound may indicate an upper airway obstruction and is usually a result of the tongue blocking the airway. When the upper airway has a partial obstruction by a foreign body or swelling, you may hear stridor, a harsh, high-pitched, crowing sound. If you can hear bubbling or gurgling in the upper airway, the patient probably has fluid in those passages, potentially impeding the exchange of gases. Suction the patient to clear the airway and reduce the risk of aspiration of fluid into the lungs. You may hear other sounds, like wheezes, a musical sound indicative of a mild lower airway obstruction. The presence of any of these abnormal sounds indicates that an airway or breathing problem exists. Remember that with a complete airway obstruction, the patient will not be able to move any air and will no longer be able to cough or talk. If you hear no sounds, the patient may not be moving any air at all and will require some action to clear the obstruction.

A patient who coughs up thick, yellow or green sputum (matter from the lungs) most likely has a respiratory infection. A patient with a chest injury may cough up blood or frothy white or pink foamlike sputum caused by blood and fluid mixing with air in the lungs. A patient with congestive heart failure may also cough up frothy sputum. The presence of either substance, regardless of its cause, indicates that an urgent, potentially critical cardiovascular and respiratory problem exists, possibly requiring oxygenation, ventilation, and other treatments. Without these treatments, the patient's condition may deteriorate rapidly to a point where the patient can no longer breathe.

Depth of Breathing

The amount of air that the patient is exchanging depends on the rate and the tidal volume. **Tidal volume** is a measure of the amount of air that is moved into or out of the lungs during one breath. The depth of the breath determines whether the tidal volume is normal, less than normal, or more than normal.

Breath Sounds

The following describes how and where to listen to assess breathing:

- First, remember that you can almost always hear a patient's breath sounds better from the patient's back; therefore, if the patient's back is accessible, listen (auscultate) there. If you cannot, listen from the front and sides **Figure 9-23**.
- Auscultate over the upper lungs (apices) at approximately 1 inch (2.5 cm) below the clavicle at the midclavicular line, the midlung fields at the third or fourth intercostal space from the patient's posterior, and the lower lungs (bases) at the sixth intercostal space, midaxillary line.
- Lift the clothing or slide the stethoscope under the clothing. If you listen over clothing, you will primarily hear the sound of the stethoscope sliding over the fabric because breath sounds are muted by clothing.
- Place the diaphragm of the stethoscope firmly against the skin to hear breath sounds.

What are you listening for? You may be able to identify one of the following sounds:

- **Normal breath sounds.** These are clear and relatively quiet during inspiration and expiration.
- **Snoring breath sounds.** These usually indicate a simple, but potentially dangerous, upper airway obstruction, usually caused by the tongue or a foreign body.
- **Wheezing breath sounds.** These suggest an obstruction or narrowing of the lower airways. **Wheezing** is a high-pitched whistling sound that is most prominent on expiration.
- **Crackles**. Wet, crackling breath sounds (usually on both inspiration and expiration) may indicate fluid in the lungs.
- **Rhonchi**. Congested breath sounds may suggest the presence of mucus in the lungs. Expect to hear low-pitched, noisy sounds that are most prominent on expiration. The patient often reports a productive cough associated with these sounds.
- **Stridor.** This is often heard before even listening with a stethoscope and may indicate that the patient has an airway obstruction in the neck or upper part of the chest. Expect to hear a brassy, crowing sound that is most prominent on inspiration.

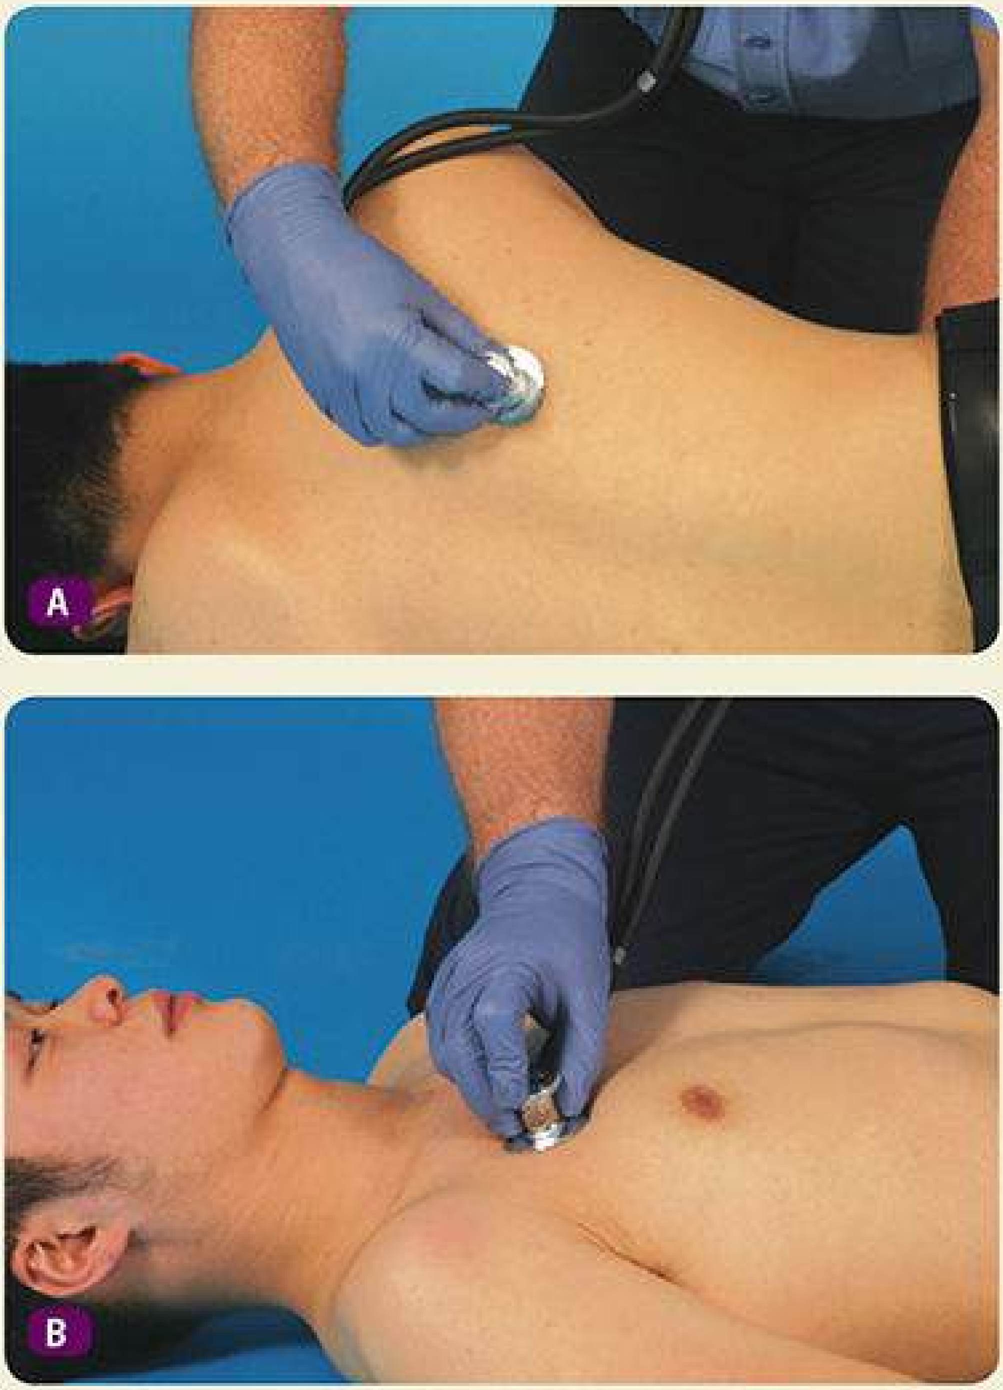


Figure 9-23 **A.** Listen to breath sounds from the patient's back (if possible), over the apices, the midlung fields, and the bases. **B.** If the patient is immobilized on a backboard or in a supine position, listen from the front and sides.

You can determine the quality or character of respirations as you are counting the number of respirations. Table 9-4 shows four ways in which the quality or character can be described. Use your sense of hearing to listen for breath sounds or use the preferred method of auscultation, listening with a stethoscope. Note any abnormal breath sounds and treat the patient accordingly.

Because the location of this complaint is the chest, carefully reevaluate the pulse rate, skin, and blood pressure (described in the next section). Inspect and palpate from the clavicles to the shoulder to the abdomen, and reassess breath sounds. Note any abnormalities found, and document those findings on the patient care report. With this information, you can develop a treatment plan and prioritize transport procedures.

Cardiovascular System

When the patient's chief complaint is associated with chest pain or other discomfort, a physical examination should include looking, listening, and feeling for abnormalities in the patient's thoracic region. Look for trauma to the chest, and listen for breath sounds. Consider the pulse and respiratory rate and the blood pressure. Pay particular attention to rate, quality, and rhythm. Consider your findings when assessing skin condition. Considering these findings will allow you to determine how well the cardiovascular and respiratory systems are functioning. Check and compare distal pulses to determine any right and left side differences. Consider auscultation for abnormal heart sounds; however, keep in mind that obtaining these sounds may be difficult in a noisy prehospital setting. Always remember that a patient's chief complaint may have a medical cause or could be the result of trauma.

Table 9-4 Characteristics of Respirations

Normal	Breathing is neither shallow nor deep Equal chest rise and fall No use of accessory muscles
Shallow	Decreased chest or abdominal wall motion
Labored	Increased breathing effort Use of accessory muscles Possible gasping Nasal flaring, supraclavicular and intercostal retractions in infants and children
Noisy	Increase in sound of breathing, including snoring, wheezing, gurgling, crowing, grunting, and stridor

Pulse Rate. After you have determined that a pulse is present, next determine its adequacy. This is done by assessing the pulse rate, pulse quality, and pulse rhythm. For an adult, the normal resting pulse rate should be between 60 and 100 beats/min and could be as much as 100 beats/min in older patients. In pediatric patients, generally the younger the patient, the faster the pulse rate. In well-conditioned athletes or in people taking heart medications such as beta-blockers, the pulse rate may be considerably lower. Table 9-5 shows the normal ranges of pulse rates for adults and children.

To obtain the pulse rate in most patients, count the number of pulses felt in a 30-second period and then multiply by two. A pulse that is weak and difficult to palpate, irregular, or extremely slow should be palpated and counted for a full minute. A pulse rate is counted as beats per minute; however, in reporting the pulse rate, it is not necessary to state or write "beats per minute" after the number.

In an adult patient, a pulse rate that is greater than 100 beats/min is described as **tachycardia**, and a rate of less than 60 beats/min is described as **bradycardia**.

Table 9-5 Normal Ranges for Pulse Rate

Age	Range (beats/min)
Adults and children (older than 10 years)	60 to 100
Preschoolers and school-aged children (2 years to 10 years)	60 to 140
Infants and toddlers (3 months to 2 years)	100 to 190
Infants (up to 3 months of age)	85 to 205

Data From Pediatric Advanced Life Support, 2012, the American Heart Association.

Pulse Quality. Always report the pulse's quality whenever reporting or recording the pulse. The pulse is generally palpated at the radial or carotid arteries in adults and at the brachial artery in infants, because it is normally strong and easily palpable at these locations. Therefore, if the pulse feels of normal strength, describe it as being strong. Describe a stronger than normal pulse as "bounding" and a pulse that is weak and difficult to feel as "weak" or "thready." With a little experience, you will be able to easily make the necessary distinctions.

Pulse Rhythm. When you are assessing the pulse, you must also determine whether the rhythm is regular or irregular. Regardless of the rate, the interval between each contraction should be the same, and the pulse should occur at a constant, regular rhythm. Document this rhythm as regular.

The rhythm is considered irregular if the heart periodically has an early or late beat or if a pulse beat is missed. If an irregular pulse is found in a patient with signs and symptoms that suggest a cardiovascular problem, the patient likely needs advanced cardiac assessment and life support. Therefore, depending on your protocols, you should call for ALS backup, arrange for an intercept by paramedics, or initiate prompt transport to definitive care. As with any deviation from expected findings it is important to determine, if possible, if this irregular rhythm is new or if it represents either a normal or a chronic condition for the patient.

Blood Pressure. Adequate blood pressure is necessary to maintain proper circulation and perfusion of the vital organ cells. **Blood pressure** is the pressure of circulating blood against the walls of the arteries. A decrease in the blood pressure may indicate one of the following:

- Loss of blood or its fluid components
- Loss of vascular tone and sufficient arterial constriction to maintain the necessary pressure even without any actual fluid or blood loss
- A cardiac pumping problem

When any of these conditions occurs and results in a drop in circulation, the body's compensatory mechanisms are activated, resulting in an increased heart rate and constriction of the arteries. Normal blood pressure is maintained, and by decreasing the blood flow to the skin and extremities, available blood volume is temporarily redirected to the vital organs so that they remain adequately perfused. However, as shock progresses, and the body's defense mechanisms can no longer keep up, the blood pressure will fall. Decreased blood pressure is a late sign of shock and indicates that the patient is in the critical stage of decompensated shock. Any patient with a markedly low blood pressure has inadequate pressure to maintain proper perfusion of all of the vital organs and needs to have his or her blood pressure and perfusion restored immediately to a normal level.

When the blood pressure becomes elevated, the body's defenses act to reduce it. Some people have chronically high blood pressure from progressive narrowing of the arteries that occurs with age, and during an acute episode, their blood pressure may increase to even higher levels. Head injury or a number of other conditions may also cause blood pressure to rise to very high levels. Abnormally high blood pressure may result in a rupture or other critical damage in the arterial system.

Blood pressure contains two key separate components: systolic pressure and diastolic pressure. **Systolic pressure** is the increased pressure that is caused along the artery with each contraction (systole) of the ventricles and the pulse wave that it produces. **Diastolic pressure** is the residual pressure that remains in the arteries during the relaxing phase of the heart's cycle (diastole), when the left ventricle is at rest. Systolic pressure represents the maximum pressure to which the arteries are subjected, and diastolic pressure represents the minimum amount of pressure that is always present in the arteries.

Early blood pressure gauges contained a column of mercury and a linear scale that was graduated in millimeters. Even though different gauges are used today, the blood pressure is still measured in millimeters of mercury (mm Hg). Blood pressure is reported as a fraction in the form of systolic pressure over diastolic pressure. Therefore, if the patient's systolic pressure is 120 and the diastolic pressure is 78, you would record it as "BP 120/78 mm Hg." You would report the patient's blood pressure verbally as "BP is 120 over 78."

Avoid taking a blood pressure on an arm if the patient has an intravenous site or other medical device in place such as an indwelling catheter or dialysis fistula; has had a mastectomy on that side; or has an injury to that arm. You can ask the patient if any of these exist if they are not visible, for example, a mastectomy. If a patient has chronic renal failure and is undergoing dialysis, ask if the patient has a fistula or any other reason that you should not take a blood pressure using that arm.

A blood pressure cuff with gauge (sphygmomanometer) contains the following components **Figure 9-24**:

- A wide outer cuff designed to be fastened snugly around the entire arm or leg
- An inflatable wide bladder sewn into a portion of the cuff
- A ball-pump with a one-way valve that allows air to enter and a turn-valve that can be closed or, when opened, will allow air to be released at a controlled speed from the cuff
- A pressure gauge calibrated in millimeters of mercury, which indicates the pressure that exists in the cuff that is being applied against the underlying artery

Most agencies carry at least three sizes of blood pressure cuffs: thigh, adult, and pediatric **Figure 9-25**. A large adult cuff is also available. You must be sure to select the appropriately sized cuff. A cuff that is too small may result in falsely high readings; a cuff that is too large may result in falsely low readings. The normal size cuff is designed to wrap around the arm 1 to 1.5 times and take up two-thirds the length from the armpit to the crease in the elbow of most adults. Use a thigh cuff with patients who are obese or have exceptionally well-developed arm muscles or to take the blood pressure of the thigh in patients who have injuries in both arms. Use a small pediatric cuff with children and exceptionally small adults. Measure blood pressure in all patients older than 3 years.

Figure 9-24

A sphygmomanometer.

Figure 9-25 Three sizes of blood pressure cuffs: thigh, adult, and pediatric.

Auscultation is the most common means of measuring a patient's blood pressure. A blood pressure cuff is applied to a patient's upper arm, allowing for the compression of the brachial artery when inflated. This compression creates turbulence and arterial vibrations that make sounds that can be heard using a stethoscope. These sounds are known as Korotkoff sounds. As the cuff is released, the blood flow returns to the artery, and Korotkoff sounds will be heard, denoting the systolic pressure. The disappearance of Korotkoff sounds indicates the diastolic pressure reading.

Follow the steps in Skill Drill 9-3 to measure blood pressure by auscultation:

1. Follow standard precautions. Explain the procedure to the patient. Examine for a dialysis fistula, central lines, mastectomy, injury to the arm, or other reason to not use this arm to take a blood pressure. If any are present, use the other arm.
2. With the patient's arm exposed, extended, and with the palm up, place the appropriately sized cuff so that it lies across the upper arm and is located with its distal edge about 1 inch (2.5 cm) above the antecubital space (the crease at the inside of the patient's elbow). Make sure the center of the inflatable bladder, which is usually marked by an arrow on the cuff, lies over the brachial artery. Next, wrap the ends so that the cuff surrounds the upper arm snugly but not tightly. Secure the cuff with the Velcro, making sure to rub your hand over the entire area where the two sides of the Velcro are in contact Step 1.

YOU are the Provider — PART 5

Following the appropriate interventions, your patient's oxygenation and ventilation status have improved; however, he is still bradycardic, hypotensive, and unresponsive. Because there was no one at the scene to provide information regarding his medical history, you continue to treat him based on his signs and symptoms, perform a reassessment, and call in your radio report to the receiving facility.

Recording Time: 20 Minutes	
Level of consciousness	Unconscious and unresponsive
Respirations	6 breaths/min (baseline); ventilations are being assisted

Pulse	38 beats/min; weak and regular
Skin	Pale and cool; cyanosis has resolved
Blood pressure	84/56 mm Hg
Spo_2	95% (with assisted ventilation)

You reassess the patient again just before arriving at the ED and note that his condition is unchanged. He is immediately evaluated by the staff physician, who determines that he has overdosed on numerous drugs—including narcotics. After further treatment in the ED, he was admitted to the intensive care unit for close observation.

9. What components of the SAMPLE history, if any, can you obtain when your patient is unresponsive? How would you obtain the information?

10. Why is reassessing your interventions so important?

3. Once the cuff has been properly secured around the upper arm, the arm should be held at about the same level as the heart. With your nondominant hand, palpate the brachial artery (in the antecubital fossa, the anterior aspect of the elbow) to determine where to place the stethoscope Step 2.
4. Place the bell (if one is present) of the stethoscope over the artery, and hold it firmly against the artery with the fingers of your nondominant hand. Hold the rubber ball-pump in the palm of your other hand and the turn-valve between your thumb and first finger Step 3.
5. Close the valve tightly, and pump the ball-pump until you no longer hear pulse sounds. Continue pumping to increase the cuff's pressure by an additional 30 mm Hg. Next, slowly turn the valve, opening it until air is steadily escaping from the cuff and you see the needle of the gauge slowly drop. Watch the gauge, and listen carefully. Note the patient's systolic pressure as the reading on the gauge at which the "taps" or "thumps" of the pulse waves can first be heard clearly. As the pressure in the cuff is progressively reduced, pulse sounds will continue for a time, then suddenly disappear. Note the patient's diastolic pressure as the reading on the gauge at which the sounds stopped Step 4.
6. As soon as the pulse sounds stop, open the valve, and release the remaining air quickly. Once you have finished measuring the blood pressure, document your findings and the time at which the blood pressure was taken. Blood pressure is most often measured by auscultation with the patient in a sitting or semisitting position. Be sure to note whether a different method or position was used. Occasionally, when a patient's blood pressure is very low, you will continue to hear pulse sounds from the reading at which they started all the way until the gauge has reached 0. When this occurs, you should record the diastolic pressure as "0" or "all the way down" to indicate that it was heard until the gauge read 0 Step 5.

Skill Drill 9-3 Obtaining Blood Pressure by Auscultation

Step 1

Follow standard precautions. Check for a dialysis fistula, central line, previous mastectomy, and injury to the arm. If any are present, use the brachial artery on the other arm. Apply the cuff snugly. The lower border of the cuff should be about 1 inch (2.5 cm) above the antecubital space.

Step 2

Support the exposed arm at the level of the heart. Palpate the brachial artery.

Step 3

Place the stethoscope over the brachial artery, and grasp the ball-pump and turn-valve.

Step 4

Close the valve, and pump to 30 mm Hg above the point at which you stop hearing pulse sounds. Note the systolic and diastolic pressures as you let air escape slowly.

Step 5

Open the valve, and quickly release remaining air.

Obtaining a patient's blood pressure accurately by auscultation may be difficult at times. Noisy environments, patient movement from tremors or seizures, external vibrations from the EMS vehicle, and excessive noises may produce sounds that mimic Korotkoff sounds and provide inaccurate readings. Other variables that may make obtaining an accurate blood pressure reading nearly impossible are uncooperative adults, infants and children, and patients who are hypotensive with poor perfusion. In these cases, measure blood pressure by palpation.

The palpation (feeling) method does not depend on your ability to hear sounds and should be used in these cases to obtain a patient's blood pressure. If possible, it is preferable that you first obtain a baseline auscultated blood pressure.

Follow the steps in **Skill Drill 9-4** to measure blood pressure by palpation:

1. Secure the appropriately sized cuff around the patient's upper arm in the manner previously described Step 1.
2. With your nondominant hand, palpate the patient's radial pulse on the same arm as the cuff Step 2. Once you have located it, do not move your fingertips until you have completed taking the blood pressure.
3. While holding the ball-pump in your other hand, close the turn-valve and slowly inflate the cuff until the pulse

disappears and then continue to inflate another 30 mm Hg Step 3. As the cuff inflates, you will no longer feel the pulse under your fingertips.

4. Open the turn-valve so that air slowly escapes from the cuff, and carefully observe the gauge Step 4. When you can again feel the radial pulse under your fingertips, note the reading on the gauge as the patient's systolic blood pressure. You will not be able to determine the diastolic pressure with this method.

5. Next, open the turn-valve further, and completely deflate the cuff Step 5. Document your findings, including the time, and note that the pressure was taken by palpation. On your patient care report, record the blood pressure as "120/P" and verbalize it as "120 palpated."

Normal Blood Pressure. Blood pressure levels vary with age and sex. Table 9-6 serves as a guideline for normal blood pressure ranges.

A patient has **hypotension** when the blood pressure is lower than the normal range and **hypertension** when the blood pressure is higher than the normal range.

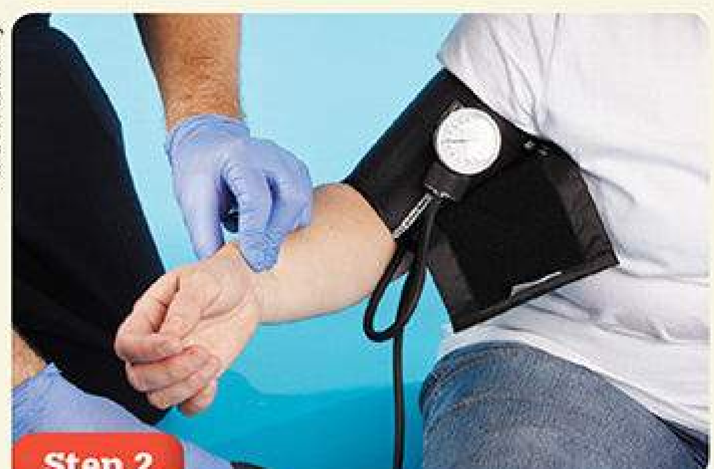
Typically, you will see children less frequently than adults; therefore, you might not remember the normal ranges for the various age groups. It is a good idea to carry a chart with you that lists normal blood pressure ranges and other vital signs. Remember, however, that blood pressure will vary somewhat with different patients and how they react to the environment around them. Often the most important information associated with the blood pressure is not the absolute value at any one point but the trend in the pressure over the course of time you are caring for a patient.

When assessing the patient's general circulation, the blood pressure, pulse, skin temperature, and capillary refill should not be assessed in an injured limb. However, once you have obtained these vital signs from an uninjured limb, you might want to compare the distal skin temperature, quality of the distal pulse, and/or capillary refill time in the injured limb with those found on the uninjured side. This information is useful in evaluating whether the injury may have compromised the circulation in the injured limb.

Skill Drill 9-4 Obtaining Blood Pressure by Palpation

Step 1

Follow standard precautions. Secure the appropriately sized cuff around the patient's upper arm.



Step 2

With your nondominant hand, palpate the patient's radial pulse on the same arm as the cuff. Once you have located it, do not move your fingertips until you have completed taking the blood pressure.

Step 3

While holding the ball-pump in your other hand, close the turn-valve and slowly inflate the cuff until the pulse disappears and then continue to inflate another 30 mm Hg. As the cuff inflates, you will no longer feel the pulse under your fingertips.

Step 4

Open the turn-valve so that air slowly escapes from the cuff, and carefully observe the gauge. When you can again feel the radial pulse under your fingertips, note the reading on the gauge as the patient's systolic blood pressure.

Step 5

Next, open the turn-valve further, and completely deflate the cuff. Document your findings, including the time, and note that the pressure was taken by palpation.

Neurologic System

Assessment of a patient's neurologic system can be very time consuming and detailed. A neurologic assessment should be performed any time you are confronted with a patient who has changes in mental status, a possible head injury, stupor, dizziness, drowsiness, or syncope. A neurologic assessment begins before you even touch the patient. It can be as simple as talking with the patient, asking questions, and receiving an appropriate reply from the patient during the primary assessment.

Evaluate the level of consciousness and orientation to determine the patient's ability to think. Use the AVPU scale if appropriate to determine the patient's mental status. Is the patient alert, oriented to person, place, time, and events? Is the patient responsive or unresponsive? Does the patient respond to verbal and painful stimuli? If the patient is responsive, evaluate speech for clarity, speed, organization, and logic. What is the patient's activity level? What are the patient's mood and thought content? What do the patient's facial expressions tell you? Is the patient angry, fearful, depressed, anxious, or restless? Does the patient appear uncomfortable? Does the patient make incomprehensible or understandable statements? Is the patient's memory affected? What is the patient's perception or view on what is happening? These are all important considerations when beginning to assess the neurologic system.

Use of the Glasgow Coma Scale (GCS) score can be helpful in providing additional information on patients with changes in mental status. The GCS (discussed further in Chapter 17, *Neurologic Emergencies*) uses parameters that test a patient's eye opening, best verbal response, and best motor response. The scale provides a numeric score that is associated with the relative severity of a patient's brain dysfunction Table 9-7. This information provides baseline data on the patient's overall neurologic status and can be used to help determine if that status is changing for better or worse. A modified GCS is used for children and infants, who respond differently from adults. When you are reporting the GCS score, document or report each section (eg, Eye opening: 3, Verbal response: 4, Motor response: 5 = GCS score of 12) to describe baseline function in each area.

Table 9-6 Normal Range for Blood Pressure

Age	Range, mm Hg
Adults	90 to 130 (systolic)
Adolescent (15 years)	110 to 131 (systolic)
Child (7 years)	96 to 115 (systolic)
Child (2 years)	88 to 106 (systolic)
Infant (1 year)	85 to 104 (systolic)
Neonate	60 to 84 (systolic)

Data Adapted From: Pediatric Advanced Life Support, 2012, the American Heart Association.

Table 9-7 Glasgow Coma Scale

Eye Opening		Best Verbal Response		Best Motor Response	
Spontaneous	4	Oriented conversation	5	Obeys commands	6
In response to speech	3	Confused conversation	4	Localizes pain	5
In response to pain	2	Inappropriate words	3	Withdraws to pain	4
None	1	Incomprehensible sounds	2	Abnormal flexion	3
		None	1	Abnormal extension	2
				None	1

Score: 13-15 may indicate mild dysfunction, although 15 is the score a person without neurologic impairment would receive.

Score: 9-12 may indicate moderate dysfunction.

Score: 8 or less is indicative of severe dysfunction.

Pupils

The pupil is the black center portion of the eye. The pupils are normally round, of approximately equal size, and adjust their size depending on the available light. The diameter and reactivity to light of the patient's pupils can reflect the status of the brain's perfusion, oxygenation, and condition. In normal room light, the pupil should appear to be about midsize. With less light, the pupils dilate to allow more light to enter the eye. When a bright light is shined near the eye, the pupils constrict **Figure 9-26A**. When a brighter light is introduced into one eye, both pupils should constrict equally to the appropriate size for the pupil receiving the most light.

In the absence of light, the pupils will become fully relaxed and dilated **Figure 9-26B**. When light is introduced, each eye sends sensory signals to the brain indicating the level of light it is receiving. Pupil size is regulated by a series of continuous motor commands that the brain automatically sends through the oculomotor nerves to each eye, causing both pupils to constrict to the same appropriate size. Normally, pupil size changes instantly with any change in light level.

Some patients normally have pupils that do not react properly to changes in light as a result of eye surgery or other conditions. A small number of patients exhibit normally unequal pupils (anisocoria) **Figure 9-26C**. If the patient or family member cannot confirm the presence of these conditions, you should presume that abnormal pupillary response indicates altered brain function as a result of central nervous system depression or injury. Specifically, evaluate if the pupils react in any of the following ways:

- Become fixed (either dilated or constricted) with no reaction to changes in light
- Dilate with introduction of a bright light and constrict when the light is removed
- React sluggishly instead of briskly
- Become unequal in size
- Become unequal in size when a bright light is introduced into or removed from one eye

Some of the causes of depressed brain function include the following:

- Injury of the brain or brain stem
- Trauma or stroke
- Brain tumor
- Inadequate oxygenation or perfusion
- Drugs or toxins (central nervous system depressants)

The mnemonic PEARRL is a useful guide in assessing the pupils. The letters stand for the following:

P Pupils
E Equal
A And
R Round
R Regular in size
L React to Light

For patients with normal pupils, you can report “Pupils are Equal And Round, Regular in size, and react properly to Light” or “Pupils = PEARRL.” Describe any abnormal findings using the longer form, such as “Pupils are equal and round, the left pupil is fixed and dilated, the right pupil is regular in size and reacts to light.”

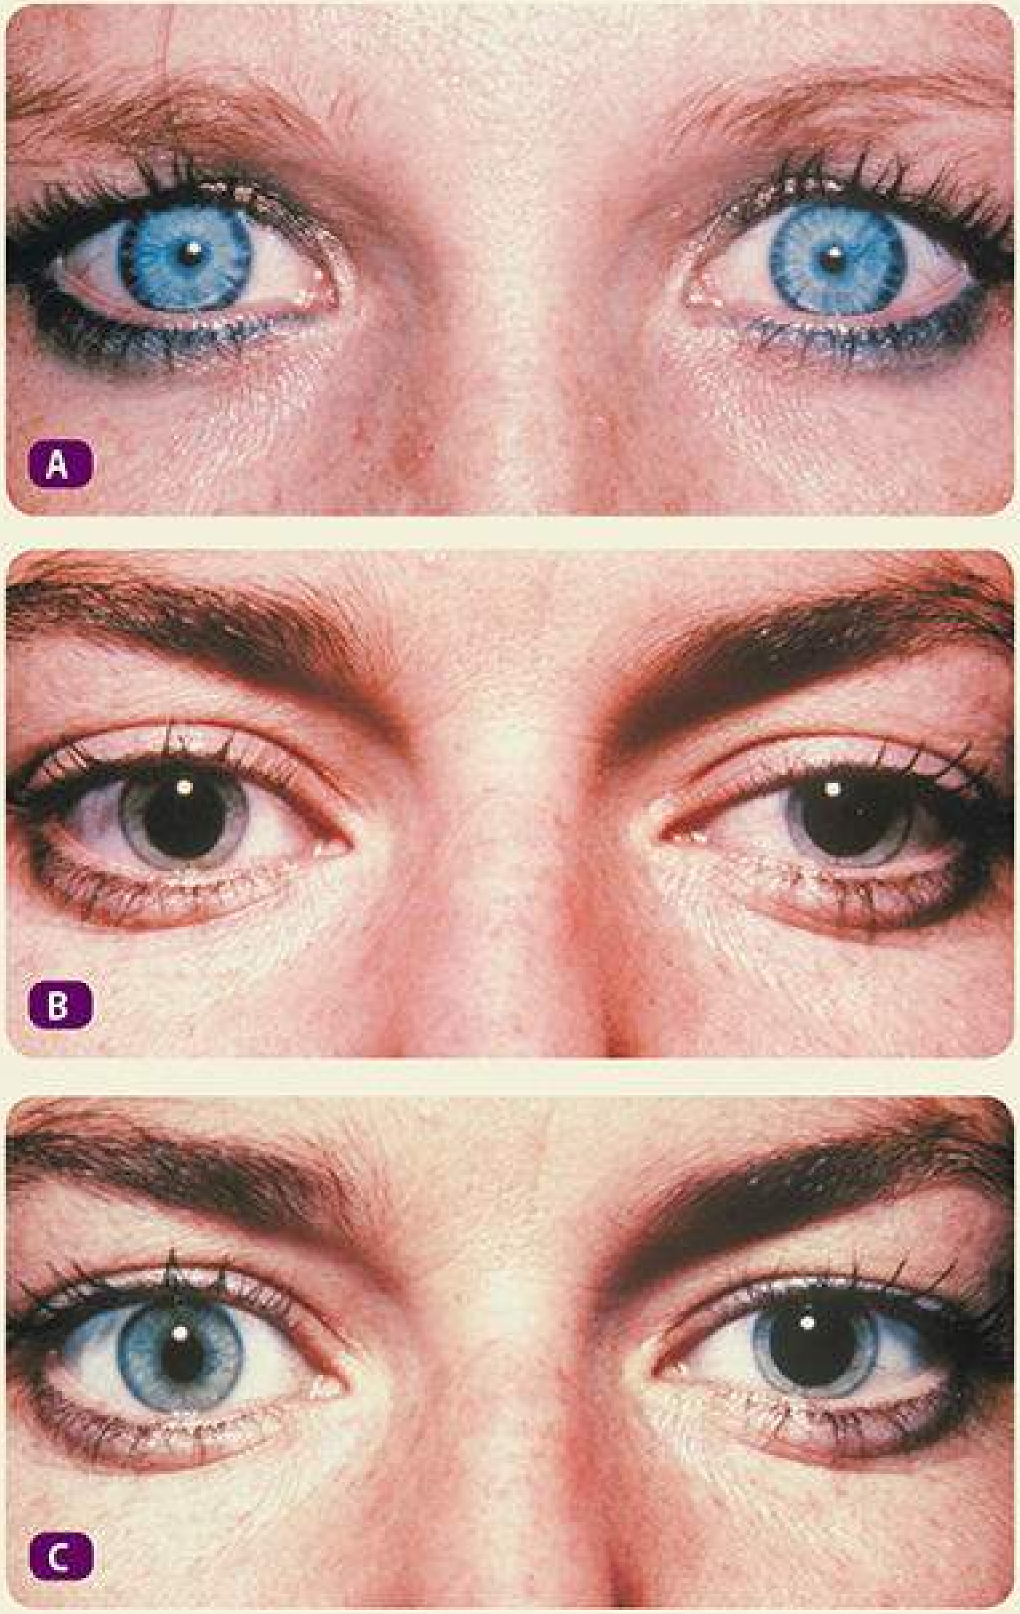


Figure 9-26 **A.** Constricted pupils. **B.** Dilated pupils. **C.** Unequal pupils.

Now perform a hands-on assessment to determine sensory and motor response. How does the patient move? Check for bilateral muscle strength and weaknesses. Complete a thorough sensory assessment. Test for pain, sensations, and position, and compare distal and proximal sensory and motor responses and one side with the other. Remember that a physical examination that deals with a specific chief complaint can be streamlined to assess a specific area of concern.

To assess neurovascular status in a conscious patient, follow the steps in **Skill Drill 9-5**:

1. **Pulse.** Palpate the pulse distal to the point of injury. First, palpate the radial pulse in the upper extremity Step 1. Second, in the lower extremity, palpate the posterior tibial and dorsalis pedis pulses Step 2.
2. **Capillary refill.** Note and record the skin color, identifying any pallor or cyanosis. Then apply firm pressure to the tip of the fingernail or toenail, which will cause the skin to blanch (turn white). If normal color does not return within 2 seconds after you release the nail, you can assume that circulation is impaired. This test is typically recommended for use in children, although it can be used in adults also Step 3.
3. **Sensation.** In the hand, check the feeling on the flesh near the tip of the index finger and thumb, as well as the little finger Step 4. In the foot, check the sensation on the flesh of the big toe Step 5 and on the lateral side of the foot Step 6. The patient's ability to sense light touch in the fingers or toes distal to the site of a fracture is a good indication that the nerve supply is intact.
4. **Motor function.** Evaluate muscular activity when the injury is proximal to the patient's hand or foot. Ask the patient to open and close a fist for an upper extremity injury and to wiggle the toes and move the foot up and down for a lower extremity injury. Sometimes, an attempt at motion will produce pain at the injury site. If this happens, do not continue this part of the examination. To avoid causing pain, do not perform this test at all if the injury involves the hand or foot itself Steps 7 through 10.

Because many of the steps require patient cooperation, you will not be able to assess sensory and motor functions in an unconscious patient.

Anatomic Regions

Head, Neck, and Cervical Spine. Inspect for abnormalities of the head, neck, and cervical spine. Gently palpate the scalp and skull for any pain, deformity, tenderness, crepitus, and bleeding **Figure 9-27**. Ask a responsive patient if he or she feels any pain or tenderness. Look at the patient's face. Is it symmetrical? Is there evidence of trauma, such as ecchymoses or hematomas? Does the patient have any facial expressions such as a smile or grimace? Check the patient's eyes, and assess pupillary function, shape, and response. Are the pupils equal in size and reactive to light, or are they constricted, dilated, or unequal? Check the color of the sclera. Assess the patient's cheek bones (zygomas) for possible injury. Check the patient's ears and nose for fluid. Next, before opening the patient's mouth, check the upper (maxillae) and lower (mandible) jaw. Once the patient's jaws have been assessed and it has been determined that movement will not create any additional pain or injury, open the patient's mouth, looking for any broken or missing teeth. If blood and secretions have impaired the airway, this should have been corrected during the primary assessment. Before moving on to the neck, note any unusual odors that may be present in the patient's mouth. This may give an indication of what type of emergency you may be dealing with.

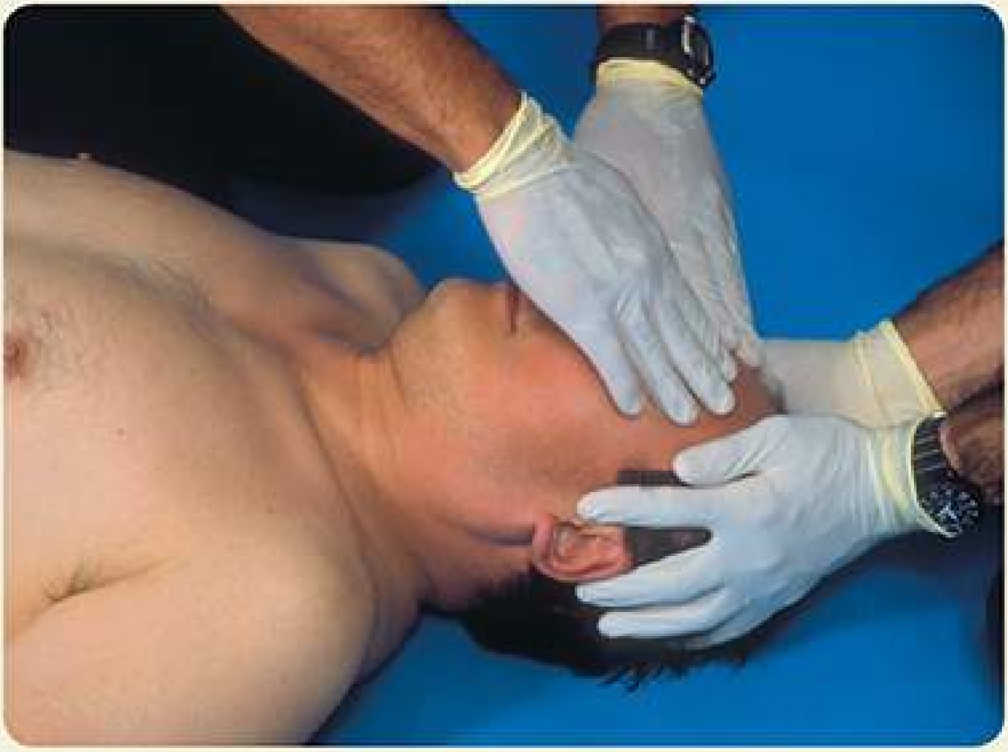

Figure 9-27 Gently palpate the head for any pain, deformity, tenderness, crepitus, and bleeding.

Skill Drill 9-5 Assessing Neurovascular Status

Step 1

Palpate the radial pulse in the upper extremity.

Step 2

Palpate the posterior tibial and dorsalis pedis pulses in the lower extremity.

Step 3

Assess capillary refill by blanching a fingernail or toenail.

Step 4

Assess sensation on the flesh near the tip of the index finger and thumb, as well as the little finger.

Step 5

On the foot, first check sensation on the flesh near the tip of the big toe.

Step 6

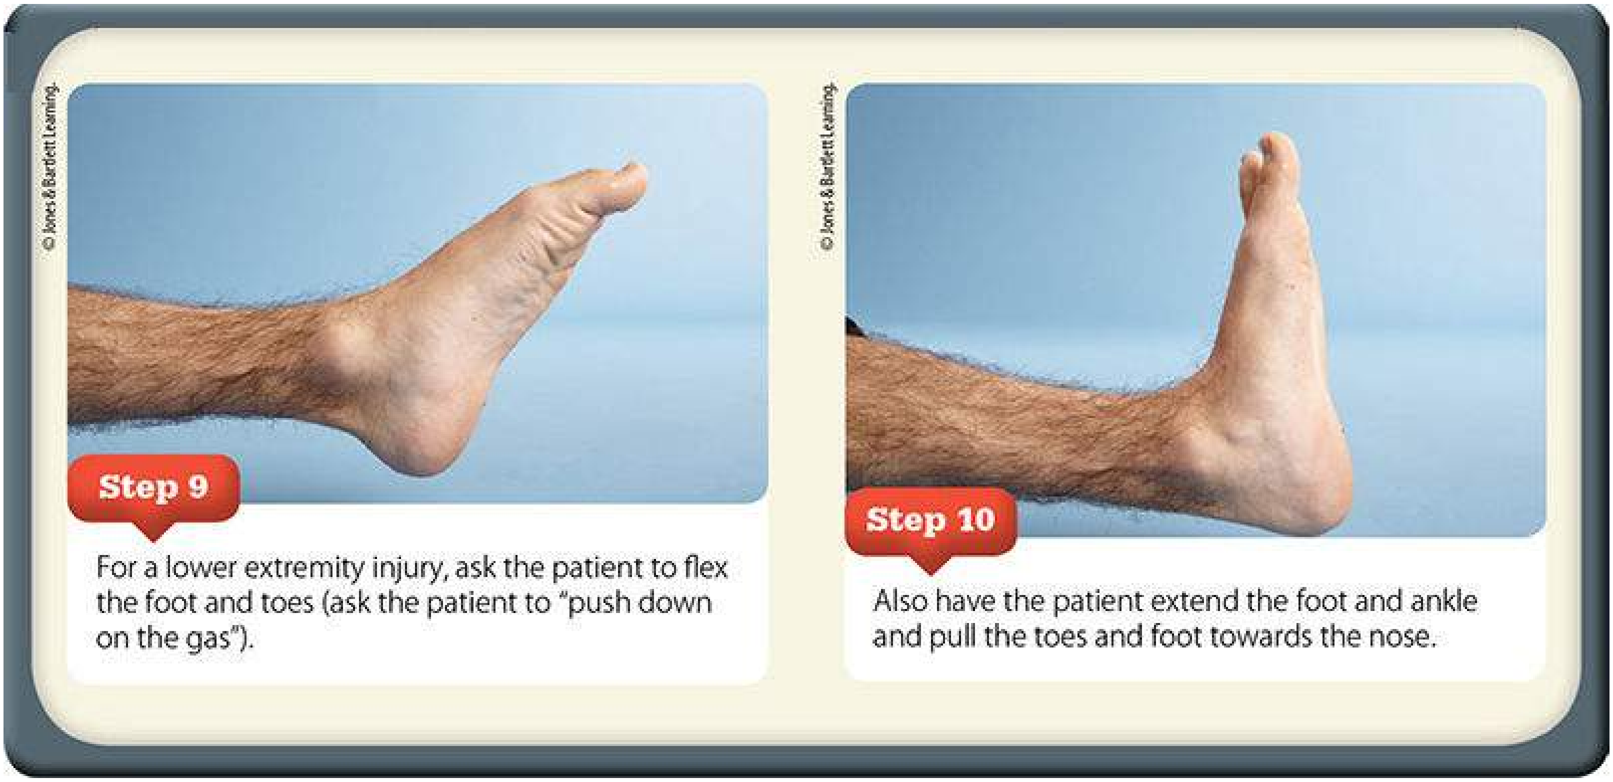
Also check sensation on the side of the foot.

Step 7

For an upper extremity injury, evaluate motor function by asking the patient to open the hand. (Perform motor tests only if the hand or foot is not injured. Stop a test if it causes pain.)

Step 8

Also ask the patient to make a fist.



Next, check the neck for signs of swelling or bleeding. Palpate the neck for signs of trauma, such as deformities, bumps, swelling, bruising, and bleeding, as well as a crackling sound produced by air bubbles under the skin, also known as **subcutaneous emphysema** **Figure 9-28**. Also, in patients in whom spinal injury is not suspected, inspect for pronounced or distended jugular veins with the patient sitting at a 45-degree angle. This is a normal finding in a person who is lying down; however, jugular venous distention in a patient who is sitting up suggests a problem with blood returning to the heart. Report and record your findings carefully.

Figure 9-28 Gently palpate the neck.

Chest. When assessing the chest, inspect, visualize, and palpate over the chest area for injury and signs of trauma, including bruising, tenderness, and swelling **Figure 9-29**.

Figure 9-29 Inspect, visualize, and palpate over the chest area for injury and signs of trauma.

When assessing breathing, watch for both sides of the chest to rise and fall together with normal breathing. Observe for abnormal breathing signs, including retractions or **paradoxical motion** (when only one section of the chest rises on inspiration while another area of the chest falls).

Retractions indicate the patient has some condition, usually medical, that is impairing the flow of air into and out of the lungs. Paradoxical motion is associated with a fracture of several ribs (flail), causing a section of the chest to move independently from the rest of the chest wall. Feel for grating of the bones as the patient breathes. Crepitus is often associated with rib fractures. Palpate the chest for subcutaneous emphysema, especially in cases of severe blunt chest trauma, as this could indicate a pneumothorax.

If the patient reports difficulty breathing or has evidence of trauma to the chest, auscultate breath sounds. This helps you to evaluate air movement in and out of the lungs. To auscultate, you need a stethoscope. The position of the patient will determine the way you proceed to check for breathing.

The goal is to hear and document the presence or absence of breath sounds. It is important to compare one side with the other. If you believe the patient's breathing is abnormal, reassess breathing and, if appropriate, assist with ventilations.

Abdomen. Look for trauma to the abdomen and for distention. Palpate the abdomen for tenderness, rigidity, and patient **guarding** Figure 9-30. As you palpate the abdomen, use "firm," "soft," "tender," or "distended" (swollen) to report your findings. If the patient is awake and alert, ask about pain as you perform the examination. The abdomen is divided into four quadrants: left upper quadrant (LUQ), left lower quadrant (LLQ), right upper quadrant (RUQ), and right lower quadrant (RLQ). Always start the palpation of the abdomen in the quadrant that is farthest from the patient's pain. Do not palpate obvious soft-tissue injuries, and be careful not to palpate too firmly. Assess for the presence of rebound tenderness, which is pain created when pressure is released.

Figure 9-30 Palpate the abdomen, evaluating for tenderness and bleeding.

Pelvis. Inspect the pelvis for symmetry and any obvious signs of injury, bleeding, and deformity **Figure 9-31**. If the patient reports no pain, gently press downward and inward on the pelvic bones. Do not rock the pelvis; this action may result in exacerbation of damage to any unstable bones. If you feel any movement or crepitus or the patient reports pain or tenderness, severe injury may be present. Injuries to the pelvis and surrounding abdomen may bleed profusely without any obvious external signs, so continue to monitor the patient's mental status, skin condition, and vital signs.

Extremities. An assessment of the patient's musculoskeletal system typically is done because of a chief complaint associated with some type of trauma. Do all extremities appear to be properly positioned, and do all extremities appear to be functioning normally? Assess for posture if standing, and look at joints, checking for range of motion. This should be done by asking the patient how much he or she can move the extremity or joint. Never force a painful joint to move. Always compare the right side with the left side, looking for weakness or atrophy, and assess equality of grip strength.

Figure 9-31 Inspect the pelvis for any obvious signs of injury, bleeding, and deformity.

Inspect each extremity for symmetry, cuts, bruises, swelling, obvious injuries, and bleeding **Figure 9-32**. Also palpate along each extremity for deformities. Ask the patient about any tenderness or pain. As you evaluate the extremities, check for pulses, motor function, and sensory function:

- **Pulse.** Check the distal pulses on the foot (dorsalis pedis or posterior tibial) **Figures 9-33** and **Figures 9-34** and wrist. Assess the pulses in the lower extremities for rate, quality, and rhythm. Is the pulse fast, slow, or irregular? Is the pulse weak, thready, or bounding? Also check circulation. Evaluate the skin color and temperature in the hands and feet. Is it normal? How does it compare with the skin color and temperature of the other extremities? Pale or cyanotic skin may indicate poor circulation in that extremity.
- **Motor function.** Ask the patient to wiggle his or her fingers and toes. An inability to move a single extremity can be the result of a bone, muscle, or nerve injury. An inability to move several extremities may be a sign of a brain abnormality or spinal cord injury. Verify that you are maintaining spinal immobilization if indicated.
- **Sensory function.** Evaluate sensory function in the extremity by asking the patient to close his or her eyes. Gently squeeze or pinch a finger or toe, and ask the patient to identify what you are doing. The inability to feel sensation in the extremity may indicate a local nerve injury. The inability to feel in several extremities may be a sign of a spinal cord injury. Ensure that you are maintaining spinal immobilization.

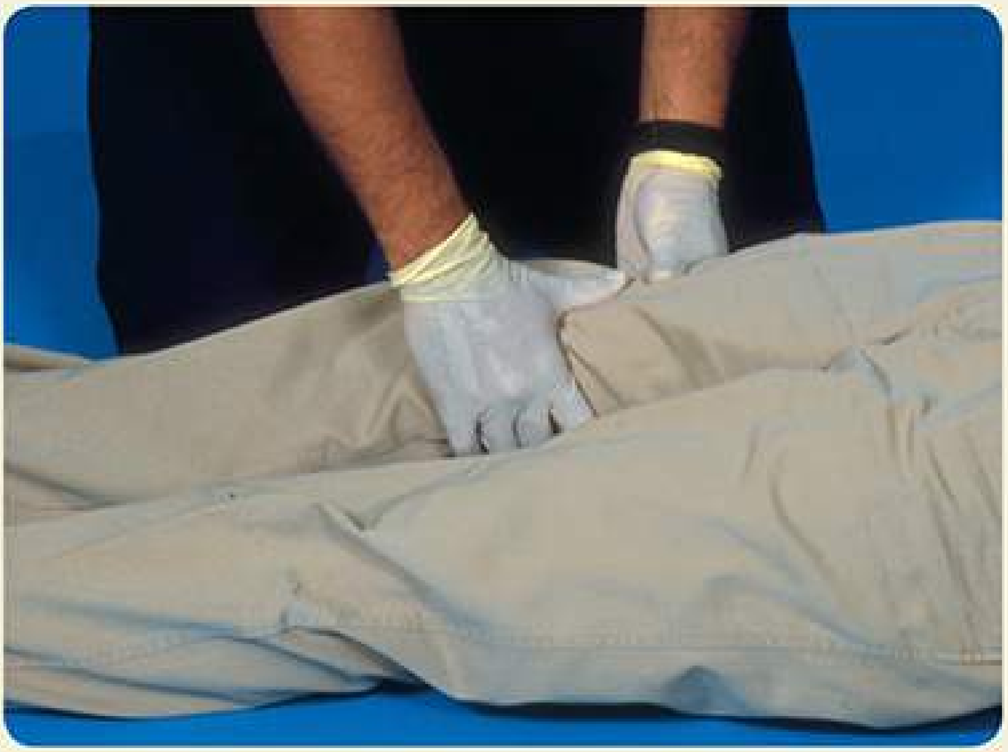


Figure 9-32 Inspect each extremity for cuts, bruises, swelling, obvious injuries, and bleeding.

Figure 9-33 Palpation of the posterior tibial pulse.

Posterior Body. Inspect the back for DCAP-BTLS, symmetry, and open wounds **Figure 9-35**. Carefully palpate the spine from the neck to the pelvis for tenderness and deformity.

Assess Vital Signs Using the Appropriate Monitoring Device

The use of monitoring equipment in the prehospital setting has continued to expand. EMTs at all levels use a wide variety of devices in the continuous monitoring of patients. It is important to remember that these devices are manufactured and subject to limitations and failures. These devices should never be used to replace your comprehensive assessment of your patient; think of these devices as simply adjuncts to the assessment and treatment of your patient. Obtaining and using information from patient monitoring devices includes, but is not limited to, data from pulse oximetry and noninvasive blood pressure monitoring.

Figure 9-34 Palpation of the dorsalis pedis pulse.

Pulse Oximetry

Pulse oximetry is an assessment tool used to evaluate the effectiveness of oxygenation. The pulse oximeter is a photoelectric device that monitors the oxygen saturation of hemoglobin (the iron-containing portion of the red blood cell to which oxygen attaches) in the capillary beds Figure 9-36. The parts that make up the pulse oximeter include a monitor and a sensing probe. The sensing probe clips onto a finger or ear lobe. The light source must have unobstructed access to a capillary bed, so dark fingernail polish might need to be removed. Results appear as a percentage on the display screen. Normally, pulse oximetry values in ambient air will vary depending on the altitude, with the majority of values falling between 95% and 99%.

The goal of applying oxygen therapy is to increase oxygen saturation to a normal level. This device is a useful assessment tool to determine the effectiveness of oxygen therapy, bronchodilator therapy, and artificial ventilations. However, the pulse oximeter does not take the place of good assessment skills and should not prevent the application of oxygen to any patient who reports difficulty breathing regardless of the pulse oximetry value seen on the monitor.

Because the device functions properly only with adequate perfusion and numbers of red blood cells, any situation that causes vasoconstriction (such as hypothermia or shock) or loss of red blood cells (such as bleeding or anemia) will result in inaccurate or misleading values. The device also presumes that oxygen is saturating the hemoglobin. Therefore, any chemical that displaces oxygen (such as carbon monoxide) may also cause misleading values.

Figure 9-35 Feel the back for tenderness, deformity, and open wounds. Carefully palpate the spine from the neck to the pelvis for tenderness and deformity. Look under the clothing for obvious injuries, including bruising and bleeding.

Figure 9-36 The pulse oximeter is a device that measures the saturation of oxygen in the blood as a percentage.

© juanrvelasco/iStock.

The pulse oximeter is a useful tool as long as you remember that the device is only a tool, not a substitute for a good assessment.

Capnography

Metabolism refers to the chemical reactions that occur in the body or cells to maintain life. To get an idea about the patient's metabolism, you can measure carbon dioxide (CO_2) levels in the air that the patient exhales. Pulse oximetry can measure the amount of oxygen available to the patient's cells for cellular metabolism, but it does not measure how much of that oxygen is being used. **Carbon dioxide** is the by-product of aerobic cellular metabolism and reflects the amount of oxygen being consumed during the process. Think of the oxygen as helping to burn the fuel in metabolism, and the carbon dioxide is the exhaust. You can learn a great deal by measuring this "exhaust" from a patient.

When you are working with ALS providers, there will be times when they may employ certain techniques to measure the amount of carbon dioxide in exhaled air to help understand the degree to which a patient is adequately perfused and ventilated. For example, **capnography** is a noninvasive method that can quickly and efficiently provide information on a patient's ventilation, circulation, and metabolism. Waveform capnography shows a graph that indicates how easily, how frequently, and how much the patient is exhaling carbon dioxide **Figure 9-37**.

Blood Glucometry

Measuring the blood glucose level of a patient who has altered mental status can prove invaluable. Blood glucometry measures the level of glucose in the patient's bloodstream. If the glucose level is low, this can help you identify the reason a patient is unresponsive. If the level is high in a patient with nausea, vomiting, abdominal pain, and a change in mental status, it may signal dangerous complications of high blood glucose.

Blood glucose should be assessed in all known diabetic patients, all patients who are unresponsive for unknown reasons, and patients with generalized malaise or weakness. In addition, a blood glucose level can be assessed on any patient whom you feel has a poor general impression.

Figure 9-37 This device is capable of monitoring multiple functions simultaneously, including continuous capnography (bottom tracing).

The LIFEPAK 15 defibrillator monitor courtesy of Physio-Control. Used with permission of Physio-Control, Inc., and according to the Material Release Form provided by Physio-Control.

To obtain a blood glucose measurement, you will need to use a lancet needle to obtain a drop of blood. Follow the steps in **Skill Drill 9-6** to assess blood glucose level:

1. Take standard precautions. Cleanse the site (finger) with antiseptic Step 1.
2. Puncture the site with the lancet needle Step 2.
3. Immediately dispose of the needle in a sharps container Step 3.
4. Obtain a drop of blood on the test strip. Insert the test strip into the glucometer and activate the device per manufacturer's instructions Step 4.
5. When finished, place a bandage over the puncture site Step 5.

Make sure you have prepped the site adequately and that the finger is clean. Do not squeeze, or "milk," the puncture site to obtain enough blood for the test strip. This process may cause changes in the blood that you obtain that result in an inaccurate reading on the meter.

Most newer glucometers take only a few seconds to give you a reading. Rapid does not always equal accurate. Glucometers should be calibrated on a regular basis to maintain accuracy. In addition, you should verify that the test strips match the glucometer you are using and that they have not expired.

Noninvasive Blood Pressure Measurement

Auscultation with a sphygmomanometer is the most common means of measuring a patient's blood pressure. Electronic measurement is another method of obtaining blood pressure readings on patients. An electronic device measures changes in pressure oscillations that occur during cuff inflation or deflation and are related to systolic, mean, and diastolic pressures. Several different types of electronic devices are used in the prehospital setting; the blood pressure cuff deflates differently in each device.

Standard noninvasive blood pressure monitoring, whether through a manual sphygmomanometer or through an electronic, automatic blood pressure cuff, is easy to use and does not involve any advanced or invasive procedures. However, these methods are prone to very inaccurate readings in moving vehicles, noisy environments, or if the cuff is not correctly sized or properly placed on the patient. When faced with readings that do not match the clinical presentation of the patient, obtain manual readings to confirm.

Skill Drill 9-6 Assessing Blood Glucose Level

Step 1

Take standard precautions. Cleanse the site (finger) with antiseptic.

Step 2

Puncture the site with the lancet needle.

Step 3

Dispose of the needle in a sharps container.

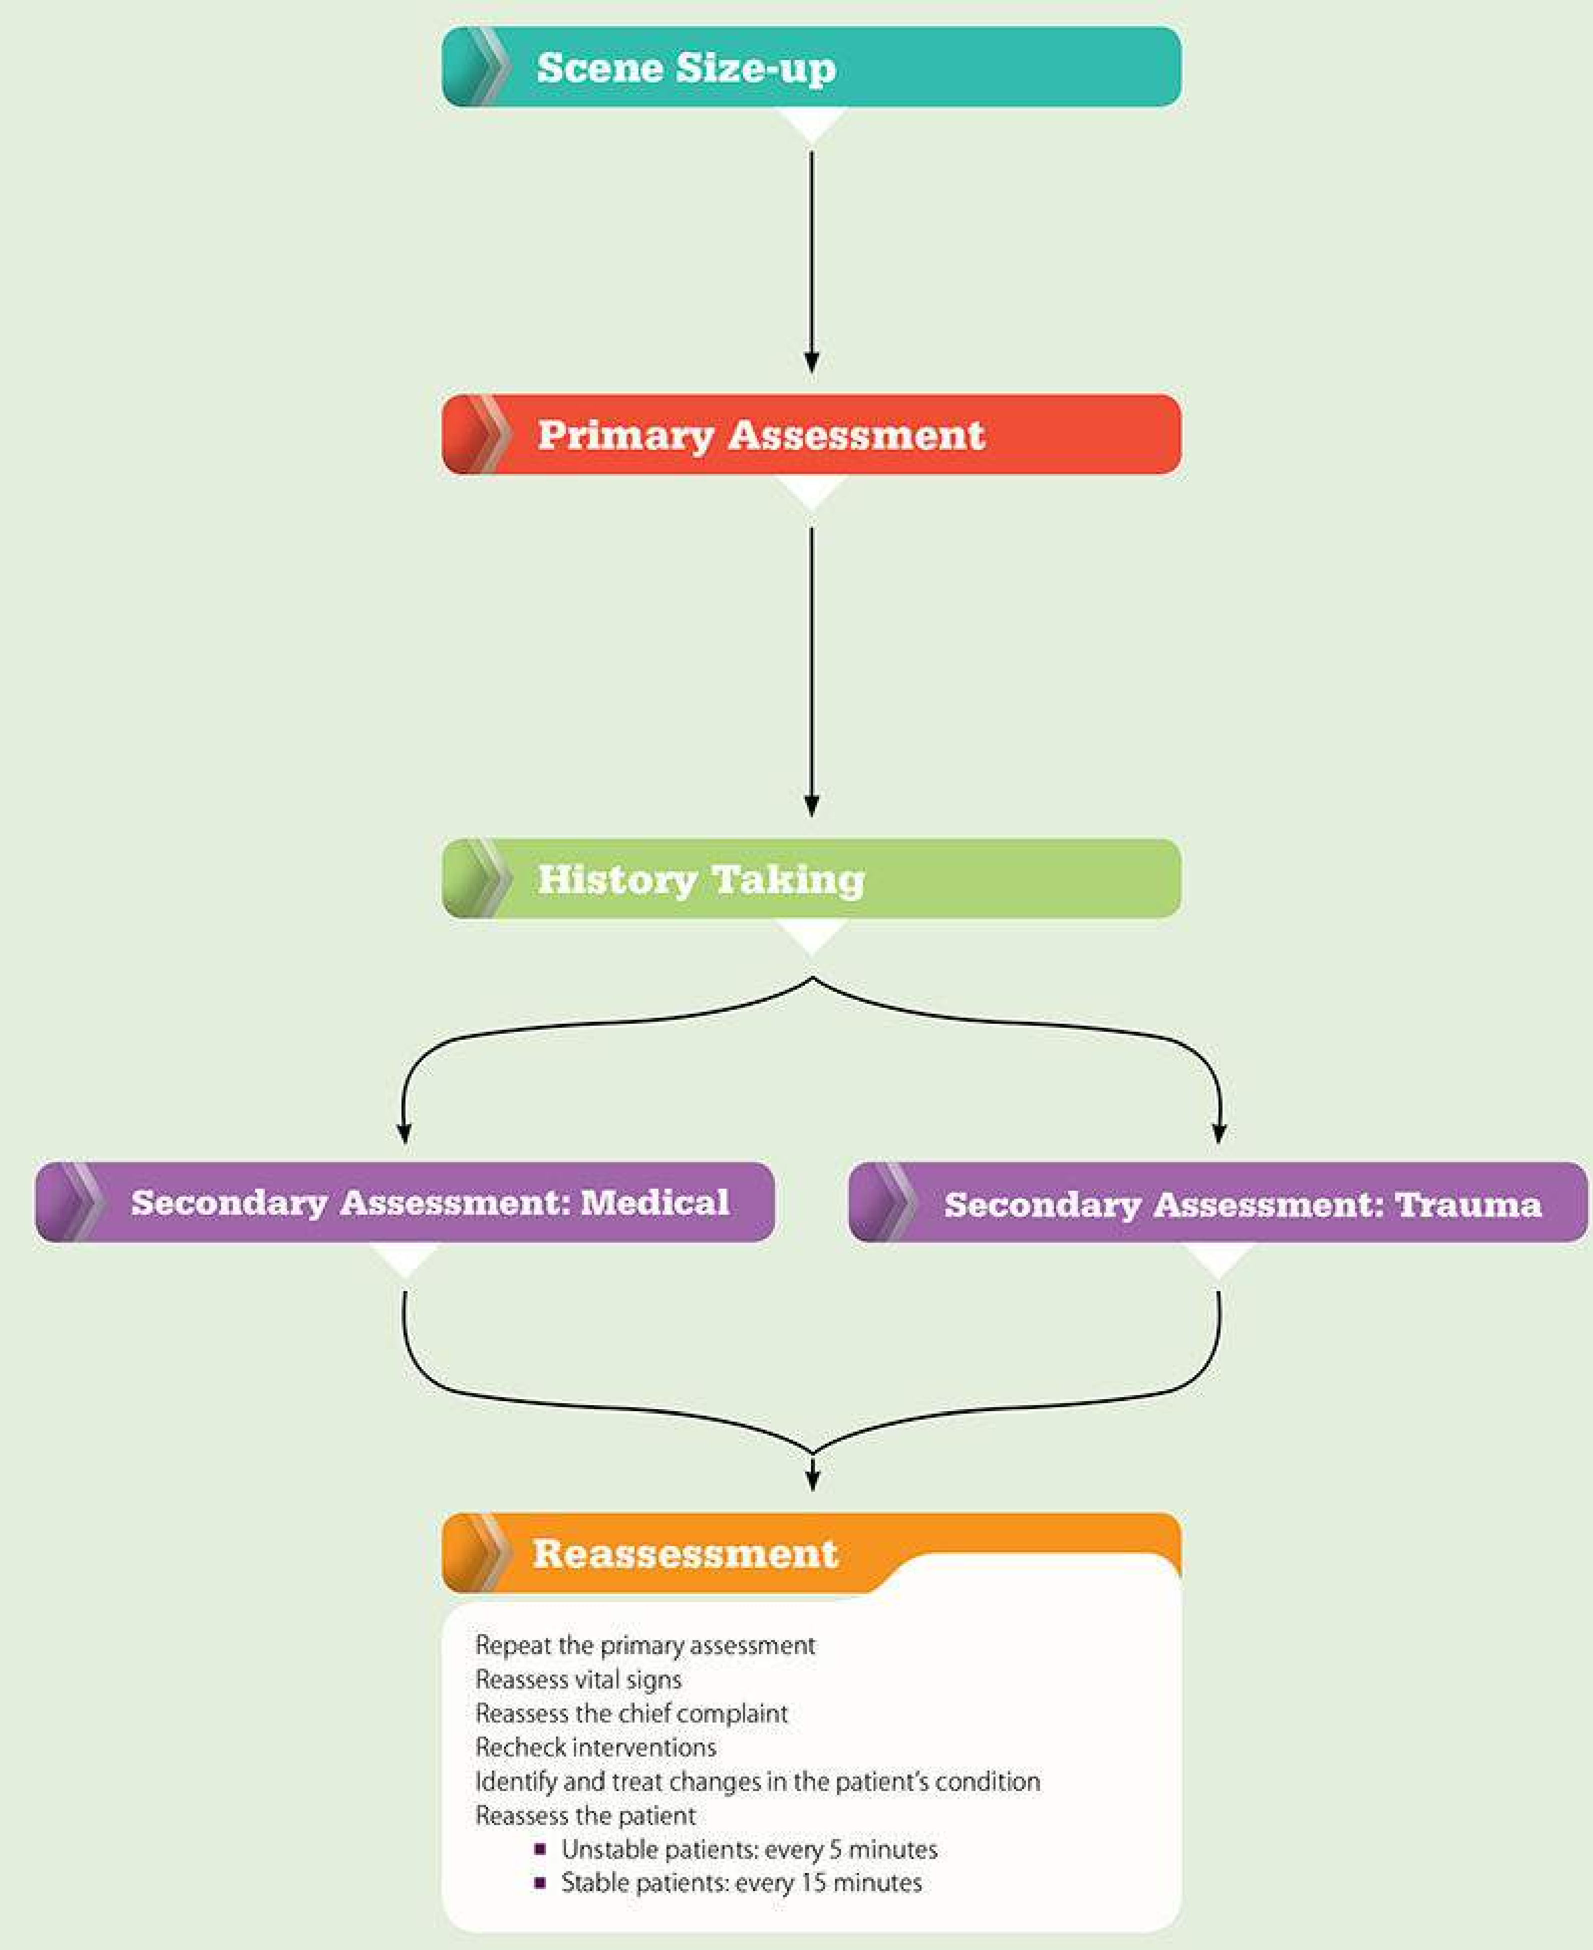
Step 4

Obtain a drop of blood on the test strip. Insert the test strip into the glucometer and activate the device per manufacturer's instructions.

Step 5

Place a bandage over the puncture site.

Patient Assessment



Reassessment

A reassessment is performed at regular intervals during the assessment process, and its purpose is to identify and treat changes in a patient's condition.

Words of Wisdom

Reassessment should take place:

- Every 5 minutes for patients in unstable condition
- Every 15 minutes for patients in stable condition

Repeat the Primary Assessment

The reassessment procedure is to simply repeat the primary assessment to identify and treat any life-threatening changes in the patient's condition.

Reassess Vital Signs

Reassess and record vital signs. Compare the baseline vital signs obtained during the primary assessment with any and all subsequent vital signs. Look for trends. Have they increased, declined, or stayed the same? If so, how fast? Reassess the mental status, airway, breathing, and circulation. Monitor skin color and temperature.

Reassess the Chief Complaint

With all emergency medical services, a reassessment must be completed to determine if the patient care plan is effective. The purpose is to ask and answer the following questions about the patient's chief complaint:

- Is the current treatment improving the patient's condition?
- Has an already identified problem gotten better?
- Has an already identified problem gotten worse?
- What is the nature of any newly identified problems?

Recheck Interventions

In the reassessment process, reevaluate everything that has been done to this point in the patient assessment process. Check all interventions. Most important are the patient's ABCs. In addition, are the bandages, spinal immobilization devices, extrication equipment, and patient securing instruments in place and appropriate for transport? Ensure management of bleeding. Ensure adequacy of other interventions, and consider the need for new interventions.

Identify and Treat Changes in the Patient's Condition

No matter what the patient's condition was prior to your arrival, which interventions were used, or which decisions on treatment and transport priorities were made, a reassessment is necessary to help monitor changes in the patient's condition. If the changes in the patient's condition are improved, simply continue whatever treatments you are providing. If the patient's condition deteriorates, prepare to modify treatments as appropriate. Document any changes, whether negative or positive.

Reassess Patient

How and when to perform a reassessment depends on the patient's condition. A patient in unstable condition should be reassessed approximately every 5 minutes, whereas a patient in stable condition should be reassessed approximately every 15 minutes.

YOU are the Provider — SUMMARY

1. What are the components of patient assessment?

There are five components in the assessment process: scene size-up, primary assessment, history taking, secondary assessment, and reassessment. Each component has an integral role in your overall treatment of the patient. The steps of assessment represent a logical approach to evaluation of a patient, but the order in which they are performed is determined by the patient's condition and the environment in which you are working.

2. Will your assessment of the patient differ if he is injured versus ill? If so, how?

The same components of patient assessment used to evaluate a medical patient are used to assess a trauma patient. The differences lie in what you find and how you treat it. For example, during the scene size-up of a trauma patient, you will evaluate the MOI to help focus your assessment of the type and severity of injuries your patient may have; you will also consider spinal immobilization. In medical patients, the NOI is assessed to help determine what category of medical condition you are dealing with (eg, cardiac, respiratory, endocrine), which will help guide your assessment in the appropriate direction.

Whether you are assessing a medical patient or a trauma patient, the key is to remain organized. Furthermore, you should assess the patient for medical conditions *and* injuries, especially if you suspect that the patient's injury was preceded by a medical condition.

3. Is spinal immobilization indicated? Why or why not?

Local protocols for spinal immobilization vary. Follow local protocols when making decisions about spinal immobilization. If you are unsure, err on the side of caution, and protect the patient's spine.

If you find that spinal immobilization is indicated, keep this in mind throughout your assessment process, modifying your assessment as appropriate to ensure that you are not unnecessarily risking additional spinal injury. Remember, however, that any life-threatening injuries must be addressed *immediately*, regardless of your suspicion of a possible spinal injury.

4. Which of these assessment findings requires your most immediate attention?

The patient's airway, which contains bloody secretions and vomitus, is in *immediate* jeopardy! Immediately use suction to clear his airway. Suction for up to 10 seconds, and then reassess his airway status. If you hear gurgling, think suction!

After ensuring that his airway is clear of secretions and vomitus, insert a simple airway adjunct—while keeping the airway open manually—to further help maintain airway patency. The airway adjunct you use depends on the patient's level of consciousness and the presence or absence of a gag reflex. The patient is responsive to pain; however, this does not always indicate an absent gag reflex. If there is no response to the test for painful stimulus, carefully insert an oropharyngeal airway, but be ready to quickly remove it if he begins to gag.

5. Does the patient require further treatment at the scene? If so, what?

At this point, you should continue to support his airway and breathing, monitor his circulatory status (ie, his pulse, which is slow), keep him warm, and be prepared to begin CPR and apply the AED. Apply spinal immobilization as directed by local protocol and prepare for immediate transport. Remember, there were no witnesses to this event; err on the side of caution and protect the patient's spine.

6. Should you remain at the scene and wait for the paramedic unit? Why or why not?

No, do not remain at the scene! Eighteen minutes is too long to remain at the scene with a patient in unstable condition, not to mention one who still needs to be moved from a second floor apartment. You should advise the paramedic ambulance of the situation, but do so while you are preparing for immediate transport. The longer you remain at the scene, the greater the chance that the patient's condition will further deteriorate.

If the paramedic ambulance arrives before you depart the scene, it would clearly be prudent to transfer care to them.

Consider an intercept with the paramedic unit at a designated location. Your EMS system protocols should have a plan for coordinating a paramedic intercept when transporting a patient in unstable condition or a patient who requires care that is beyond your level of training.

7. How has your patient's condition changed from the previous assessments?

Your patient's condition has obviously deteriorated. Compared with earlier assessments, which revealed that he was responsive to pain, he is now unconscious and unresponsive. Furthermore, his oxygen saturation is declining despite assisted ventilation with high-flow oxygen, and cyanosis is developing around his mouth (perioral/circumoral cyanosis).

His heart rate and blood pressure—although still unstable—are essentially unchanged compared with previous assessments. However, they must still be closely monitored for further deterioration.

The findings of your reassessment (eg, unresponsive, low Spo_2 level, cyanosis) point to a problem with his oxygenation and ventilation status that may be caused by more than one factor. His head may not be properly positioned, the simple airway adjunct may need to be repositioned, his airway may be filling with blood or vomitus, or he is not being adequately ventilated.

8. What should you do in response to the patient's change in condition?

Deterioration of a patient's condition should immediately prompt you to repeat the primary assessment, which begins by reassessing airway, breathing, and circulation.

Make sure his head is correctly positioned. Look in his mouth for secretions, and remove them with suction if present. Reassess the position of the simple airway adjunct; is the nasal airway protruding from his nose? If an oral airway is in place, is it protruding from his mouth? Reassess the mask-to-face seal of the bag-valve mask (BVM); is it adequate, or is there air leaking in all directions? Are you ventilating at the appropriate rate (10 to 12 breaths/min in an adult) with the appropriate volume (each breath delivered over 1 second—just enough to cause visible chest rise)?

A rapid, yet careful reassessment of the ABCs will often reveal the cause of the patient's status change, thus allowing you to rapidly correct it.

9. What components of the SAMPLE history, if any, can you obtain when your patient is unresponsive? How would you obtain the information?

In the absence of any family members, caregivers, or bystanders who know the patient, it may not be possible to obtain a complete and accurate SAMPLE history; however, it may be possible to obtain certain components of the SAMPLE history. Obtaining this information relies on your good assessment skills and "thinking outside the box."

Signs and symptoms can be established by simply assessing the patient; although signs and symptoms alone will not tell you what the patient's underlying problem is, they will enable you to direct your initial treatment accordingly.

Look for a medical alert bracelet, a medical alert card, or medical information posted in the patient's home. Are there any prescription medication bottles present? Is there medical equipment present (eg, home oxygen, nebulizer) that indicates an underlying condition? Although an unresponsive patient cannot speak, you can learn something about his or her conditions based on the medications found at the scene.

10. Why is reassessing your interventions so important?

The main purpose of reassessing the interventions you have performed on a patient is to determine their effectiveness. If your intervention has been effective, you should see an improvement in the patient's condition. If your intervention has not been effective, the patient's condition will have remained unchanged or will have deteriorated. Intervention reassessment also enables you to determine if you need to make modifications to existing interventions, cease an intervention, or perform another intervention.

For example, if a conscious patient is receiving oxygen via a nonrebreathing mask, and your reassessment reveals that he is now unresponsive, you may need to ensure that the airway is clear of secretions, or modify the way you are oxygenating the patient.

The mere performance of an intervention does not mean that it will cause your patient's condition to improve, nor does it mean that it will not cause his or her condition to deteriorate. Reassess, reassess, reassess!

Narrative

9-1-1 dispatch for a "man down." Law enforcement personnel responded and ensured the scene was secure prior to EMS arrival. On arrival at the scene, found the patient, a 25-year-old man, lying prone on the kitchen floor of his second-floor apartment. A neighbor was present but did not know what happened and has no knowledge of the patient's medical history. The patient was responsive to pain. Manually stabilized the patient's head, and rolled him to a supine position to provide immediate care. Opened his airway with the jaw-thrust maneuver, and noted bloody secretions and vomitus coming from his mouth. Immediately suctioned his oropharynx until clear of debris, and inserted a nasal airway. Assessment of his breathing revealed it to be slow and shallow; began assisting ventilations with a BVM attached to high-flow oxygen. Secondary assessment revealed no obvious signs of trauma, and law enforcement's search of the patient's apartment revealed no medical records, medication bottles, drug paraphernalia, or anything else suspicious. Unable to obtain SAMPLE history. Blood glucose level was assessed and read 108 mg/dL. A paramedic unit was available but was 18 minutes away from our location, so decision was made to continue treatment and begin immediate transport. Applied spinal immobilization, applied a blanket for warmth, moved the patient down a flight of stairs with the assistance of Engine Company 13, and loaded him into the ambulance. Began transport to hospital; EMT Jones from Engine Company 13 accompanied us with the patient to provide assistance. Reassessment revealed that the patient was now completely unresponsive, his oxygen saturation had declined, and cyanosis was developing around his mouth. EMS used suction to clear his oropharynx, inserted an oral airway, and continued to assist ventilations. Intervention reassessment revealed improvement in the patient's oxygenation status; however, he remained unresponsive, bradycardic, and hypotensive. Continued to assist patient's ventilations, and reassessed his condition approximately every 5 minutes as treatment would allow. Patient's condition remained unchanged throughout transport. Delivered him to the emergency department staff without incident, and gave verbal report to attending physician. Medic 80 returned to service at 1923.**End of report**

Prep Kit

Ready for Review

- The assessment process begins with the scene size-up, which identifies real or potential hazards. The patient should not be approached until these hazards have been dealt with in a way that eliminates or minimizes risk to the EMTs and the patient(s).
- The primary assessment is performed on all patients. It includes forming an initial general impression of the patient, including the level of consciousness, and identifies any life-threatening conditions to the ABCs. A primary assessment is performed to assist in prioritizing time and mode of transport. Any life threats identified must be treated before moving on to the next step of the assessment.
- Airway, breathing, and circulation are assessed to evaluate the patient's general condition.
- History taking includes an investigation of the patient's chief complaint or history of present illness. A SAMPLE history is generally taken during this step of the assessment process. This information may be obtained from the patient, family, friends, bystanders, caregivers, or medical alert devices or documentation.
- By using the SAMPLE mnemonic, you will be able to determine the patient's signs and symptoms, allergies, medications, pertinent past history, last oral intake, and events leading up to the illness or injury.
- The secondary assessment is a systematic physical examination of the patient. The secondary assessment may be a systematic head-to-toe physical examination or an assessment that focuses on a certain area or region of the body, often determined through the chief complaint. Circumstances will dictate which aspects of the physical examination will be used. The secondary assessment is performed on scene or, more often, in the back of the ambulance en route to the hospital. If the patient has serious life threats, you may not have time to perform a secondary assessment.
- The reassessment is performed on all patients. It gives you an opportunity to reevaluate the chief complaint and to reassess interventions to ensure that they are still being delivered correctly. Information from the reassessment may be used to identify and treat changes in the patient's condition.
- A patient in stable condition should be reassessed every 15 minutes, whereas a patient in unstable condition should be reassessed every 5 minutes.
- The assessment process is systematic and dynamic. Each assessment you perform will be slightly different, depending on the needs of the patient. The result will be a process that will enable you to quickly identify and treat the needs of all patients, both medical and trauma related, in a way that meets their unique needs.

Vital Vocabulary

accessory muscles The secondary muscles of respiration. They include the neck muscles (sternocleidomastoids), the chest pectoralis major muscles, and the abdominal muscles.

altered mental status Any deviation from alert and oriented to person, place, time, and event, or any deviation from a patient's normal baseline mental status.

auscultate To listen to sounds within an organ with a stethoscope.

AVPU scale A method of assessing the level of consciousness by determining whether the patient is awake and alert, responsive to verbal stimuli or pain, or unresponsive; used principally early in the assessment process.

blood pressure The pressure that the blood exerts against the walls of the arteries as it passes through them.

bradycardia A slow heart rate, less than 60 beats/ min.

breath sounds An indication of air movement in the lungs, usually assessed with a stethoscope.

capillary refill A test that evaluates distal circulatory system function by squeezing (blanching) blood from an area such as a nail bed and watching the speed of its return after releasing the pressure.

capnography A noninvasive method to quickly and efficiently provide information on a patient's ventilatory status, circulation, and metabolism; effectively measures the concentration of carbon dioxide in expired air over time.

carbon dioxide Carbon dioxide is a component of air and typically makes up 0.3% of air at sea level; also a waste product exhaled during expiration by the respiratory system.

chief complaint The reason a patient called for help; also, the patient's response to questions such as "What's wrong?" or "What happened?"

coagulate To form a clot to plug an opening in an injured blood vessel and stop bleeding.

conjunctiva The delicate membrane that lines the eyelids and covers the exposed surface of the eye.

crackles A crackling, rattling breath sound that signals fluid in the air spaces of the lungs.

crepitus A grating or grinding sensation caused by fractured bone ends or joints rubbing together; also air bubbles under the skin that produce a crackling sound or crinkly feeling.

cyanosis A blue-gray skin color that is caused by a reduced level of oxygen in the blood.

DCAP-BTLS A mnemonic for assessment in which each area of the body is evaluated for Deformities, Contusions, Abrasions, Punctures/penetrations, Burns, Tenderness, Lacerations, and Swelling.

diaphoretic Characterized by light or profuse sweating.

diastolic pressure The pressure that remains in the arteries during the relaxing phase of the heart's cycle (diastole) when the left ventricle is at rest.

distracting injury Any injury that prevents the patient from noticing other injuries he or she may have, even severe injuries; for example, a painful femur or tibia fracture that prevents the patient from noticing back pain associated with a spinal fracture.

focused assessment A type of physical assessment typically performed on patients who have sustained nonsignificant mechanisms of injury or on responsive medical patients. This type of examination is based on the chief complaint and focuses on one body system or part.

frostbite Damage to tissues as the result of exposure to cold; frozen or partially frozen body parts are frostbitten.

general impression The overall initial impression that determines the priority for patient care; based on the patient's surroundings, the mechanism of injury, signs and symptoms, and the chief complaint.

Golden Hour The time from injury to definitive care, during which treatment of shock and traumatic injuries should occur because survival potential is best; also called the Golden Period.

guarding Involuntary muscle contractions of the abdominal wall to minimize the pain of abdominal movement; a sign of peritonitis.

history taking A step within the patient assessment process that provides detail about the patient's chief complaint and an account of the patient's signs and symptoms.

hypertension Blood pressure that is higher than the normal range.

hypotension Blood pressure that is lower than the normal range.

hypothermia A condition in which the internal body temperature falls below 95°F (35°C) after exposure to a cold environment.

incident command system A system implemented to manage disasters and mass- and multiple-casualty incidents in which section chiefs, including finance, logistics, operations, and planning, report to the incident commander. Also referred to as the incident management system.

jaundice Yellow skin or sclera that is caused by liver disease or dysfunction.

labored breathing Breathing that requires greater than normal effort; may be slower or faster than normal and characterized by grunting, stridor, and use of accessory muscles.

mechanism of injury (MOI) The forces, or energy transmission, applied to the body that cause injury.

metabolism The biochemical processes that result in production of energy from nutrients within the cells.

nasal flaring Widening of the nostrils, indicating that there is an airway obstruction.

nature of illness (NOI) The general type of illness a patient is experiencing.

OPQRST A mnemonic used in evaluating a patient's pain: Onset, Provocation/palliation, Quality, Region/radiation, Severity, and Timing.

orientation The mental status of a patient as measured by memory of person (name), place (current location), time (current year, month, and approximate date), and event (what happened).

palpate To examine by touch.

paradoxical motion The motion of the portion of the chest wall that is detached in a flail chest; the motion—in during inhalation, out during exhalation—is exactly the opposite of normal chest wall motion during breathing.

perfusion The flow of blood through body tissues and vessels.

personal protective equipment (PPE) Protective equipment that blocks exposure to a pathogen or a hazardous material.

pertinent negatives Negative findings that warrant no care or intervention.

priapism A painful, tender, persistent erection of the penis; can result from spinal cord injury, erectile dysfunction drugs, or sickle cell disease.

primary assessment A step within the patient assessment process that identifies and initiates treatment of immediate and potential life threats.

pulse The pressure wave that occurs as each heartbeat causes a surge in the blood circulating through the arteries.

pulse oximetry An assessment tool that measures oxygen saturation of hemoglobin in the capillary beds.

reassessment A step within the patient assessment process performed at regular intervals during the assessment process to identify and treat changes in a patient's condition. A patient in unstable condition should be reassessed every 5 minutes, whereas a patient in stable condition should be reassessed every 15 minutes.

responsiveness The way in which a patient responds to external stimuli, including verbal stimuli (sound), tactile stimuli (touch), and painful stimuli.

retractions Movements in which the skin pulls in around the ribs during inspiration.

rhonchi Coarse, low-pitched breath sounds heard in patients with chronic mucus in the upper airways.

SAMPLE history A brief history of a patient's condition to determine signs and symptoms, allergies, medications, pertinent past history, last oral intake, and events leading to the injury or illness.

scene size-up A step within the patient assessment process that involves a quick assessment of the scene and the surroundings to provide information about scene safety and the mechanism of injury or nature of illness before you enter and begin patient care.

sclera The tough, fibrous, white portion of the eye that protects the more delicate inner structures.

secondary assessment A step within the patient assessment process in which a systematic physical examination of the patient is performed. The examination may be a systematic exam or an assessment that focuses on a certain area or region of the body, often determined through the chief complaint.

shallow respirations Respirations characterized by little movement of the chest wall (reduced tidal volume) or poor chest excursion.

sign Objective findings that can be seen, heard, felt, smelled, or measured.

situational awareness Knowledge and understanding of your surroundings and situation and the risk they potentially pose to your safety or the safety of the EMS team.

sniffing position An upright position in which the patient's head and chin are thrust slightly forward to keep the airway open.

spontaneous respirations Breathing that occurs without assistance.

standard precautions Protective measures that have traditionally been developed by the Centers for Disease Control and Prevention (CDC) for use in dealing with objects, blood, body fluids, and other potential exposure risks of communicable disease.

stridor A harsh, high-pitched, breath sound, generally heard during inspiration, that is caused by partial blockage or narrowing of the upper airway; may be audible without a stethoscope.

subcutaneous emphysema A characteristic crackling sensation felt on palpation of the skin, caused by the presence of air in soft tissues.

symptom Subjective findings that the patient feels but that can be identified only by the patient.

systolic pressure The increased pressure in an artery with each contraction of the ventricles (systole).

tachycardia A rapid heart rate, more than 100 beats/min.

tidal volume The amount of air (in milliliters) that is moved in or out of the lungs during one breath.

triage The process of establishing treatment and transportation priorities according to severity of injury and medical need.

tripod position An upright position in which the patient leans forward onto two arms stretched forward and thrusts the head and chin forward.

two- to three-word dyspnea A severe breathing problem in which a patient can speak only two to three words at a time without pausing to take a breath.

vasoconstriction Narrowing of a blood vessel.

vital signs The key signs that are used to evaluate the patient's overall condition, including respirations, pulse, blood pressure, level of consciousness, and skin characteristics.

wheezing A high-pitched, whistling breath sound that is most prominent on expiration, and which suggests an obstruction or narrowing of the lower airways; occurs in asthma and bronchiolitis.

Assessment *in Action*

You are dispatched to a motel for an unknown medical emergency. The room is small with two beds and two occupants. The patient is a 33-year-old woman lying supine on the bed. She opens her eyes when you speak to her but is lethargic and reports fever, chills, vomiting, and diarrhea. The man in the room tells you she has been sick for several days and has not eaten in the past 2 days. Your assessment reveals pain and tenderness in the right lower abdominal quadrant. Her vital signs are a blood pressure level of 100/60 mm Hg; a pulse rate of 140 beats/min, strong and bounding; and a respiratory rate of 24 breaths/min and shallow. Her skin is flushed and hot to the touch. The patient reports no significant medical history and does not take any medications.

1. What is the first concern when entering this room?

   A. ABCs
   B. Physical assessment
   C. Scene safety
   D. Vital signs

2. What is this patient responsive to?

   A. Verbal stimuli
   B. Painful stimuli
   C. Noxious stimuli
   D. Unresponsive

3. What is this patient's chief complaint?

   A. Lower right quadrant pain
   B. Fever and chills
   C. Dyspnea
   D. Palpitations

4. Which of the following terms would be used to describe the patient's pulse rate of 140 beats/min?

   A. Bradycardia
   B. Dyspnea
   C. Tachycardia
   D. Tachypnea

5. What is a pertinent negative?

   A. A negative finding that requires further care and/or intervention
   B. A negative finding that requires advanced life support
   C. A negative finding that implies another condition may be present
   D. A negative finding that requires no further care or intervention

6. What is a primary assessment?

   A. A systematic physical examination
   B. Physical examination performed at regular intervals
   C. A process that identifies life threats
   D. A process that identifies the nature of illness

7. How would you proceed if you found an unsafe condition on scene?

8. Describe an objective finding for the patient.

9. Describe a subjective finding for the patient.

10. How does the mnemonic SAMPLE assist you in assessing the patient?

Airway

10 Airway Management

CHAPTER
10

Airway Management

National EMS Education Standard Competencies

Airway Management, Respiration, and Artificial Ventilation

Applies knowledge of general anatomy and physiology to patient assessment and management in order to assure a patent airway, adequate mechanical ventilation, and respiration for patients of all ages.

Airway Management

› Airway anatomy (pp 388–392)
› Airway assessment (pp 400–405)
› Techniques of assuring a patent airway (pp 405–408)

Respiration

› Anatomy of the respiratory system (pp 388–392)
› Physiology and pathophysiology of respiration
- Pulmonary ventilation (pp 393–395)
- Oxygenation (pp 395–396)
- Respiration (pp 396–397)
  - External (p 396)
  - Internal (pp 396–397)
  - Cellular (pp 396–397)

› Assessment and management of adequate and inadequate ventilation (pp 402–405)
› Supplemental oxygen therapy (pp 416–425)

Artificial Ventilation

› Assessment and management of adequate and inadequate ventilation (pp 425–435)
› Artificial ventilation (pp 426–435)

› Minute ventilation (pp 393–394)
› Alveolar ventilation (pp 393–394)
› Effect of artificial ventilation on cardiac output (p 427)

Pathophysiology

Applies fundamental knowledge of the pathophysiology of respiration and perfusion to patient assessment and management.

Knowledge Objectives

1. Describe the major structures of the respiratory system. (pp 387–392)
2. Discuss the physiology of breathing. (pp 392–397)
3. Give the signs of adequate breathing. (p 400)
4. Give the signs of inadequate breathing. (p 401)
5. Describe the assessment and care of a patient with apnea. (p 402)
6. Explain how to assess for adequate and inadequate respiration, including the use of pulse oximetry. (pp 402–405)
7. Explain how to assess for a patent airway. (p 405)
8. Describe how to perform the head tilt–chin lift maneuver. (pp 405–406)
9. Describe how to perform the jaw-thrust maneuver. (pp 406–407)
10. Explain the importance of and techniques for suctioning. (pp 408–411)
11. Explain how to measure and insert an oropharyngeal (oral) airway. (pp 411–413)
12. Describe how to measure and insert a nasopharyngeal (nasal) airway. (pp 413–416)
13. Explain the use of the recovery position to maintain a clear airway. (p 416)
14. Describe the importance of giving supplemental oxygen to patients who are hypoxic. (p 416)
15. Discuss the basics of how oxygen is stored and the various hazards associated with its use. (pp 416–422)
16. Explain the use of a nonrebreathing mask and the oxygen flow requirements for its use. (p 423)
17. Describe the indications for using a nasal cannula rather than a nonrebreathing face mask. (p 423)
18. Describe the indications for using a humidifier during supplemental oxygen therapy. (p 425)
19. Describe how to perform mouth-to-mouth or mouth-to-mask ventilation. (pp 427–428)
20. Describe the use of a one- or two-person bag-valve mask (BVM) and a manually triggered ventilation (MTV) device. (pp 428–435)
21. Describe the signs associated with adequate and inadequate artificial ventilation. (p 434)
22. Describe the use of continuous positive airway pressure (CPAP). (pp 435–439)
23. Explain how to recognize and care for a foreign body airway obstruction. (pp 440–442)

Skills Objectives

1. Demonstrate use of pulse oximetry. (pp 403–404, Skill Drill 10-1)
2. Demonstrate how to position the unconscious patient. (pp 405–406, Skill Drill 10-2)
3. Demonstrate how to perform the head tilt–chin lift maneuver. (pp 405–406)
4. Demonstrate how to perform the jaw-thrust maneuver. (pp 406–407)
5. Demonstrate how to operate a suction unit. (p 410)
6. Demonstrate how to suction a patient’s airway. (pp 410–411, Skill Drill 10-3)
7. Demonstrate the insertion of an oral airway. (pp 411–413, Skill Drill 10-4)
8. Demonstrate the insertion of an oral airway with a 90-degree rotation. (pp 412–414, Skill Drill 10-5)
9. Demonstrate the insertion of a nasal airway. (pp 413–416, Skill Drill 10-6)
10. Demonstrate how to place a patient in the recovery position. (p 416)
11. Demonstrate how to place an oxygen cylinder into service. (pp 421–422, Skill Drill 10-7)
12. Demonstrate the use of a partial rebreathing mask in providing supplemental oxygen therapy to patients. (p 424)
13. Demonstrate the use of a Venturi mask in providing supplemental oxygen therapy to patients. (p 424)
14. Demonstrate the use of a humidifier in providing supplemental oxygen therapy to patients. (p 425)
15. Demonstrate mouth-to-mask ventilation. (pp 427–429, Skill Drill 10-8)
16. Demonstrate how to assist a patient with ventilations using the BVM. (pp 431–433, Skill Drill 10-9)
17. Demonstrate the use of a manually triggered ventilation device to assist in delivering artificial ventilation to the patient.

(pp 434–435)
18. Demonstrate the use of an automatic transport ventilator to assist in delivering artificial ventilation to the patient. (p 435)
s
19. Demonstrate the use of CPAP. (pp 435–439, Skill Drill 10-10)

Introduction

The single most important step in caring for patients is to make sure that life threats are addressed. A primary component of that is to ensure that patients can breathe adequately. When the ability to breathe is disrupted, oxygen delivery to the body tissues and cells is compromised. Cells require a constant supply of oxygen to survive. Within seconds of being deprived of oxygen, vital organs such as the heart and brain may not function normally. Therefore, it is imperative that you recognize airway and breathing inadequacies and correct them immediately. Brain tissue will begin to die within 4 to 6 minutes without oxygen.

Oxygen reaches body tissues and cells through two separate but related processes: breathing and circulation. During inhalation, oxygen moves from the atmosphere into the lungs, then crosses the alveolar membrane onto hemoglobin by a process called **diffusion**. Diffusion is a process in which molecules move from an area of higher concentration to an area of lower concentration. Next, red blood cells carry the hemoglobin, and therefore oxygen, through the body, ultimately delivering it to the capillaries to oxygenate the body's cells. At the same time, carbon dioxide, produced by cells in the tissues of the body, moves from the blood into the air sacs by diffusion. The blood, enriched with oxygen, travels through the body by the pumping action of the heart. The carbon dioxide then leaves the body during exhalation.

As an EMT, you must be able to locate the parts of the respiratory system, understand how the system works, and be able to recognize which patients are breathing adequately and which patients are breathing inadequately. This will enable you to determine how best to treat your patients.

This chapter reviews the anatomy, physiology, and pathophysiology of the respiratory system. It describes how to assess patients quickly and to carefully determine their airway and ventilation status. The equipment, procedures, and guidelines that you will need to manage a patient's airway and breathing are described in detail. You will learn several ways to open a patient's airway and specific techniques for removing foreign objects or fluids that may be blocking the airway. Because airway management equipment can be dangerous if used improperly, the chapter thoroughly discusses airway adjuncts, oxygen therapy devices, and artificial ventilation methods.

YOU are the Provider — PART 1

You and your partner are dispatched to a residence at 145 Landa Street for a man with trouble breathing. The patient's wife, who called 9-1-1, told the dispatcher that her husband is "breathing funny" and is not responding to her appropriately. The time is 1510 hours, the temperature outside is 39°F (4°C), and a fine mist is falling.

1. What is the function of the respiratory system?
2. What is the difference between ventilation and respiration?
3. How often should you assess a patient's airway and breathing status?

Anatomy of the Respiratory System

The respiratory system consists of all the structures in the body that make up the **airway** and help us breathe, or ventilate **Figure 10-1**. The airway is divided into the upper and lower airway. Structures that help us breathe include the diaphragm, the muscles of the chest wall, the accessory muscles of breathing, and the nerves from the brain and spinal cord to those muscles. Ventilation is the exchange of air between the lungs and environment. The diaphragm and muscles of the chest wall are responsible for the regular rise and fall of the chest that accompany normal breathing.

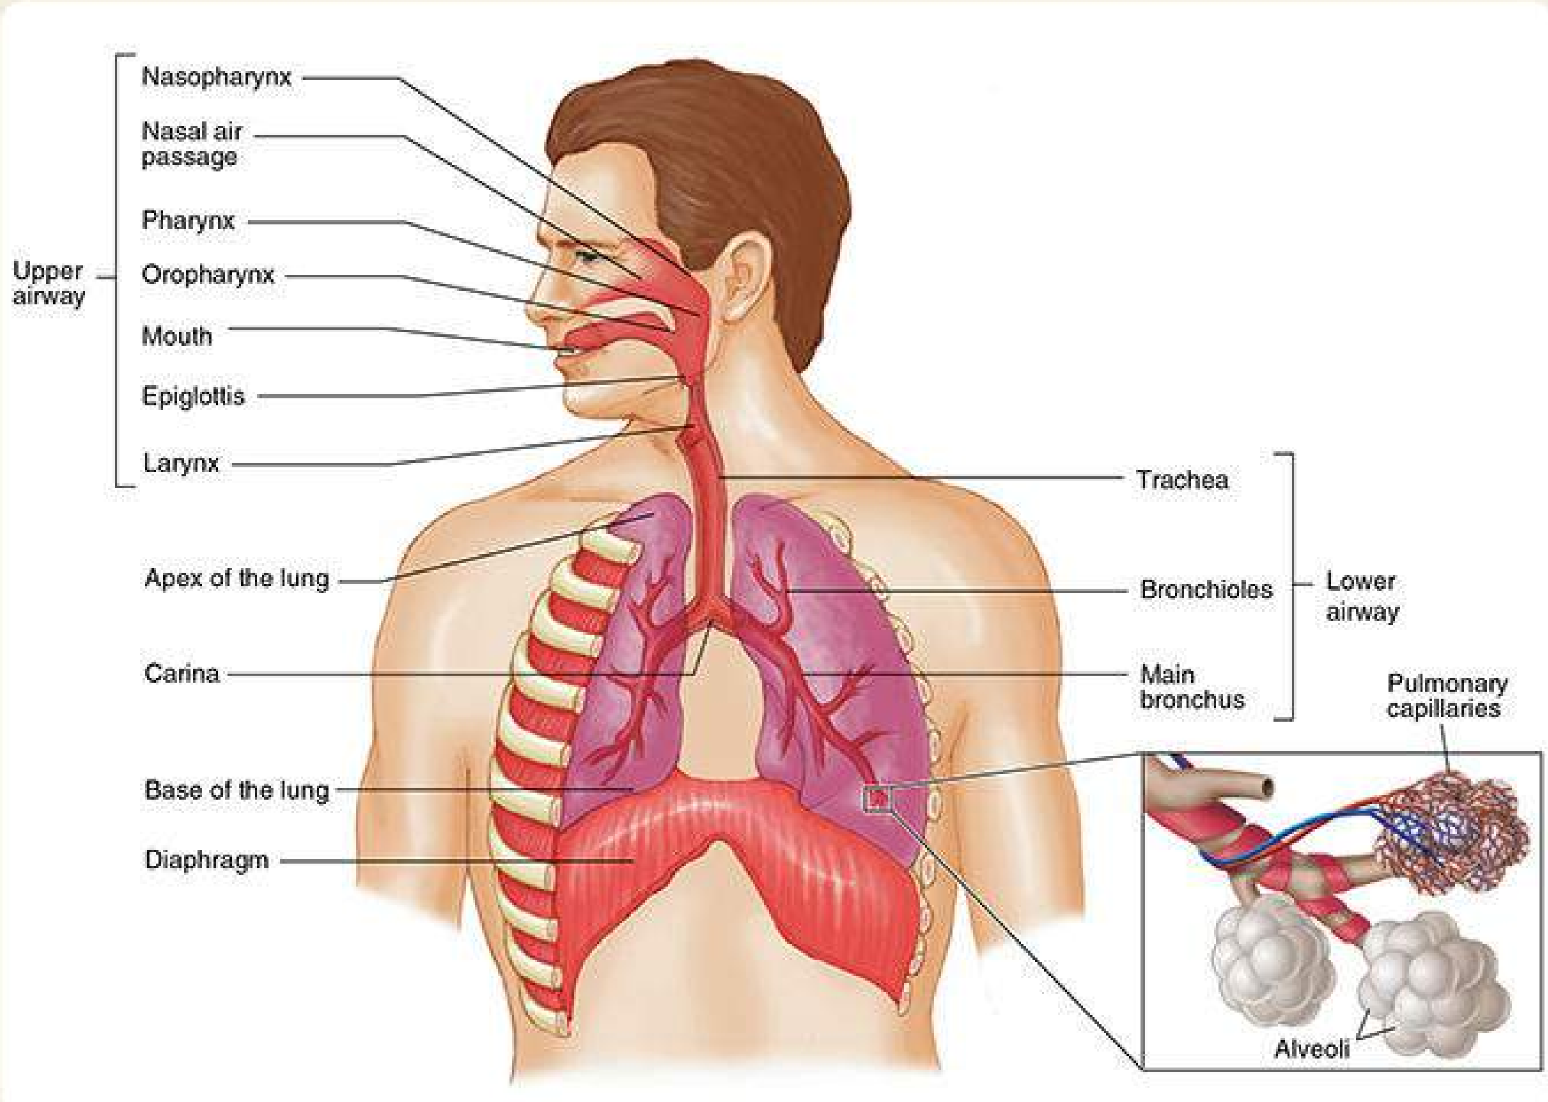

Figure 10-1 The upper and lower airways contain the structures in the body that help us breathe.

Anatomy of the Upper Airway

The upper airway consists of all anatomic airway structures above the level of the vocal cords. These include the nose, mouth, jaw, oral cavity, pharynx, and larynx. Its major functions are to warm, filter, and humidify air as it enters the body through the nose and mouth. The pharynx (throat) is a muscular tube that extends from the nose and mouth to the level of the esophagus and trachea. The pharynx is composed of the nasopharynx, oropharynx, and the laryngopharynx (also called the hypopharynx) **Figure 10-2**. The laryngopharynx is the lowest portion of the pharynx. At the base, it splits into two lumens, the larynx anteriorly and the esophagus posteriorly.

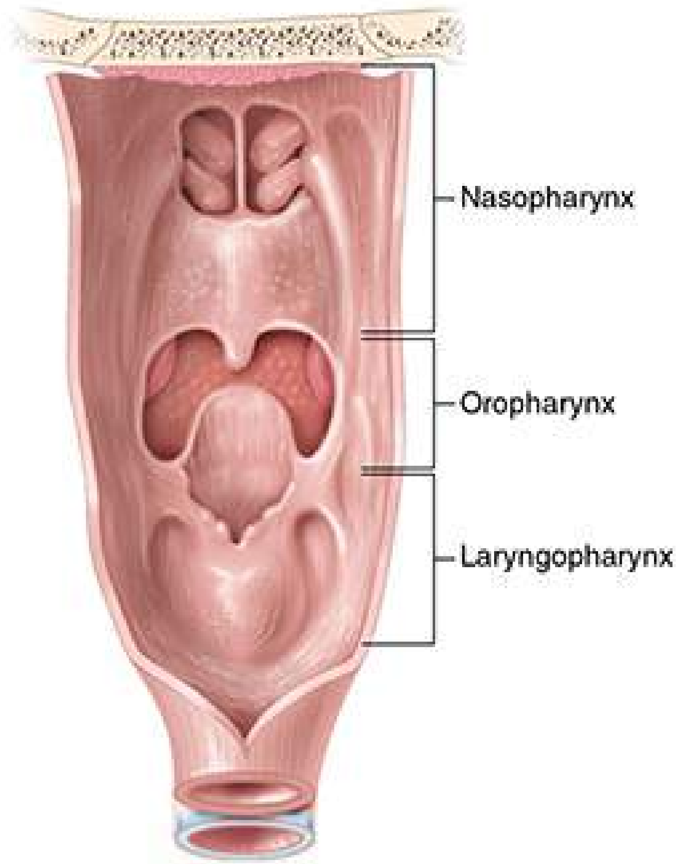

Figure 10-2 The pharynx.

Nasopharynx

During inhalation, air typically enters the body through the nose and passes into the **nasopharynx**. The nasopharynx is lined with a ciliated mucous membrane that keeps contaminants such as dust and other small particles out of the respiratory tract. In addition, the mucous membrane warms and humidifies air as it enters the body.

Oropharynx

The **oropharynx** forms the posterior portion of the oral cavity, which is bordered superiorly by the hard and soft palates, laterally by the cheeks, and inferiorly by the tongue **Figure 10-3**. Superior to the larynx, the epiglottis helps separate the digestive system from the respiratory system. Its function is to prevent food and liquid from entering the larynx during swallowing. When swallowing occurs, the larynx is elevated and the epiglottis folds over the glottis to prevent **aspiration** of contents into the trachea.

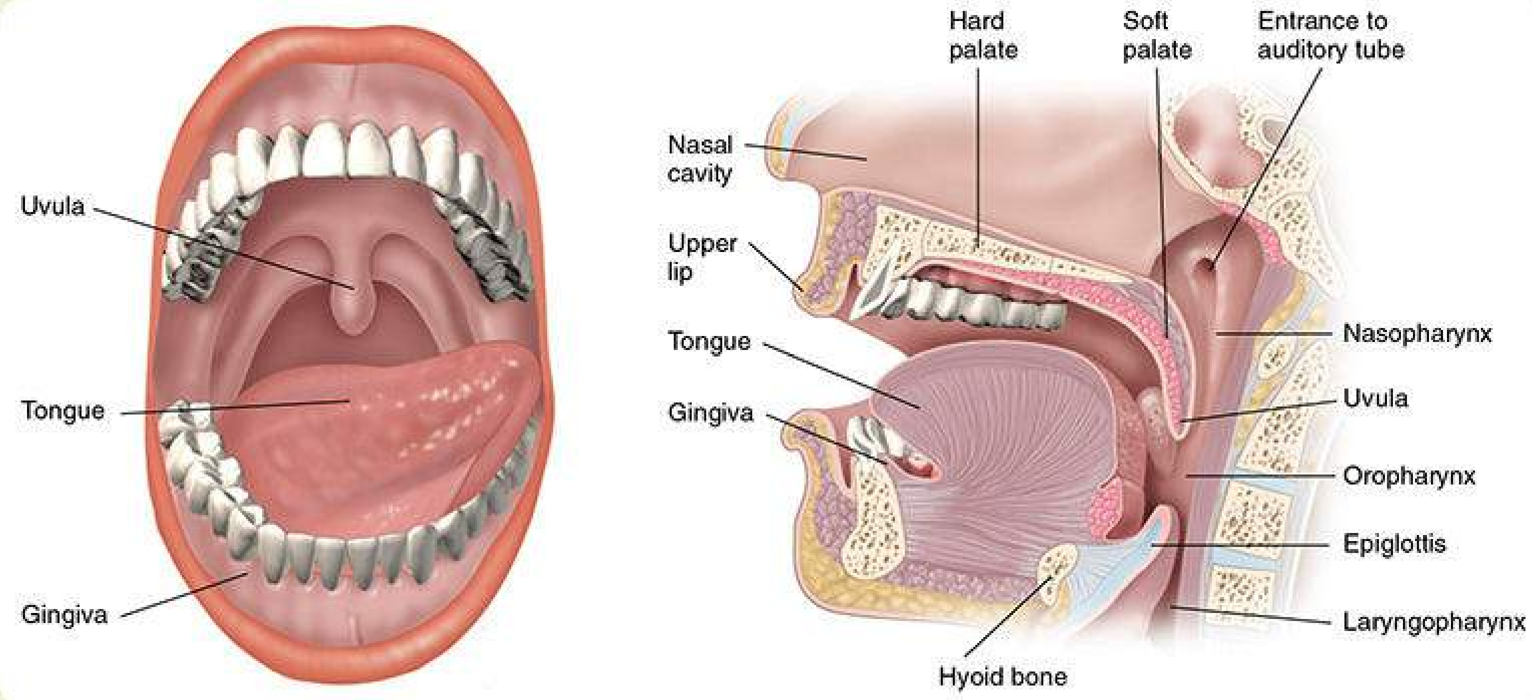

Figure 10-3 The oral cavity.

Larynx

The **larynx** is a complex structure formed by many independent cartilaginous structures **Figure 10-6**. It marks where the upper airway ends and the lower airway begins.

Special Populations

Although the maneuvers, techniques, and indications for airway management are essentially the same in children as they are in adults, several anatomic differences in the child make mastery of these techniques difficult.

Infants and small children have a proportionately larger occiput (posterior portion of the cranium), which causes the head to flex when the child lies supine; this position itself can cause an airway obstruction. When positioning the airway of an infant or child, place a folded towel under the child's shoulders to maintain a neutral position of the head.

Compared with adults, children have a proportionately smaller mandible and a proportionately larger tongue **Figure 10-4**. Both factors increase the incidence of airway obstruction in children.

The child's epiglottis is more floppy and omega-shaped than an adult's **Figure 10-5**.

In general, the infant's and the child's airway is smaller and narrower at all levels. The larynx lies more superior and anterior than an adult's. The larynx is also funnel-shaped due to the narrow, underdeveloped cricoid cartilage. In children younger than 8 years, the narrowest portion of the airway is at the cricoid ring. Further narrowing of the child's inherently narrow airway, such as that caused by soft-tissue swelling or foreign body aspiration, can result in a major increase in airway resistance and breathing inadequacy.

Children do not have well-developed chest musculature, and their ribs and cartilage are softer and more pliable than an adult's. As a result, the thoracic cavity cannot optimally contribute to lung expansion. Children rely heavily on their diaphragm for breathing, which moves their abdomen in and out. For this reason, infants and children are commonly referred to as "belly breathers." The child's epiglottis and surrounding structures.

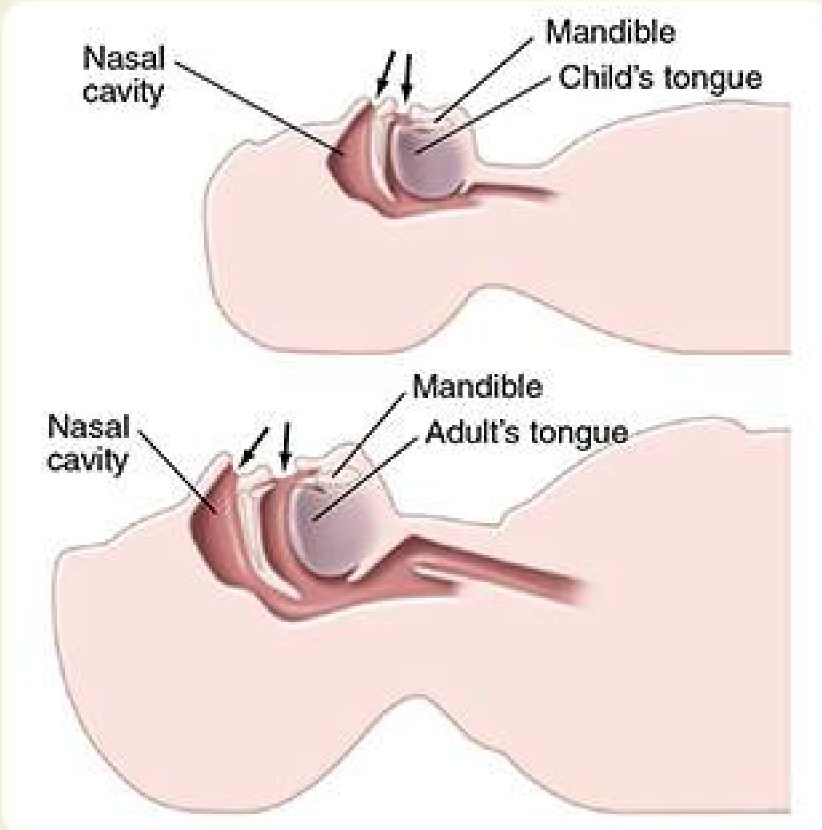

Figure 10-4 In children, the mandible is proportionately smaller and the tongue is proportionately larger than in an adult.

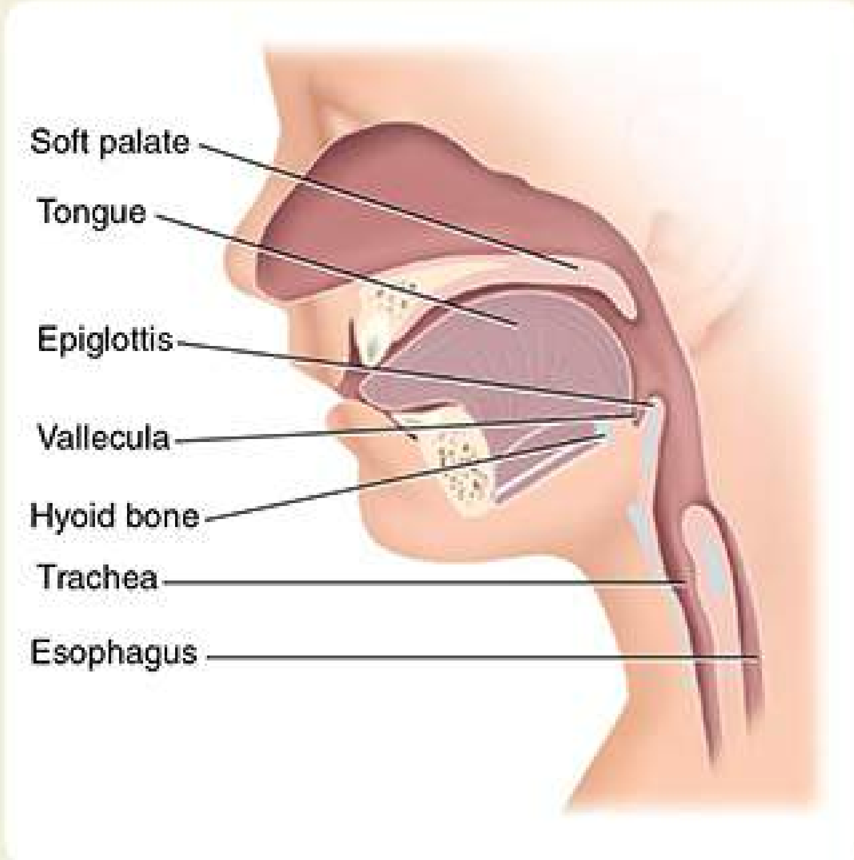

Figure 10-5 The child's epiglottis and surrounding structures.

The thyroid cartilage is a shield-shaped structure formed by two plates that join in a V shape anteriorly to form the laryngeal prominence known as the Adam's apple.

The cricoid cartilage, or cricoid ring, lies inferiorly to the thyroid cartilage; it forms the lowest portion of the larynx. The cricoid cartilage is the first ring of the trachea and the only lower airway structure that forms a complete ring. The cricothyroid membrane is the elastic tissue that connects the thyroid cartilage superiorly to the cricoid ring inferiorly.

The **glottis**, also called the glottic opening, is the space between the vocal cords and the narrowest portion of the adult's airway. The lateral borders of the glottis are the **vocal cords**. These white bands of thin muscle tissue are partially separated at rest and serve as the primary center for speech production. In addition, the vocal cords contain defense reflexes that protect the lower airway, causing a spasmodic closure to the lower airway to prevent substances from entering the trachea (eg, water, vomitus).

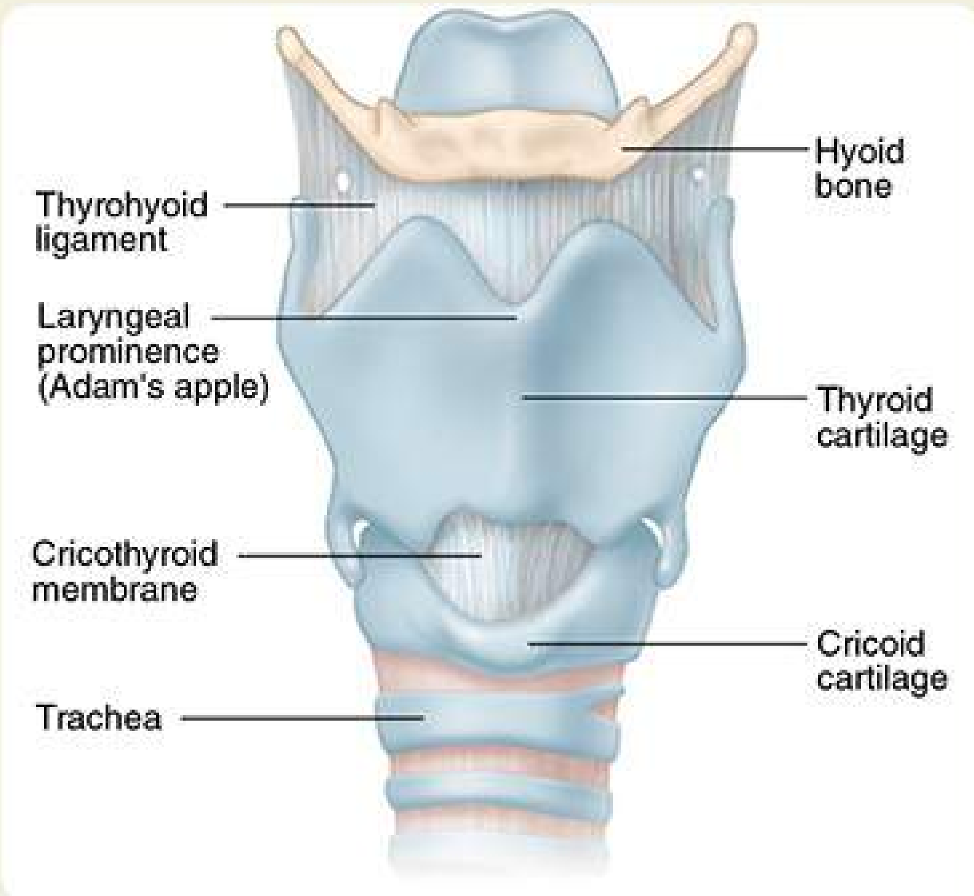

Figure 10-6 The larynx.

Anatomy of the Lower Airway

The function of the lower airway is to deliver oxygen to the alveoli. Its external boundaries are the fourth cervical vertebra and the xiphoid process, which is the narrow, cartilaginous, lower tip of the sternum. Internally, the lower airway spans the glottis to the pulmonary capillary membrane.

The trachea, or windpipe, is the conduit for air entry into the lungs. This tubular structure is approximately 10 to 12 cm in length and consists of C-shaped cartilaginous rings. The trachea begins directly below the cricoid cartilage and descends anteriorly down the midline of the neck into the thoracic cavity. Once in the thoracic cavity, the trachea divides at the level of the carina into the two mainstem bronchi (right and left). The hollow bronchi are supported by cartilage and distribute air into the right and left lungs.

The lungs consist of the entire mass of tissue that includes the smaller bronchi, bronchioles, and alveoli Figure 10-7. The lungs are surrounded by a serous membrane called the pleura. All lung tissue is covered with a thin, slippery outer membrane called the visceral pleura. The parietal pleura lines the inside of the thoracic cavity. A small amount of fluid is found between these two layers and serves as a lubricant to prevent friction during breathing.

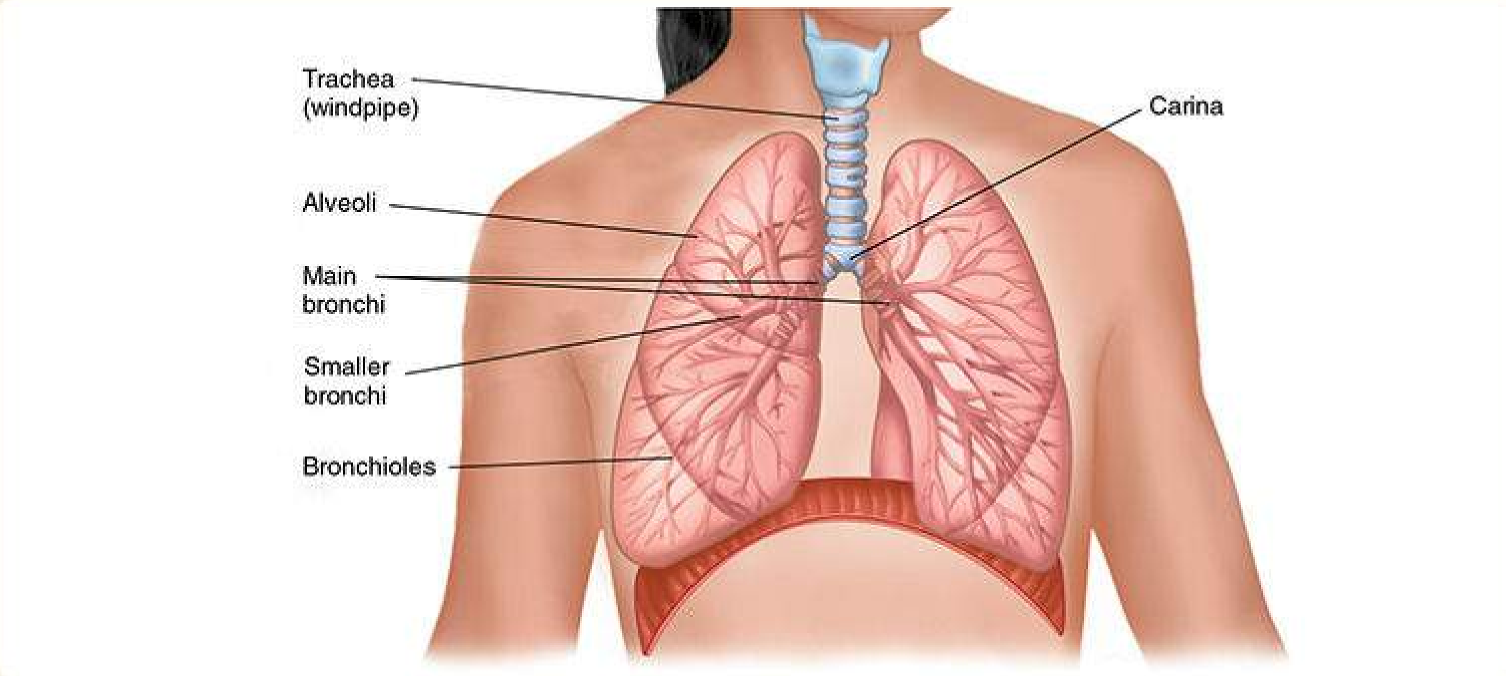

Figure 10-7 The trachea and the lungs are lower airway structures.

On entering the lungs, each bronchus divides into increasingly smaller bronchi, which in turn subdivide into bronchioles. The **bronchioles** are thin, hollow tubes made of smooth muscle. The tone of these smooth muscles allows the bronchioles to dilate or constrict in response to various stimuli. The smaller bronchioles branch into alveolar ducts that end at the alveolar sacs.

The alveoli, located at the end of the airway, are millions of thin-walled, balloonlike sacs that serve as the functional site for the exchange of oxygen and carbon dioxide. Surrounding each of these sacs is an intricate bed of blood vessels, known as pulmonary capillaries. Oxygen diffuses through the lining of the alveoli into the pulmonary capillaries where, depending on adequate blood volume and pressure, it is carried back to the heart for distribution to the rest of the body. At the same time, carbon dioxide (waste) diffuses from the pulmonary capillaries into the alveoli, where it is exhaled and removed from the body.

The chest cage (thoracic cavity) contains the lungs, one on each side **Figure 10-8**. The boundaries of the thorax are the rib cage anteriorly, superiorly, and posteriorly and the diaphragm inferiorly. Each individual rib plays a part in the overall protection of the thorax. In between each rib are intercostal muscles that can assist with breathing; however, they generally are not used unless the patient is in respiratory distress. Within the chest cage, you will find the lungs, which hang freely within the chest cavity. Between the lungs is a space called the **mediastinum**, which is surrounded by tough connective tissue. This space contains the heart, the great vessels, the esophagus, the trachea, the major bronchi, and many nerves. The mediastinum effectively separates the right lung space from the left lung space. In addition to the respiratory and circulatory structures found in the chest cage, an important structure of the nervous system is also found in the thorax—the **phrenic nerve**. The phrenic nerve innervates the diaphragm muscle, allowing it to contract. Contraction of the diaphragm occurs in a downward direction and is necessary for adequate breathing to occur.

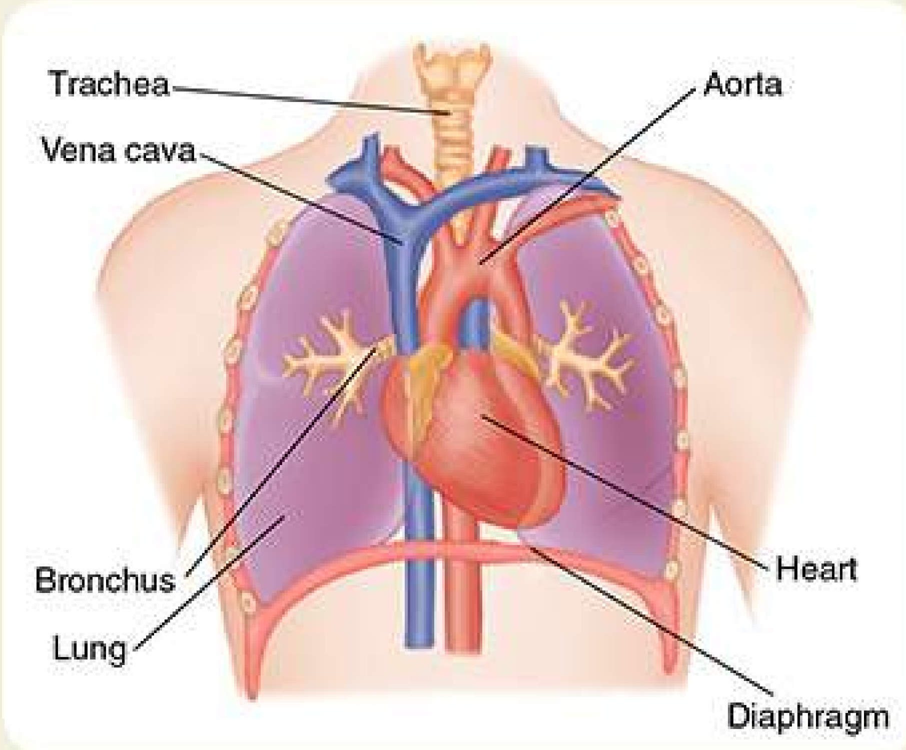

Figure 10-8 The thoracic cavity contains important anatomic structures for respiration, including the lungs and bronchi, heart, great vessels (the vena cava and aorta), and trachea.

Physiology of Breathing

The respiratory and cardiovascular systems work together to ensure that a constant supply of oxygen and nutrients is delivered to every cell in the body and carbon dioxide and waste products are removed from every cell. The following sections will describe the process of ventilation, oxygenation, and respiration; however, you first need to understand how the processes of breathing and circulation are connected.

As described earlier, air enters the body through the oral and nasal cavities and travels into the lungs. This occurs because a negative pressure is created in the chest. Eventually the air reaches the alveolar sacs where oxygen diffuses across the alveolar membrane and enters the bloodstream. At the same time, carbon dioxide diffuses from the bloodstream into the alveoli. The carbon dioxide is exhaled from the lungs, and the oxygen is transported back to the heart, where it is distributed to the rest of the body.

The heart pumps blood to the tissues of the body through a series of arteries and veins. Arteries carry blood away from the heart and eventually branch into capillaries. Once in the capillaries, the exchange of nutrients and waste products takes place. Oxygen and nutrients leave the capillaries and enter the cells. At the same time, waste products, such as carbon dioxide, diffuse from the cells back into the blood of the capillaries. From here, the deoxygenated blood travels back to the heart. The deoxygenated blood enters the right side of the heart through the right atrium. The right ventricle then pumps the blood to the lungs for oxygenation and removal of carbon dioxide. The oxygenated blood then travels back to the heart and into the left atrium. The left ventricle then pumps the oxygenated blood to the rest of the body. Refer back to Chapter 6, *The Human Body*, for an illustration of this process.

It is important to understand that the respiratory and circulatory systems work together to facilitate oxygen delivery to the tissues of the body **Table 10-1**. When one of these systems is compromised, oxygen delivery is not effective and cellular death could result.

Table 10-1 Ventilation, Oxygenation, and Respiration

Function	Definition
Ventilation	The physical act of moving air into and out of the lungs.
Oxygenation	The process of loading oxygen molecules onto hemoglobin molecules in the bloodstream.
Respiration	The actual exchange of oxygen and carbon dioxide in the alveoli as well as the tissues of the body.

Words of Wisdom

Ventilation is the physical act of moving air in and out of the lungs. Ventilation is required for adequate respiration. If ventilation is adequate, other problems may hinder respiration. Examples of interruptions of ventilation include trauma such as flail chest, foreign body airway obstruction, or an injury to the spinal cord that disrupts the phrenic nerve, which innervates the diaphragm.

Ventilation

Pulmonary ventilation, the process of moving air into and out of the lungs, is necessary for oxygenation and respiration to occur. Adequate, continuous ventilation is essential for life and therefore is one of the highest priorities in treating any patient. If a patient is not breathing or is breathing inadequately, you must immediately intervene to ensure adequate ventilation.

Inhalation

The active, muscular part of breathing is called **inhalation**. When a person inhales, the diaphragm and intercostal muscles contract, allowing air to enter the body and travel to the lungs. When it contracts, the diaphragm moves down slightly, enlarging the thoracic cage from top to bottom. When the intercostal muscles contract, they lift the ribs up and out. The combined actions of these structures enlarge the thorax in all directions. Take a deep breath to see how your chest expands.

The lungs have no muscle tissue; therefore, they cannot move on their own. They need the help of other structures to be able to expand and contract during inhalation and exhalation. Therefore, the ability of the lungs to function properly is dependent on the movement of the chest and supporting structures. These structures include the thorax, the thoracic cage (chest), the diaphragm, the intercostal muscles, and the accessory muscles of breathing. Accessory muscles are secondary muscles of respiration.

Partial pressure is the term used to describe the amount of gas in air or dissolved in fluid, such as blood. Partial pressure is measured in millimeters of mercury (mm Hg). The partial pressure of oxygen in air residing in the alveoli (Pao_2) is 104 mm Hg. Carbon dioxide (co_2) enters the alveoli from the blood and causes a partial pressure of 40 mm Hg.

Deoxygenated arterial blood from the right side of the heart has lower levels of oxygen (Pao_2) than carbon dioxide

($Paco_2$). The body attempts to equalize the two, which results in oxygen diffusion across the membrane into the blood and carbon dioxide diffusion in the opposite direction. The carbon dioxide is then eliminated from the lungs as waste during exhalation. This process occurs in reverse when the arterial blood reaches the tissues. Oxygen diffuses into the tissue fluid and then into the cells, and carbon dioxide diffuses out of the cells into the tissue fluid and blood.

The air pressure outside the body, called the atmospheric pressure, is normally higher than the air pressure within the thorax. During inhalation, the thoracic cage expands and the air pressure within the thorax decreases, creating a slight vacuum. This pulls air in through the trachea, causing the lungs to fill. When the air pressure outside equals the air pressure inside, air stops moving. Gases, such as oxygen, will move from an area of higher pressure to an area of lower pressure until the pressures are equal. At this point, the air stops moving, and inhalation stops.

It may help you to understand this if you think of the thoracic cage as a bell jar in which balloons are suspended. In this example, the balloons are the lungs. The base of the jar is the diaphragm, which moves up and down slightly with each breath. The ribs, which are the sides of the jar, maintain the shape of the chest. The only opening into the jar is a small tube at the top, similar to the trachea. During inhalation, the bottom of the jar moves down slightly, causing a decrease in pressure in the jar and creating a slight vacuum. As a result, the balloons fill with air **Figure 10-9**.

The entire process of inspiration is focused on delivering oxygen to the alveoli. However, not all of the air you breathe actually reaches the alveoli. **Table 10-2** reviews terminology discussed in Chapter 6, *The Human Body*, as it relates to the processes of inspiration and ventilation. The average tidal volume, the amount of air in milliliters (mL) moved into or out of the lung during a single breath, for an average adult man is approximately 500 mL. Breathing becomes deeper as the tidal volume responds to the increased metabolic demand for oxygen. However, as noted previously, not all inspired air reaches the alveoli for gas exchange. Dead space is described as the portion of inspired air that fails to reach the alveoli.

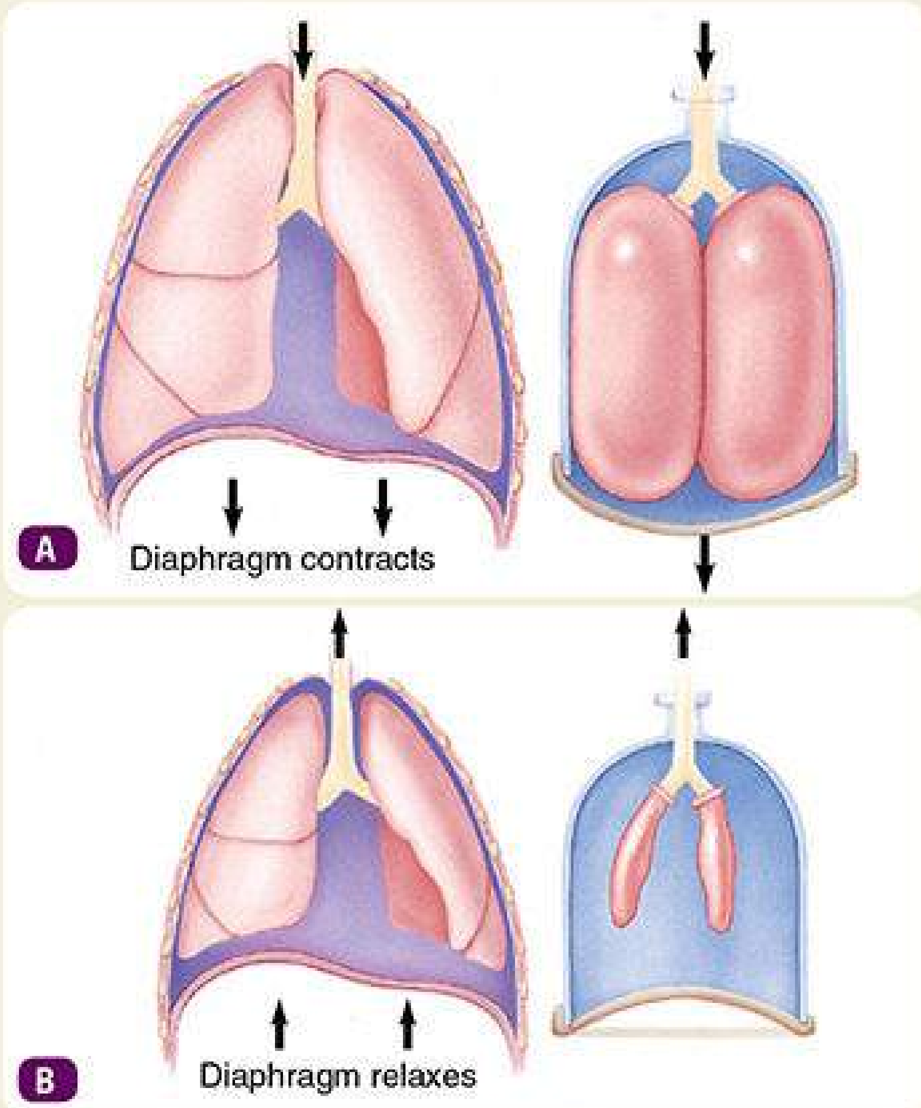

Figure 10-9 The mechanism of ventilation can be illustrated by using a bell jar. **A.** Inhalation and chest expansion, anatomic (left) and bell jar (right). **B.** Exhalation and chest contraction, anatomic (left) and bell jar (right).

Exhalation

Unlike inhalation, **exhalation** does not normally require muscular effort; therefore, it is a passive process. During exhalation, the diaphragm and the intercostal muscles relax. In response, the thorax decreases in size, and the ribs and muscles assume a normal resting position. When the size of the thoracic cage decreases, air in the lungs is compressed into a smaller space. The air pressure within the thorax then becomes higher than the outside pressure, and the air is pushed out through the trachea.

Remember that air will reach the lungs only if it travels through the trachea. This is why clearing and maintaining an open airway is so important. Clearing the airway means removing obstructing material, tissue, or fluids from the nose, mouth, and throat. Maintaining the airway means keeping the airway **patent** so that air can enter and leave the lungs freely **Figure 10-10**.

Table 10-2 Ventilation Terminology

Term	Definition
Tidal volume	The amount of air (in mL) that is moved in or out of the lungs during one breath.
Residual volume	The air that remains in the lungs after maximal expiration.
Alveolar ventilation	The volume of air that reaches the alveoli; calculated by subtracting the amount of dead space air from the tidal volume.
Minute volume	The volume of air moved through the lungs in 1 minute; calculated by multiplying tidal volume and respiratory rate.
Alveolar minute volume	The volume of air moved through the lungs in 1 minute minus the dead space; calculated by multiplying tidal volume (minus dead space) and respiratory rate.
Vital capacity	The amount of air that can be forcibly expelled from the lungs after breathing in as deeply as possible.
Dead space	The portion of the tidal volume that does not reach alveoli and thus does not participate in gas exchange.

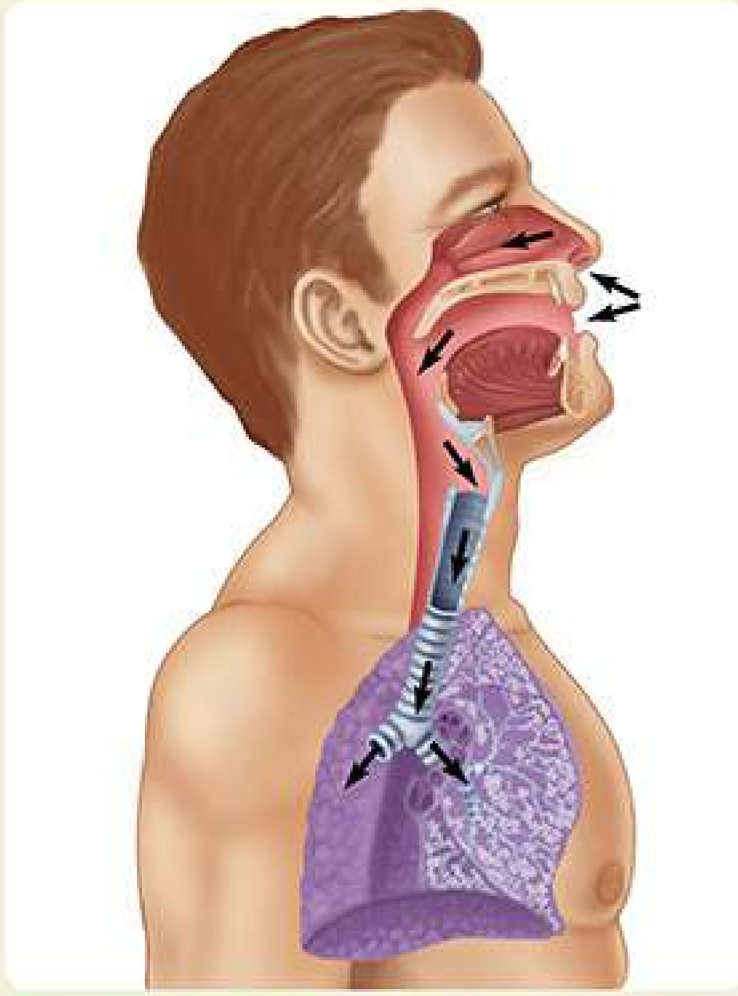

Figure 10-10 Air reaches the lungs only if it travels through the trachea. Maintaining the airway means keeping the airway patent so that air can enter and leave the lungs freely.

© Jones & Bartlett Learning.

Air may also pass into the chest cavity through an abnormal opening in the throat or chest wall as a result of trauma, remaining outside the bronchi and never reaching the alveoli. In later chapters, you will learn how to recognize and manage these potentially life-threatening conditions.

Regulation of Ventilation

The body’s need for oxygen is constantly changing. The respiratory system must be able to accommodate the changes in oxygen demand by altering the rate and depth of ventilation. The regulation of ventilation involves a complex series of receptors and feedback loops that sense gas concentrations in the body fluids and send messages to the respiratory center in the brain to adjust the rate and depth of ventilation accordingly. Failure to meet the body’s needs for oxygen may result in **hypoxia**. Hypoxia is an extremely dangerous condition in which the tissues and cells of the body do not get enough oxygen. If this process is not corrected, patients may die quickly.

For most people, the drive to breathe is based on pH changes (related to carbon dioxide levels) in the blood and cerebrospinal fluid. However, patients with chronic obstructive pulmonary diseases (COPD) have difficulty eliminating carbon dioxide through exhalation; thus, they always have higher levels of carbon dioxide. This condition potentially alters their drive for breathing. The theory is that respiratory centers in the brain gradually adjust to accommodate high levels of carbon dioxide. In patients with COPD, the body uses a “backup system” to control breathing. This theory of secondary control of breathing, called **hypoxic drive**, is based on levels of oxygen dissolved in plasma. This is different from the primary control of breathing that uses carbon dioxide as the driving force. Hypoxic drive is typically found in end-stage COPD. Providing high concentrations of oxygen over time will increase the amount of oxygen dissolved in plasma.

However, many believe this could potentially negatively affect the body's drive to breathe.

Regardless of the current research, it still remains certain that caution should be taken when administering high concentrations of oxygen to patients with obstructive pulmonary disease. However, it is important to remember that high concentrations of oxygen should never be withheld from any patient who needs it. Patients with severe respiratory and/ or circulatory compromise should receive high concentrations of oxygen regardless of their underlying medical conditions.

Patients who are breathing inadequately will show varying signs and symptoms of hypoxia. The onset and degree of tissue damage caused by hypoxia often depend on the quality of ventilations. Early signs of hypoxia include restlessness, irritability, apprehension, fast heart rate (tachycardia), and anxiety. Late signs of hypoxia include mental status changes, a weak (thready) pulse, and cyanosis. Conscious patients will complain of shortness of breath (**dyspnea**) and may not be able to talk in complete sentences. The best time to give a patient oxygen is before signs and symptoms of hypoxia appear.

Oxygenation

Oxygenation is the process of loading oxygen molecules onto hemoglobin molecules in the bloodstream. Adequate oxygenation is required for internal respiration to take place; however, it does not guarantee internal respiration is taking place. Oxygenation requires that the air used for ventilation contains an adequate percentage of oxygen. Ventilation without oxygenation can occur in places where oxygen levels in the breathing air have been depleted, such as in mines and confined spaces. Ventilation without adequate oxygenation also occurs in climbers who ascend too quickly to an altitude of lower atmospheric pressure. At high altitudes, the percentage of oxygen remains the same, but the atmospheric pressure makes it difficult to adequately bring sufficient amounts of oxygen into the body.

Words of Wisdom

Oxygenation can be disrupted through carbon monoxide poisoning. Carbon monoxide has a much greater affinity for hemoglobin than oxygen (250 times more), which makes proper transport of oxygen to tissues difficult.

Respiration

All living cells perform a specific function and need energy to survive. Cells take energy from nutrients through a series of chemical processes. The name given to these processes as a whole is **metabolism (cellular respiration)**. During metabolism, each cell combines nutrients (such as sugar) and oxygen and produces energy and waste products, primarily water and carbon dioxide. Each cell in the body requires a continuous supply of oxygen and a regular means of disposing of waste (carbon dioxide). The body provides for these requirements through respiration.

Respiration is the process of exchanging oxygen and carbon dioxide. This exchange occurs by diffusion, a process in which a gas moves from an area of greater concentration to an area of lower concentration. In the body, gases diffuse rapidly across a short distance of only micrometers, and the diffusion occurs rapidly.

External Respiration

External respiration (pulmonary respiration) is the process of breathing fresh air into the respiratory system and exchanging oxygen and carbon dioxide between the alveoli and the blood in the pulmonary capillaries **Figure 10-11**.

Fresh air that is inspired into the lungs contains about 21% oxygen, 78% nitrogen, and 0.3% carbon dioxide. As this air reaches the alveoli, it comes into contact with a fluid called **surfactant**. Surfactant reduces surface tension within the alveoli and keeps them expanded, thus making it easier for the gas exchange between oxygen and carbon dioxide to take place. It is important to remember that while adequate ventilation is necessary for external respiration to take place, it does not guarantee that external respiration is being achieved.

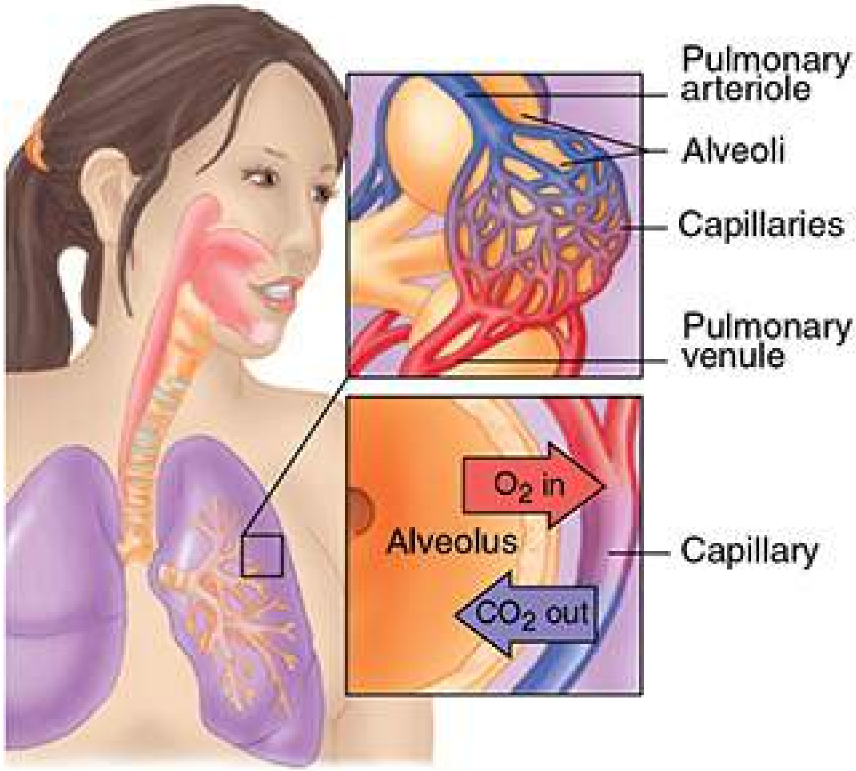

Figure 10-11 External respiration.

Once the oxygen crosses the alveolar membrane, it is bound to hemoglobin, an iron-containing molecule that has a great affinity for oxygen molecules. Found in red blood cells, hemoglobin molecules low in oxygen concentration are pumped from the right side of the heart into the capillaries of the pulmonary circulation. The capillaries surround alveoli containing high concentrations of oxygen (from inspired air). The hemoglobin molecules pick up fresh oxygen as it crosses the alveolar membrane and transport it back to the left side of the heart, where it is pumped out to the rest of the body. Under normal conditions, 96% to 100% of the hemoglobin receptor sites contain oxygen.

Internal Respiration

The exchange of oxygen and carbon dioxide between the systemic circulatory system and the cells of the body is called **internal respiration**. As blood travels through the body, it supplies oxygen and nutrients to various tissues and cells. Oxygen passes from the blood in the capillaries to the cells within the body's tissues. At the same time, carbon dioxide and cell waste pass from the cells into the capillaries, where they are then transported in the venous system back to the lungs **Figure 10-12**.

Every cell in the body needs a constant supply of oxygen to survive. Whereas some tissues are more resilient than others, eventually all cells will die if deprived of oxygen **Figure 10-13**. To deliver adequate amounts of oxygen to the tissues of the body, sufficient levels of external ventilation and perfusion must take place.

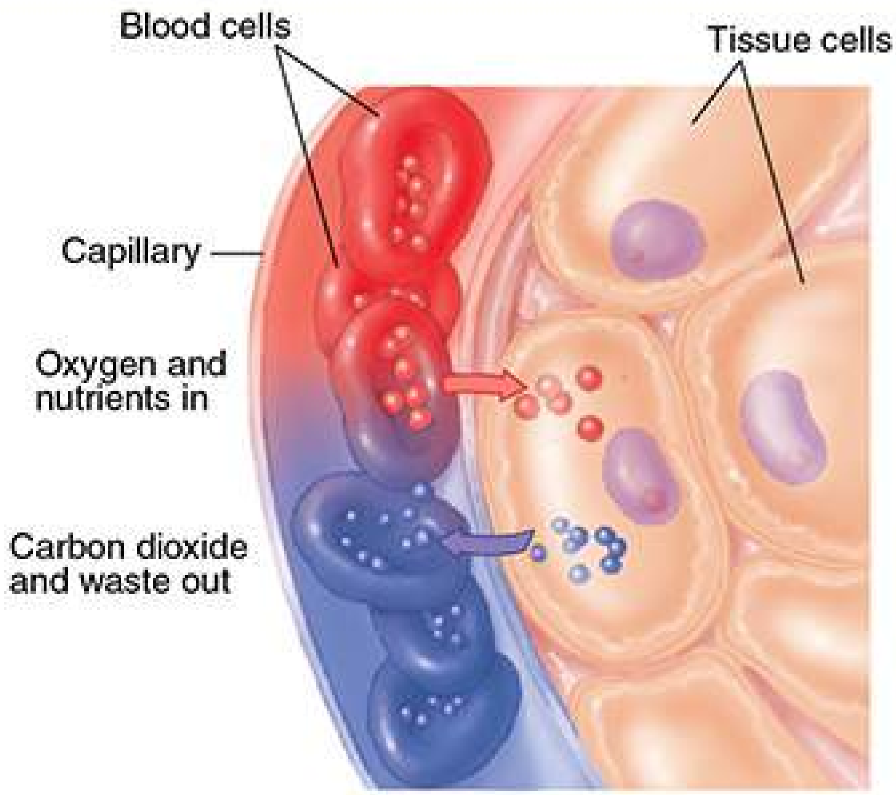

Figure 10-12 Internal respiration.

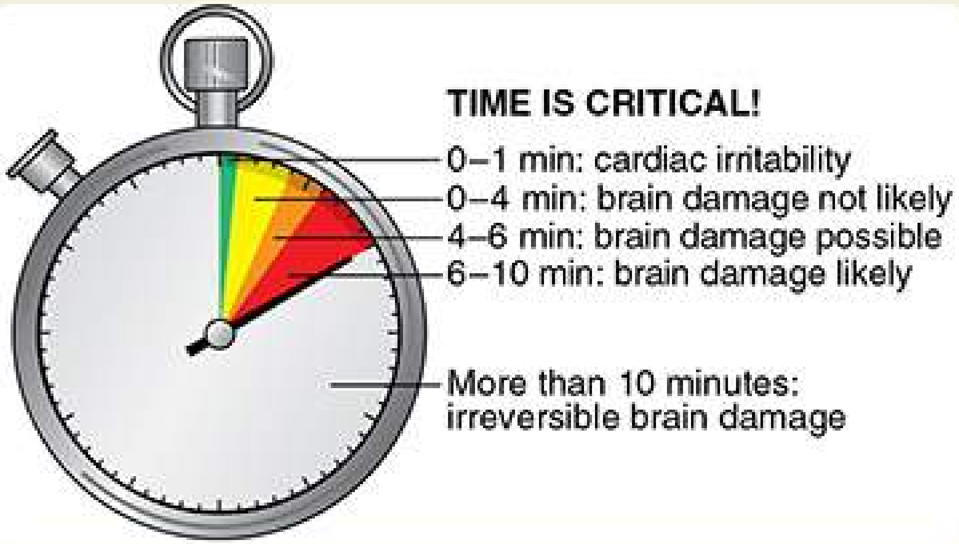

Figure 10-13 Cells need a constant supply of oxygen to survive. Some cells may be severely or permanently damaged after 4 to 6 minutes without oxygen.

In the presence of oxygen, cells convert glucose into energy through a process known as **aerobic metabolism**. Energy is produced through a series of biochemical reactions. Without adequate oxygen, the cells do not completely convert glucose into energy, and lactic acid and other toxins accumulate in the cell. This process, **anaerobic metabolism**, cannot meet the metabolic demands of the cell. If this process is not corrected, the cells will eventually die. This is why adequate levels of perfusion (circulation of blood within an organ or tissue) and external ventilation must be present for aerobic internal respiration to take place. However, while these elements are necessary for internal respiration, they do not guarantee that aerobic internal respiration will take place.

When cells use oxygen to convert glucose to energy, carbon dioxide, the main waste product, accumulates in the cell. Carbon dioxide is then transported through the circulatory system and back to the lungs for exhalation.

It is important to understand the processes of ventilation, oxygenation, and respiration. The overall goal of these mechanisms is to deliver an adequate supply of oxygen to the cells of the body. When one of these processes fails or becomes disrupted, cells are going to die. By recognizing the signs and symptoms of inadequate tissue perfusion and oxygenation, you can immediately intervene and correct a potentially life-threatening condition.

Pathophysiology of Respiration

Multiple conditions inhibit the body's ability to effectively deliver oxygen to the cells. Disruption of pulmonary ventilation, oxygenation, and respiration will cause immediate effects on the body. As an EMT, you need to recognize these conditions and correct them immediately.

Factors in the Nervous System

Chemical factors are commonly involved in respiratory control issues because of the level of complexity of the human body. A complex series of chemical reactions are constantly taking place. For example, **chemoreceptors** monitor the levels of oxygen, carbon dioxide, hydrogen ions, and the pH of the cerebro-spinal fluid and then provide feedback to the respiratory centers to modify the rate and depth of breathing based on the body's needs at any given time. Central chemoreceptors in the medulla respond quickly to slight elevations in carbon dioxide or a decrease in the pH of the cerebrospinal fluid. The peripheral chemoreceptors, located in the carotid arteries and the aortic arch, are sensitive to decreased levels of oxygen in arterial blood as well as to low pH levels.

When serum carbon dioxide or hydrogen ion levels increase because of medical or traumatic conditions involving the respiratory system, chemoreceptors stimulate the medulla to increase the respiratory rate, thus removing more carbon dioxide or acid from the body. One area in the medulla is responsible for initiating inspiration based on the information received from the chemoreceptors. Another area in the medulla is primarily responsible for motor control of the inspiratory and expiratory muscles.

In addition, stimulation from the pons affects the rate and depth of respirations. If one item in this process is disrupted, then the respiratory process will be affected.

Ventilation/Perfusion Ratio and Mismatch

The lung has a functional role of placing ambient air in proximity to circulating blood to permit gas exchange by simple diffusion. To accomplish this action, air and blood flow must be directed to the same place at the same time. In other words, ventilation (air flow, V) and perfusion (blood flow, Q) must be matched. A failure to match ventilation and perfusion lies behind most abnormalities in oxygen and carbon dioxide exchange.

When ventilation is compromised but perfusion continues, blood passes over some alveolar membranes without gas exchange taking place. This, in turn, results in a lack of oxygen diffusing across the membrane and into blood circulation. Carbon dioxide is also not able to diffuse across the membrane into the lungs and is therefore recirculated within the bloodstream. This condition could lead to severe hypoxemia if this problem is not recognized and treated.

Similar problems can occur when perfusion across the alveolar membrane is disrupted. Even though the alveoli are filled with fresh oxygen, disruption in blood flow does not allow for optimal exchange of gases across the membrane. This results in less oxygen absorption in the bloodstream and less carbon dioxide removal. This can also lead to hypoxemia, and you need to provide immediate intervention to prevent further cellular damage or death.

Factors Affecting Pulmonary Ventilation

Maintaining a patent airway is critical to the delivery of oxygen to the tissues of the body. There are many intrinsic and extrinsic factors that cause airway obstructions.

Intrinsic Factors

Intrinsic conditions such as infections, allergic reactions, and unresponsiveness (tongue obstruction) can cause significant restrictions on the ability to maintain an open airway. Swelling from infections and allergic reactions can be fatal if not aggressively managed with medications and possibly advanced airway maneuvers.

Some factors affecting pulmonary ventilation are not necessarily directly part of the respiratory system. The central and peripheral nervous systems play key roles in the regulation of breathing. Interruptions to these systems can have a drastic effect on the ability to breathe efficiently. Medications that depress the central nervous system lower the respiratory rate and tidal volume. This lower rate and volume will decrease minute volume as well as alveolar volume. As a result, this increases the amount of carbon dioxide in the respiratory and circulatory systems, resulting in an overall increase of carbon dioxide levels in the bloodstream, known as **hypercarbia**. Trauma to the head and spinal cord can also interrupt nervous control of ventilation, resulting in decreased respiratory function and even failure. In addition to medications and trauma, conditions such as muscular dystrophy can also affect nervous control. This disease causes degeneration of muscle fibers resulting in a gradual weakening of muscles, slowing motor development, and loss of muscle contractility. Curvature of the spine is also likely in patients with muscular dystrophy and can impair pulmonary function.

The tongue is the most common airway obstruction in the unresponsive patient. This airway obstruction, while easily corrected, can result in hypoxia and hinder adequate tissue perfusion. Obstruction of the airway by the tongue is also associated with hypercarbia. Snoring respirations and the position of the head and/or neck are good indicators that the tongue may be obstructing the airway. Prompt correction of this obstruction is necessary for adequate oxygenation.

Patients with allergic reactions not only suffer from a potential airway obstruction from swelling, but may also have a decrease in pulmonary ventilation from bronchoconstriction. As the bronchioles constrict, air is forced through smaller lumens resulting in decreased ventilation. This condition is also found in patients suffering from COPD, such as emphysema.

Extrinsic Factors

Extrinsic factors affecting pulmonary ventilation can include trauma or foreign body airway obstruction. Trauma to the airway or chest requires immediate evaluation and intervention. The impact of an injury such as a broken jaw is often overlooked. Patients with a fracture to the mandible, especially unconscious patients, may not be able to maintain an open airway on their own and may require the insertion of an airway adjunct. Blunt or penetrating trauma and burns can disrupt airflow through the trachea and into the lungs, quickly resulting in oxygenation deficiencies. In addition, trauma to the chest wall can result in structural damage to the thorax, leading to inadequate pulmonary ventilation. Swelling, punctures, and bruising have a tremendous effect on the ability to deliver oxygen to the alveoli and into the bloodstream. Proper airway management and high concentrations of oxygen are crucial to the outcome in these situations.

Factors Affecting Respiration

External elements in the environment can affect the overall process of respiration. For proper respiration to take place at the cellular level, both oxygenation and perfusion need to function efficiently.

External Factors

Adequate respiration requires proper ventilation and oxygenation. Here, external factors such as atmospheric pressure and the partial pressure of oxygen in the ambient air play a key role in the overall process of respiration. At high altitudes, the percentage of oxygen remains the same, but the partial pressure decreases because the total atmospheric pressure decreases. The low partial pressure of oxygen can make it difficult (or impossible) to adequately oxygenate tissue, thus interrupting internal respiration. In addition, closed environments, such as mines and trenches, may also have decreases in ambient oxygen, resulting in poor oxygenation and respiration.

Carbon monoxide, along with other toxic and poisonous gases, displaces oxygen in the environment and makes proper oxygenation and respiration difficult. Carbon monoxide, in particular, has a much greater affinity for hemoglobin than oxygen (250 times more), and occupies all the sites on hemoglobin that are normally occupied by oxygen. Loading the hemoglobin with carbon monoxide instead of oxygen prohibits oxygen delivery to the tissues. This results in severe hypoxemia which, if uncorrected, can rapidly lead to death.

Internal Factors

Conditions that reduce the surface area for gas exchange also decrease the body’s oxygen supply, leading to inadequate tissue perfusion. Medical conditions such as pneumonia, pulmonary edema, and COPD/emphysema may also result in a disturbance of cellular metabolism. These conditions decrease the surface area of the alveoli either by damaging the alveoli or by leading to an accumulation of fluid in the lungs.

Nonfunctional alveoli inhibit the diffusion of oxygen and carbon dioxide. As a result, blood entering the lungs from the right side of the heart bypasses the alveoli and returns to the left side of the heart in an unoxygenated state, a condition called **intrapulmonary shunting**.

Drowning victims and/or patients with pulmonary edema have fluid in the alveoli. This accumulation of fluid inhibits adequate gas exchange at the alveolar membrane and results in decreased oxygenation and respiration. In addition, exposure to certain environmental conditions, like high altitudes, or occupational hazards, such as epoxy resins, over time can result in fluid accumulation or other abnormal conditions, resulting in impaired oxygenation. These conditions can interrupt the process of aerobic respiration at the cellular level, resulting in anaerobic respiration and an increase in lactic acid accumulation.

Other conditions affecting cells of the body include hypoxia, hypoglycemia (low blood glucose), and infection. As oxygen and glucose levels decrease, the body is unable to maintain a homeostatic balance with regard to energy production. At this point, the energy production cannot meet the needs of the body, and cellular death is likely if the condition is not corrected. Infection also increases the metabolic needs of the body and disrupts homeostasis. If not corrected, the cells will die as well.

Circulatory Compromise

For respiration to take place, the circulatory system must function efficiently to deliver oxygen to the tissues of the body. When this system becomes compromised, the perfusion of oxygen is not enough to meet the oxygen demands of the tissues.

Obstruction of blood flow to individual cells and tissue is typically related to trauma emergencies you may encounter. These conditions include pulmonary embolism, a simple or **tension pneumothorax**, open pneumothorax (sucking chest wound), hemothorax, and hemopneumothorax. All of these conditions limit the ability for gas exchange at the tissue level as a result of their effects on the respiratory and circulatory systems. In addition, conditions such as heart failure and cardiac tamponade inhibit the ability of the heart to effectively pump oxygenated blood to the tissues.

Blood loss and anemia, a deficiency of red blood cells, result in a decreased ability of blood to carry oxygen. Without sufficient circulating red blood cells, there is not enough hemoglobin to carry oxygen to the tissues.

When the body is in a state of shock, oxygen is not being delivered to the cells efficiently. Hypovolemic shock is an abnormal decrease in blood volume that causes inadequate oxygen delivery to the body. In contrast, vasodilatory shock is not determined by the amount of circulating blood, but by the size of the blood vessels. As the diameter of the blood vessels increases, the blood pressure in the circulatory system decreases. As the systemic blood pressure falls, oxygen is not delivered effectively to the tissues. Both forms of shock result in poor tissue perfusion that leads to anaerobic metabolism. Any patient suspected of being in shock should be treated aggressively to prevent further interruptions to tissue perfusion.

Patient Assessment

Recognizing Adequate Breathing

Breathing is something that all people do every day; yet, most of the time, you are not aware of your own breathing or the breathing of others around you. Breathing should be a smooth flow of air moving into and out of the lungs. As a general rule, unless you are directly assessing the patient's airway, you should not be able to see or hear a patient breathe. Signs of normal (adequate) breathing for adult patients are as follows:

- A normal rate (between 12 and 20 breaths/min)
- A regular pattern of inhalation and exhalation
- Clear and equal lung sounds on both sides of the chest (**bilateral**)
- Regular and equal chest rise and fall (chest expansion)
- Adequate depth (tidal volume)

Recognizing Abnormal Breathing

An adult who is awake, alert, and talking to you generally has no immediate airway or breathing problems. However, you should always have supplemental oxygen and a **bag-valve mask (BVM)** or pocket mask close at hand to assist with breathing if necessary. An adult who is breathing normally will have respirations of 12 to 20 breaths/min **Table 10-3**.

Adult patients who are breathing slower (fewer than 12 breaths/min) than normal should be evaluated for inadequate breathing by assessing the depth of respirations. Patients with shallow depth of breathing (reduced tidal volume) may require assisted ventilations, even if the respiratory rate is within normal limits.

YOU are the Provider — PART 2

You arrive at the patient's residence, enter his home, and find him sitting on the couch. He is a 55-year-old man with a history of congestive heart failure and high blood pressure. He is conscious, but appears sleepy, and can only speak in two-word sentences before stopping to catch his breath. As your partner opens the jump kit, you assess the patient.

Recording Time: 0 Minutes	
Appearance	Obvious breathing difficulty; skin is moist
Level of consciousness	Conscious; appears sleepy
Airway	Open; no secretions or foreign bodies
Breathing	Labored breathing; rapid respiratory rate
Circulation	Skin, cool and moist; radial pulse, rapid and weak

4. Is this patient's airway patent?
5. Is he breathing adequately? Why or why not?
6. How should you manage his present airway and breathing status?

Table 10-3 Normal Respiratory Rate Ranges

Adults	12 to 20 breaths/min
Children	15 to 30 breaths/min
Infants	25 to 50 breaths/min

Note: These ranges are per the NHTSA 2009 EMT National EMS Education Standards. Ranges presented in other courses may vary.

Words of Wisdom

The respiratory status of a patient is so important that it should be noted at the beginning of your radio report, after mental status. Any changes during treatment or transport should be immediately reported to the receiving hospital. Respiratory status, along with any changes, should also be clearly documented in your patient care report.

A patient with inadequate breathing may appear to be working hard to breathe, which is called **labored breathing**. It requires effort and, especially among children, may involve the use of accessory muscles, including the neck muscles (sternocleidomastoid), the chest pectoralis major muscles, and the abdominal muscles **Figure 10-14**.

Accessory muscles are not used during normal breathing. More information about recognizing labored breathing and respiratory distress in children is found in later chapters. Signs of inadequate breathing in adult patients are as follows:

- Respiratory rate of fewer than 12 breaths/min or more than 20 breaths/min in the presence of shortness of breath (dyspnea)
- Irregular rhythm, such as a patient taking a series of deep breaths followed by periods of apnea
- Diminished, absent, or noisy auscultated breath sounds
- Reduced flow of expired air at the nose and mouth
- Unequal or inadequate chest expansion, resulting in reduced tidal volume
- Increased effort of breathing (use of accessory muscles)
- Shallow depth (reduced tidal volume)

Figure 10-14 The accessory muscles of breathing are used when a patient is having difficulty breathing, but not during normal breathing. The accessory muscles include the sternocleidomastoid, pectoralis major, and abdominal muscles.

- Skin that is pale, cyanotic (blue), cool, or moist (clammy)
- Skin pulling in around the ribs or above the clavicles during inspiration (**retractions**)

When you are assessing a patient with a potential airway compromise, pay particular attention to the external environment. Conditions such as high altitude and enclosed spaces alter the partial pressure of oxygen in the environment, making the process of oxygenation difficult for the patient. In addition, poisonous gases, such as carbon monoxide, displace oxygen in the environment and alter the overall metabolism of the patient. The external environment should be taken into consideration when deciding on the appropriate treatment.

You should be aware that a patient may appear to be breathing after his or her heart has stopped. These occasional, gasping breaths are called **agonal gasps**. They occur when the respiratory center in the brain continues to send signals to the respiratory muscles. These gasps do not provide adequate oxygen because they are infrequent, gasping respiratory efforts. In patients with agonal gasps, you will need to provide artificial ventilations and, most likely, chest compressions.

Some patients may have irregular respiratory breathing patterns that are related to a specific condition. For example, Cheyne-Stokes respirations are often seen in patients with stroke and patients with serious head injuries **Figure 10-15**.

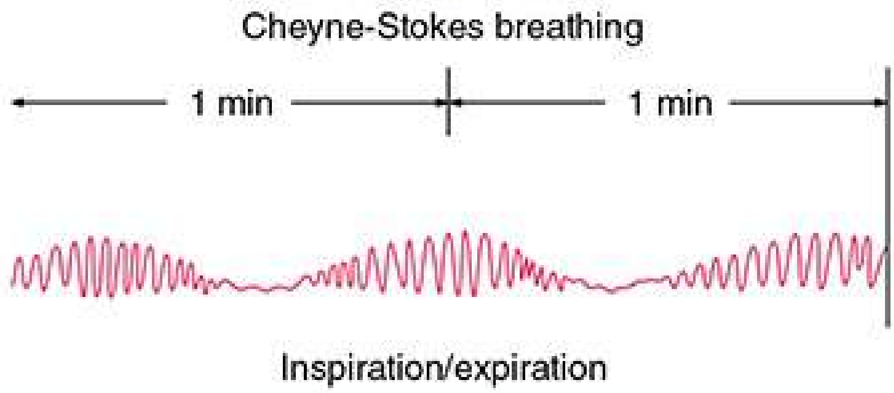

Figure 10-15 Cheyne-Stokes breathing shows irregular respirations followed by a period of apnea.

Cheyne-Stokes respirations are an irregular respiratory pattern in which the patient breathes with an increasing rate and depth of respirations that is followed by a period of **apnea**, or lack of spontaneous breathing, followed again by a pattern of increasing rate and depth of respiration. Serious head injuries may also cause changes in the normal respiratory rate and pattern of breathing. The result may be irregular, ineffective respirations that may or may not have an identifiable pattern (**ataxic respirations**). Patients experiencing a metabolic or toxic disorder may display other abnormal respiratory patterns such as Kussmaul respirations. Kussmaul respirations are characterized as deep, rapid respirations commonly seen in patients with metabolic acidosis.

Whereas rapid breathing is a compensatory mechanism to help patients in respiratory distress, some patients are so ill that their bodies are unable to compensate for their respiratory distress. You need to be vigilant when monitoring patients in respiratory distress because their condition may decline rapidly.

Patients with inadequate breathing have inadequate minute volume and need to be treated immediately. This condition is most easily recognized in patients who are unable to speak in complete sentences when at rest or who have a fast or slow respiratory rate, both of which may result in a reduction in tidal volume. Emergency medical care includes airway management, supplemental oxygen, and ventilatory support.

Assessment of Respiration

Even though a patient may be ventilating appropriately, the actual exchange of oxygen and carbon dioxide at the tissue level may be compromised. You must assess for signs of adequate and inadequate respiration in all patients.

As stated earlier, there are external factors that may disrupt the process of respiration. Be aware of the patient's environment and assess the quality of ambient air when approaching the patient. High altitudes and poisonous gases should always be considered when assessing respiration. Environmental factors can dramatically affect respiration and alter metabolism in your patient. If there is more than one patient with similar symptoms, consider the presence of poisonous or toxic gases. If your EMS unit carries a handheld carbon monoxide detector, assess ambient air before entering the location. However, if you enter a space and suspect the quality of the ambient air is not safe, remove yourself and the patient (if possible) from the scene immediately and contact the appropriate resource.

A patient's level of consciousness and skin color are excellent indicators of respiration. During normal respiration, oxygen and carbon dioxide diffuse in and out of tissues. When you are assessing the brain and skin tissues, it will be apparent if the patient has adequate oxygen levels reaching these areas. A patient with an altered level of consciousness may not have adequate oxygen levels reaching the brain. This lack of oxygen can cause rapid changes in the patient's mental status. Therefore, when treating patients with an altered mental status, always consider the possibility that these patients may not be getting adequate oxygen levels to their brain and that you need to consider the possible underlying causes. Be sure to determine a baseline mental status on the patient. The baseline mental status of some patients is abnormal because of a medical condition. Ask family members to describe the patient's normal mental status.

Poor skin color indicates inadequate respiration, just as an altered level of consciousness does. As oxygen fails to reach the skin tissue of the body, either from a lack of perfusion or poor oxygenation, the color of the skin changes to reflect the low level of oxygenation. Pale skin and mucous membranes, commonly referred to as pallor, are typically associated with poor perfusion caused by illness or shock. As this condition worsens, cyanosis becomes noticeable first peripherally, in the fingertips, and then centrally, in the mucous membranes and around the lips. Eventually, if the poor perfusion or oxygenation is not corrected, anaerobic metabolism will take place. This could cause the skin to become marked with blotches of different colors, commonly referred to as mottling.

Several methods can be used to assess proper oxygenation, including the use of **pulse oximetry**.

Oxygen saturation (Spo_2) is the measure of the percentage of hemoglobin molecules that are bound in arterial blood. Because hemoglobin delivers 97% of the oxygen delivered to the body's tissues, oxygen saturation is an excellent indication of the amount of oxygen available to the end organs. Oxygen dissolved in plasma delivers the other 3% to the body's tissues.

Within the past few years the pulse oximeter has become standard equipment in the treatment of emergency patients **Figure 10-16**. The pulse oximeter provides a rapid, reliable, noninvasive, real-time indication of a patient's oxygenation status. A pulse oximetry reading should not be the sole determinant of a patient's respiratory status. This value should be interpreted together with a full clinical assessment of the patient. This device can be used to assess the adequacy of oxygenation during positive-pressure ventilation and assess the overall impact of interventions on your patient.

A pulse oximeter measures the percentage of hemoglobin saturation. Under normal conditions, the Spo_2 should be 98% to 100% while breathing room air. Although no definitive threshold for normal values exists, an Spo_2 of less than 96% in a non-smoker may indicate hypoxemia. An Spo_2 of 90% or lower generally requires treatment unless the patient has a chronic condition causing perpetually low oxygen saturations. In conditions such as stroke or heart attack, oxygen is applied when the Spo_2 drops below 94%. Pulse oximeters are highly reliable in Spo_2 readings above 85%; however, readings below that are less reliable but certainly indicate profound hypoxemia. Pulse oximeters can take as long as 60 seconds to reflect changes in a patient's oxygenation status. More simply stated, a pulse oximeter placed on a patient's finger typically reflects a patient's oxygenation status one minute ago. This time delay is important to understand as respiratory insufficiency can develop in a patient well before the pulse oximetry values begin to decline. It is critical to monitor the patient and supplement your assessment with the information from the pulse oximeter.

Figure 10-16 A pulse oximeter.

Pulse oximetry is considered a routine vital sign and can be used as part of any patient assessment. Whereas there are no true contraindications to using pulse oximetry, you must be aware of the limitations associated with this device. To function properly, the pulse oximeter must find a pulsation in the selected tissue. The most commonly used site is a finger. Follow the steps in **Skill Drill 10-1** to measure pulse oximetry:

1. Clean the patient's finger, and remove nail polish as needed. Place the index or middle finger into the pulse oximeter probe. Turn on the pulse oximeter, and note the LED reading of the Sp_2 **Step 1**.

2. Palpate the radial pulse to ensure that it correlates with the LED display on the pulse oximeter **Step 2**.

In patients with significant vasoconstriction or very low perfusion states (including cardiac arrest), there may not be enough peripheral perfusion to be detected by the sensor. In these cases, move the sensor to a more central location (bridge of the nose or earlobe). Always consult the manufacturer's guidelines for proper placement and troubleshooting of these devices. An inaccurate pulse oximetry reading may be caused by the following:

- Hypovolemia
- Severe peripheral vasoconstriction (chronic hypoxia, smoking, or hypothermia)
- Time delay in detecting respiratory insufficiency
- Dark or metallic nail polish
- Dirty fingers
- Carbon monoxide poisoning

When carbon monoxide is present in the inspired gas, it displaces oxygen from the hemoglobin. Pulse oximetry measures hemoglobin saturation, but it is unable to distinguish between oxygen saturation and carbon monoxide saturation. Therefore, in cases of carbon monoxide poisoning, the Spo_2 can be normal in the context of hypoxia.

The pulse oximeter is a valuable adjunct to aid in decision making, but is not a replacement for a complete assessment. Because of many factors, the pulse oximeter may give falsely high or low readings. When you are conducting a complete patient assessment, consider using pulse oximetry readings as one additional measure while obtaining all of the other comprehensive information you need. Assess the patient for signs and symptoms of adequate oxygenation. If a patient has signs, such as cyanosis, pale or clammy skin, or symptoms, such as shortness of breath and normal Spo_2, treat the patient's condition, not the environment.

Skill Drill 10-1 Performing Pulse Oximetry

Step 1

Clean the patient's finger, and place the index or middle finger into the pulse oximeter probe. Turn on the pulse oximeter, and note the LED reading of the Spo$_2$.

Step 2

Palpate the radial pulse to ensure that it correlates with the LED display on the pulse oximeter.

Pulse oximetry cannot measure the effectiveness of ventilation nor provide information about cellular metabolism. To assess ventilation, you will need to measure exhaled carbon dioxide levels. Carbon dioxide is a by-product of aerobic metabolism.

End-tidal co$_2$ is the partial pressure or maximal concentration of co$_2$ at the end of an exhaled breath. When the co$_2$ level is low or absent, it indicates a decrease in the level of co$_2$ in the lungs. This may be caused by absent or decreased ventilation or from cardiac arrest, ineffective CPR, hypothermia, or shock. When cardiac output increases, end-tidal co$_2$ levels generally increase—a reflection of improved oxygen delivery.

End-tidal co$_2$ is measured by capnometry and capnography devices. **Capnometry** typically refers to a device that provides a digital numerical reading of the end-tidal co$_2$ level. **Capnography** provides both a numerical reading and a graph, or real-time image, of the end-tidal carbon dioxide levels from breath to breath. The digital display of end-tidal co$_2$ is expressed in millimeters of mercury (mm Hg) **Figure 10-17**. The normal range is 35 to 45 mm Hg. Although in the past end-tidal co$_2$ monitoring was primarily used to assess proper advanced airway placement, it is now used routinely on many respiratory distress calls. Paramedic or other ALS providers use these devices as a secondary means to determine proper placement of an advanced airway, assess a patient's ventilatory status, and avoid inadvertent hyperventilation of patients with head injuries, which has been linked to poor outcomes. Additionally, waveform capnography provides data that can be used to determine changes in cardiac output. It also offers the first indication of return of spontaneous circulation (ROSC) after cardiac arrest.

Figure 10-17 A capnometer.

Opening the Airway

Emergency medical care begins with ensuring an open airway. If you cannot immediately open and maintain a patent airway, you cannot provide effective patient care. Regardless of the patient's condition, the airway must remain patent at all times.

When you respond to a call and find an unconscious patient, you need to quickly assess for a pulse and breathing; if the patient has a pulse, you need to determine whether breathing is adequate. Remember that airway and breathing are two separate components that are closely related to each other. However, you must understand that adequate breathing does not always equate to an adequate airway. To most effectively open the airway and assess breathing, the unresponsive patient should be in the supine position. However, if your patient is in a situation that delays placement in a supine position (for example, entrapped in a vehicle), the patient's airway must be opened and assessed in the position in which you find the patient. If your patient is found in the prone position (lying facedown), he or she must be repositioned to allow for assessment of airway and breathing and to begin CPR, should it become necessary. Today health care workers are taught to begin CPR with high-quality compressions if cardiac arrest is suspected. The patient should be log rolled as a unit so the head, neck, and spine all move together without twisting. While care should be taken to avoid injury, remember that airway management almost always takes priority and should not be delayed when caring for patients with life-threatening conditions. Unconscious patients, especially when there are no witnesses who can rule out trauma, should be moved as a unit because of the potential for spinal injury. To position the unconscious patient in order to open the airway, follow the steps in **Skill Drill 10-2**:

1. Kneel beside the patient. Make sure you kneel far enough away so that the patient, when rolled toward you, does not come to rest in your lap. Place your hands behind the patient's head and neck to provide inline stabilization of the cervical spine as your partner straightens the patient's legs **Step 1**.
2. Have your partner place his or her hands on the patient's far shoulder and hip **Step 2**.
3. As you call the count to control movement, have your partner turn the patient toward you by pulling on the far shoulder and hip. Control the head and neck so that they move as a unit with the rest of the torso. In this way, the head and neck stay in the same vertical plane as the back. This single motion will minimize aggravation of any potential

spine injury. At this point, apply a cervical collar. Place the patient's arms at his or her side **Step 3**.

4. Once the patient is positioned, maintain an open airway and check for breathing **Step 4**.

In an unconscious patient, the most common airway obstruction is the patient's tongue, which falls back into the throat when the muscles of the throat and tongue relax **Figure 10-18**. Dentures (false teeth), blood, vomitus, mucus, food, and other foreign objects may also create an airway obstruction. Therefore, always be prepared to help clear and maintain a patent airway with the use of suction and placement of an airway adjunct, such as an oral or nasal airway.

Head Tilt–Chin Lift Maneuver

Opening the airway to relieve an obstruction can often be done quickly and easily by simply tilting the patient's head back and lifting the chin in what is known as the **head tilt–chin lift maneuver**. For patients who have not sustained or are not suspected of having sustained spinal trauma, this simple maneuver is sometimes all that is needed for the patient to resume breathing.

To perform the head tilt–chin lift maneuver, follow these steps:

1. With the patient in a supine position, position yourself beside the patient's head.
2. Place the heel of one hand on the patient's forehead, and apply firm backward pressure with your palm to tilt the patient's head back. This extension of the neck will move the tongue forward, away from the back of the throat, and clear the airway if the tongue is blocking it.
3. Place the fingertips of your other hand under the lower jaw near the bony part of the chin. Do not compress the soft tissue under the chin, as this may block the airway.
4. Lift the chin upward, bringing the entire lower jaw with it, helping to tilt the head back. Do not use your thumb to lift the chin. Lift so that the teeth are nearly brought together, but avoid closing the mouth completely. Continue to hold the forehead to maintain the backward tilt of the head **Figure 10-19**.

Skill Drill 10-2 Positioning the Unconscious Patient

Step 1

Support the head while your partner straightens the patient's legs.

Step 2

Have your partner place his or her hand on the patient's far shoulder and hip.

Step 3

Roll the patient as a unit with the EMT at the patient's head calling the count to begin the move.

Step 4

Open and assess the patient's airway and breathing status.

Words of Wisdom

Causes of airway obstruction include:

- Relaxation of the tongue in an unresponsive patient
- Foreign objects (food, small toys, dentures)
- Blood clots, broken teeth, or damaged oral tissue following trauma
- Airway tissue swelling (infection, allergic reaction)
- Aspirated vomitus (stomach contents)

Jaw-Thrust Maneuver

The head tilt–chin lift maneuver will open the airway in most patients. However, if you suspect a cervical spine injury, use the jaw-thrust maneuver. The **jaw-thrust maneuver** is a technique to open the airway by placing the fingers behind the angle of the jaw and lifting the jaw upward. You can easily seal a mask around the mouth while doing the jaw-thrust maneuver. Refer to Chapter 28, *Head and Spine Injuries,* for a more detailed discussion of these types of injuries.

Perform the jaw-thrust maneuver in an adult using the following steps **Figure 10-20**:

1. Kneel above the patient's head. Place your fingers behind the angles of the lower jaw, and move the jaw upward. Use your thumbs to help position the lower jaw to allow breathing through the mouth and nose.
2. The completed maneuver should open the airway with the mouth slightly open and the jaw jutting forward.

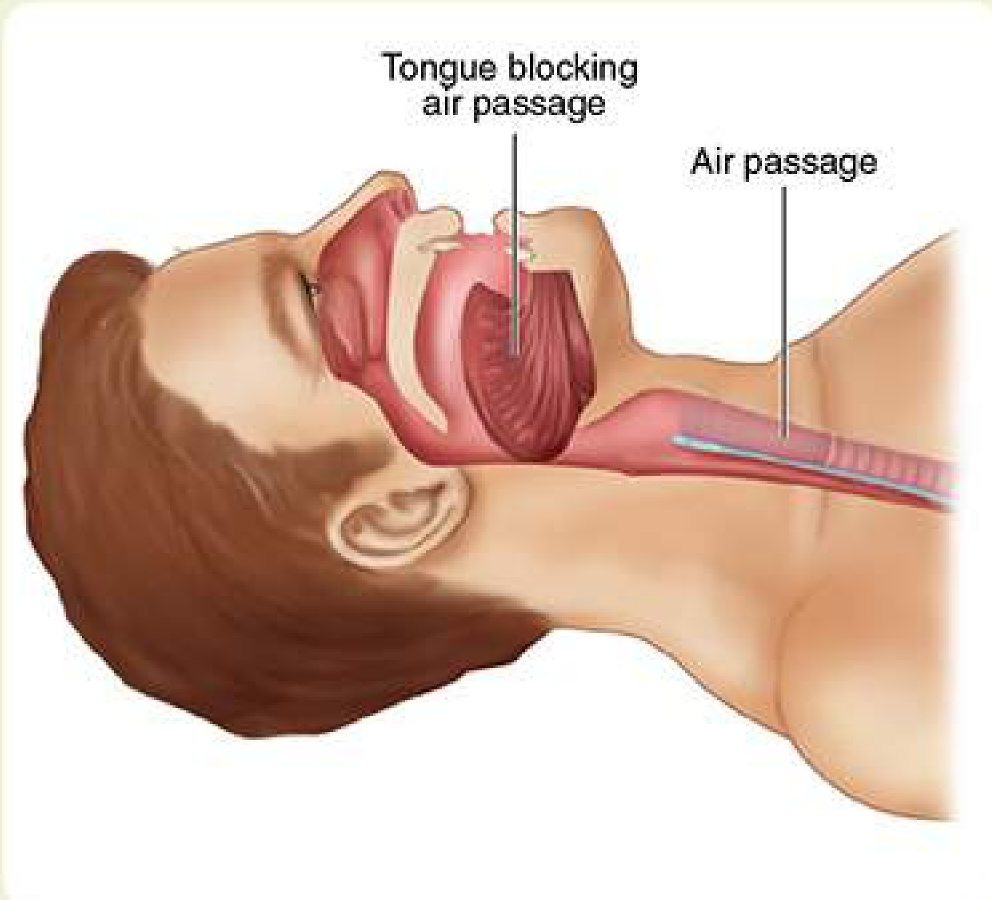

Figure 10-18 The most common airway obstruction is the patient's own tongue, which falls back into the throat when the muscles of the throat and tongue relax.

Figure 10-19 The head tilt–chin lift maneuver is a simple technique for opening the airway in a patient without a suspected cervical spine injury.

Special Populations

Patients with a history of rheumatoid arthritis or Down syndrome are predisposed to instability of the cervical spine, specifically at the first and second cervical vertebrae. The head tilt–chin lift maneuver should be avoided on these patients. Excessive force or hyperextension of the neck can cause partial dislocation of the cervical spine, which can potentially lead to paralysis. It is often better to open the airway of these patients using a jaw-thrust maneuver.

Patients who have a pulse may start to breathe on their own once the airway has been opened. Assess whether breathing has returned by quickly looking at the chest and observing for obvious movement **Figure 10-21**.

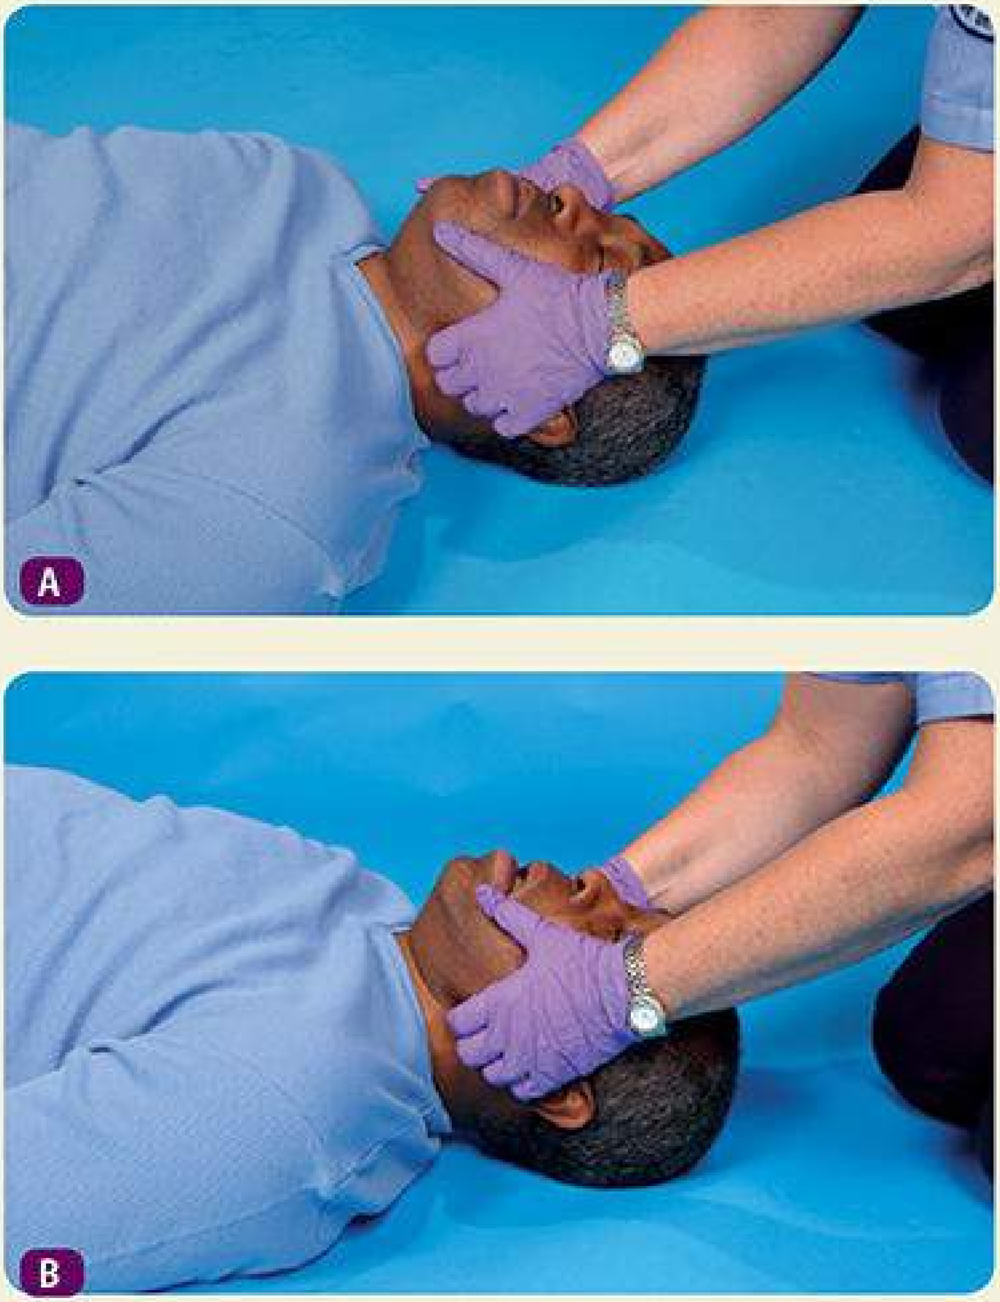

Figure 10-20 Performing the jaw-thrust maneuver. **A.** Kneeling above the patient's head, place your fingers behind the angles of the lower jaw, and move the jaw upward. Use your thumbs to help position the lower jaw. **B.** The completed maneuver should look like this.

With complete airway obstruction, there will be no movement of air. However, you may see the chest and abdomen rise and fall considerably with the patient's frantic attempts to breathe. This is why the presence of chest wall movement alone does not indicate if adequate breathing is present. Regular chest wall movement indicates a respiratory effort is present. Observing chest and abdominal movement is often difficult with a fully clothed patient. You may see little, if any, chest movement, even with normal breathing. This is particularly true in some patients with chronic lung disease if you discover that there is no movement of air.

Figure 10-21 Looking at the chest and observing for obvious movement can be used to assess whether breathing has spontaneously returned.

▶ Opening the Mouth

Even though you may have opened the airway with a head tilt–chin lift or jaw-thrust maneuver, the patient's mouth may still be closed. To open the mouth, place the tips of your index finger and thumb on the patient's teeth. Then, open the mouth by pushing your thumb on the lower teeth and index finger on the upper teeth. This pushing motion will cause the index finger and thumb to cross over each other, which is why this is called the cross-finger technique.

Suctioning

You must keep the airway clear so that you can ventilate the patient properly. If the airway is not clear, you will force the fluids and secretions into the lungs and possibly cause a complete airway obstruction. Therefore, suctioning is your next priority. If you have any doubt about the situation, remember this rule: If you hear gurgling, the patient needs suctioning!

YOU are the Provider — PART 3

Your partner begins treating the patient while you obtain his vital signs and ask his wife what he was doing when his respiratory distress began. She tells you that he began reporting slight shortness of breath the day before, but it suddenly worsened today when he was sitting on the couch reading the newspaper.

Recording Time: 2 Minutes	
Respirations	30 breaths/min, labored
Pulse	120 beats/min, weak
Skin	Cool and moist; cyanosis around the mouth
Blood pressure	126/60 mm Hg
Oxygen saturation (Spo_2)	88% (on oxygen)

7. What is cyanosis? What does it indicate?

8. What does the patient's oxygen saturation indicate?

Suctioning Equipment

Portable, hand-operated, and fixed (mounted) suctioning equipment is essential for resuscitation **Figure 10-22**.

A portable suctioning unit must provide enough vacuum pressure and flow to allow you to suction the mouth and nose effectively. Hand-operated suctioning units with disposable chambers are reliable, effective, and relatively inexpensive. A fixed suctioning unit should generate airflow of more than 40 L/ min and a vacuum of more than 300 mm Hg when the tubing is clamped.

Figure 10-22 Suctioning equipment is essential for resuscitation. **A.** Hand-operated unit. **B.** Fixed unit. **C.** Portable unit.

A portable or fixed suctioning unit should be fitted with the following:

- Wide-bore, thick-walled, nonkinking tubing
- Plastic, rigid pharyngeal suction tips, called **tonsil tips** or Yankauer tips
- Nonrigid plastic catheters, called French or whistle-tip catheters
- A nonbreakable, disposable collection bottle
- Water for rinsing the tips

A **suction catheter** is a hollow, cylindrical device that is used to remove fluids from the patient's airway. A tonsil-tip catheter is the best kind of catheter for infants and children. The plastic tips have a large diameter and are rigid, so they do not collapse **Figure 10-23**.

Tips with a curved contour allow for easy, rapid placement in the oropharynx. Nonrigid plastic catheters, sometimes called French or whistle-tip catheters, are used to suction the nose and liquid secretions in the back of the mouth and in situations in which you cannot use a rigid catheter, such as for a patient with a **stoma** **Figure 10-24**. A stoma is an opening through the skin that goes into an organ or other structure.

For example, a rigid catheter could break off a patient's tooth, whereas a flexible catheter may be inserted along the cheeks without injury. Before you insert any catheter, make sure to measure for the proper size. Use the same technique you would use when measuring for an oropharyngeal airway. Be careful not to touch the back of the airway with a suction catheter. This can activate the gag reflex, causing vomiting, and increase the possibility of aspiration.

Figure 10-23 Tonsil-tip (Yankauer tip) catheters are the best for suctioning because they have wide-diameter tips and are rigid.

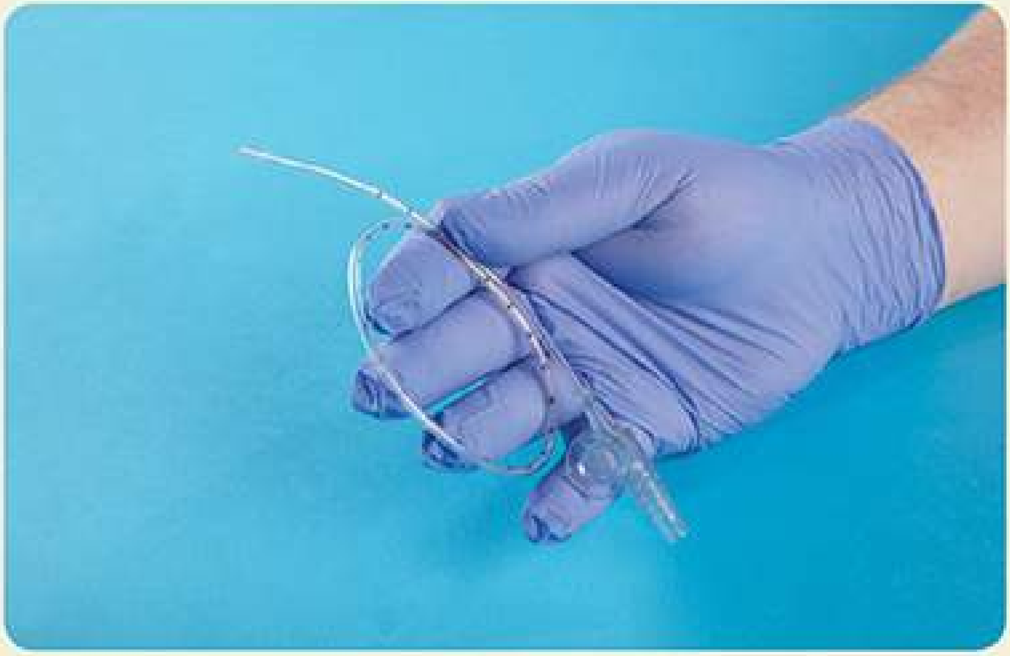

Figure 10-24 French, or whistle-tip, catheters are used in situations in which rigid catheters cannot be used, such as with a patient who has a stoma, patients whose teeth are clenched, or if suctioning the nose is necessary.

Words of Wisdom

Any time there are fluids in the airway, the risk of aspiration increases. Aspiration may increase the risk of mortality by 30% to 70%.

Techniques of Suctioning

Inspect your suctioning equipment regularly to make sure it is in proper working condition. Turn on the suction, clamp the tubing, and make sure that the unit generates a vacuum of more than 300 mm Hg. Check that a battery-charged unit has charged batteries. Ensure that your suctioning equipment is placed at the patient's head and is easily accessible. Follow these general steps to operate the suction unit:

1. Check the unit for proper assembly of all its parts.
2. Turn on the suctioning unit and test it to ensure a vacuum pressure of more than 300 mm Hg.
3. Select and attach the appropriate suction catheter to the tubing.

Never suction the mouth or nose for more than 15 seconds at one time for adult patients, 10 seconds for children, and 5 seconds for infants. Suctioning removes oxygen from the airway along with the obstructive material and can result in hypoxia. Rinse the catheter and tubing with water to prevent clogging of the tube with dried vomitus or other secretions. Repeat suctioning only after the patient has been adequately ventilated and reoxygenated.

Use extreme caution when suctioning a conscious or semiconscious patient. Put the tip of the suction catheter in only as far as you can visualize. Be aware that suctioning may induce vomiting.

To properly suction a patient, follow the steps in Skill Drill 10-3:

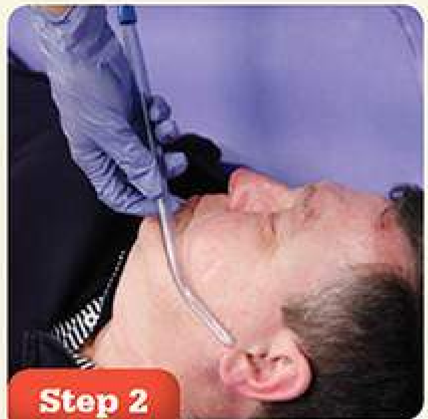
1. Turn on the assembled suction unit. To test the suction, clamp the tubing, and make sure that the unit generates a vacuum of more than 300 mm Hg **Step 1**.
2. Measure the catheter to the correct depth by measuring the catheter from the corner of the patient's mouth to the edge of the earlobe or angle of the jaw **Step 2**.
3. Before applying suction, turn the patient's head to the side (unless you suspect cervical spine injury). Open the patient's mouth using the cross-finger technique or tongue-jaw lift, and insert the tip of the catheter to the depth measured. Do not suction while inserting the catheter **Step 3**.
4. Insert the catheter to the premeasured depth and apply suction in a circular motion as you withdraw the catheter. Do not suction an adult for more than 15 seconds **Step 4**.

At times, a patient may have secretions or vomitus that cannot be suctioned quickly and easily, and some suction units cannot effectively remove solid objects such as teeth, foreign bodies, and food. In these cases, you should remove the catheter from the patient's mouth, log roll the patient to the side, and then clear the mouth carefully with your gloved finger. Only attempt to remove an object if it is visible during examination of the open mouth; blind sweeps of the back of the oropharynx may push an object farther down in the airway, making the obstruction worse. A patient who requires assisted ventilations may also produce frothy secretions as quickly as you can suction them from the airway. In this situation, suction the patient's airway for 15 seconds (less time in infants and children), and then ventilate the patient for 2 minutes. Continue this alternating pattern of suctioning and ventilating until all secretions have been cleared from the patient's airway. Continuous ventilation is not appropriate if vomitus or other particles are present in the airway.

Skill Drill 10-3 Suctioning a Patient's Airway

Step 1

Make sure the suctioning unit is properly assembled and turn it on. Clamp the tubing, and make sure that the unit generates a vacuum of more than 300 mm Hg.



Step 2

Measure the catheter from the corner of the mouth to the earlobe or angle of the jaw.

Step 3

Turn the patient's head to the side (unless you suspect cervical spine injury), open the mouth using the cross-finger technique or tongue-jaw lift, and insert the catheter to the predetermined depth without suctioning.

Step 4

Apply suction in a circular motion as you withdraw the catheter. Do not suction an adult for more than 15 seconds.

Clean and decontaminate your suctioning equipment after each use according to the manufacturer's guidelines. Place all disposable suctioning equipment (such as catheter, suction tubing) in a biohazard bag.

Words of Wisdom

Suctioning Time Limits:

Adult: 15 seconds

Child: 10 seconds

Infant: 5 seconds

Basic Airway Adjuncts

The primary function of an airway adjunct is to prevent obstruction of the upper airway by the tongue and allow the passage of air and oxygen to the lungs.

Oropharyngeal Airways

An **oropharyngeal (oral) airway** has two principal purposes. The first is to keep the tongue from blocking the upper airway. The second is to make it easier to suction the oropharynx if necessary. Suctioning is possible through an opening down the center or along either side of the oropharyngeal airway **Figure 10-25**.

Figure 10-25 An oral airway is used for unconscious patients who have no gag reflex. It keeps the tongue from blocking the airway and makes suctioning the airway easier.

Indications for the oral airway include the following:

- Unresponsive patients without a gag reflex (breathing or apneic)
- Any apneic patient being ventilated with a BVM

Contraindications for the oral airway include the following:

- Conscious patients
- Any patient (conscious or unconscious) who has an intact gag reflex

The **gag reflex** is a protective reflex mechanism that prevents food and other particles from entering the airway. If you try to insert an oral airway in a patient with an intact gag reflex, the result may be vomiting or a spasm of the vocal cords. If the patient gags while you are attempting to insert an oral airway, immediately remove the adjunct and prepare to log roll the patient and suction the oropharynx, should vomiting occur. An oral airway is also a safe, effective way to help maintain the airway of a patient with a possible spinal injury. The use of an oral airway may make manual airway maneuvers such as the head tilt–chin lift and the jaw thrust easier to maintain; however, manual maneuvers are often still needed to ensure that the airway remains open.

You must clearly understand when and how this device is used. If the oropharyngeal airway is too large, it could actually push the tongue back into the pharynx, blocking the airway. Conversely, an oral airway that is too small could block the airway directly, just like any foreign body obstruction. The following steps should be used when inserting an oropharyngeal airway **Skill Drill 10-4**:

1. To select the proper size, measure from the patient's earlobe or angle of the jaw to the corner of the mouth **Step 1**.
2. Open the patient's mouth with the cross-finger technique. Hold the airway upside down with your other hand. Insert the airway with the tip facing the roof of the mouth **Step 2**.
3. Rotate the airway 180 degrees. When inserted properly, the airway will rest in the mouth with the curvature of the airway following the contour of the anatomy. The flange should rest against the lips or teeth, with the other end opening into the pharynx **Step 3**.

Take care to avoid injuring the hard palate (roof of the mouth) as you insert the airway. Roughness can cause bleeding that may aggravate airway problems or even cause vomiting.

Special Populations

In children, the only acceptable method of inserting an oral airway is to use a tongue blade to hold the tongue down while inserting the airway. Because the airways of children are undeveloped, rotating an oropharyngeal airway in the posterior pharynx may cause damage. For more discussion on pediatric airways, see Chapter 34, *Pediatric Emergencies*.

If you encounter difficulty while inserting the oral airway, insert the airway with a 90-degree rotation **Skill Drill 10-5**:

1. Use a tongue depressor or bite stick to depress the tongue, ensuring the tongue remains forward **Step 1**.
2. Insert the oral airway sideways from the corner of the mouth, until the flange reaches the teeth **Step 2**.
3. Rotate the oral airway 90 degrees, removing the depressor or bite stick as you exert gentle backward pressure on the oral airway until it rests securely in place against the lips and teeth **Step 3**.

In some cases, a patient may become responsive and regain the gag reflex after you have inserted an oral airway. If this occurs, gently remove the airway by pulling it out, following the normal curvature of the mouth and throat. Be prepared for the patient to vomit. Have suction available, and log roll the patient onto his or her side and allow any fluids to drain out.

Skill Drill 10-4 Inserting an Oral Airway

Step 1

Size the airway by measuring from the patient's earlobe to the corner of the mouth.

Step 2

Open the patient's mouth with the cross-finger technique. Hold the airway upside down with your other hand. Insert the airway with the tip facing the roof of the mouth.

Step 3

Rotate the airway 180°. Insert the airway until the flange rests on the patient's lips and teeth. In this position, the airway will hold the tongue forward.

Nasopharyngeal Airways

A **nasopharyngeal (nasal) airway** is usually used with an unresponsive patient or a patient with an altered level of consciousness who has an intact gag reflex and is not able to maintain his or her airway spontaneously **Figure 10-26**.

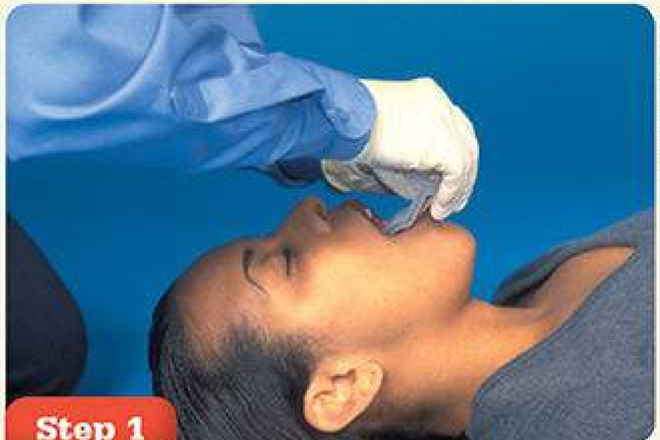
Patients with an altered mental status or who have just had a seizure may also benefit from this type of airway. If a patient has sustained severe trauma to the head or face, consult medical control before inserting a nasopharyngeal airway. Use extreme care with such trauma patients. If the nasal airway is accidentally pushed through a hole caused by a fracture of the base of the skull, it may penetrate into the brain.

Special Populations

When managing the airway of an older patient, be aware of the presence of dentures or other dental appliances. If dentures are tight-fitting and allow for effective airway management, leave them in place. However, if the dentures are loose, remove them to avoid potential airway obstruction.

Skill Drill 10-5

Inserting an Oral Airway With a 90° Rotation



Step 1

Depress the tongue so that it remains forward.

Step 2

Insert the oral airway sideways from the corner of the mouth, until the flange reaches the teeth.

Step 3

Rotate the oral airway at a 90° angle. Remove the bite stick as you exert gentle backward pressure on the oral airway until it rests securely in place against the lips and teeth.

This type of airway is usually better tolerated by patients who have an intact gag reflex. It is not as likely as the oropharyngeal airway to cause vomiting. Coat the airway well with a water-soluble lubricant before it is inserted. Be aware that slight bleeding may occur even when the airway is inserted properly. However, never force the airway into place.

Indications for the nasopharyngeal airway include the following:

- Semiconscious or unconscious patients with an intact gag reflex
- Patients who otherwise will not tolerate an oropharyngeal airway

Contraindications for the nasopharyngeal airway include the following:

- Severe head injury with blood draining from the nose
- History of fractured nasal bone

Follow these steps to ensure correct placement of the nasopharyngeal airway **Skill Drill 10-6**:

1. Before inserting the airway, be sure you have selected the proper size. Measure from the tip of the patient's nose to the earlobe. In almost all patients, one nostril is larger than the other **Step 1**.
2. The airway should be placed in the larger nostril, with the curvature of the device following the curve of the floor of the nose. If using the right nare, the bevel should face the septum **Step 2**. If using the left nare, insert the airway with the tip of the airway pointing upward, which will allow the bevel to face the septum.

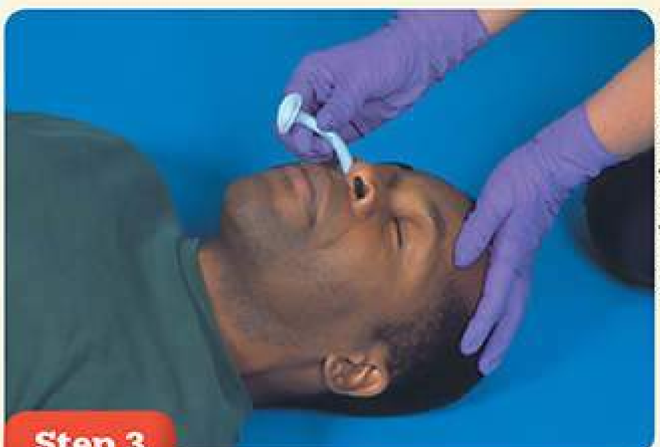
Skill Drill 10-6 Inserting a Nasal Airway

Step 1

Size the airway by measuring from the tip of the nose to the patient's earlobe. Coat the tip with a water-soluble lubricant.

Step 2

Insert the lubricated airway into the larger nostril with the curvature following the floor of the nose. If using the right nare, the bevel should face the septum. If using the left nare, insert the airway with the tip of the airway pointing upward, which will allow the bevel to face the septum.



Step 3

Gently advance the airway. If using the left nare, insert the nasopharyngeal airway until resistance is met. Then rotate the nasopharyngeal airway 180° into position. This rotation is not required if using the right nostril.

Step 4

Continue until the flange rests against the nostril. If you feel any resistance or obstruction, remove the airway and insert it into the other nostril.

3. Advance the airway gently **Step 3**. If using the left nare, insert the nasal airway until resistance is met. Then rotate the nasal airway 180^{o} into position. This rotation is not required if using the right nostril.
4. When completely inserted, the flange rests against the nostril. The other end of the airway opens into the posterior pharynx **Step 4**. If the patient becomes intolerant of the nasal airway, you may have to remove it. Gently withdraw

the airway from the nasal passage. Precautions similar to those used when removing an oral airway should be followed.

Figure 10-26 A nasal airway is better tolerated than an oral airway by patients who have an intact gag reflex.

Safety Tips

Wear a mask and protective eyewear whenever airway management involves suctioning. Body fluids can become aerosolized, and exposure to the mucous membranes of your mouth, nose, and eyes can easily occur.

Maintaining the Airway

The **recovery position** is used to help maintain a clear airway in an unconscious patient who is not injured and is breathing on his or her own with a normal respiratory rate and adequate tidal volume (depth of breathing) **Figure 10-27**.

Take the following steps to put the patient in the recovery position:

Figure 10-27 In the recovery position, the patient is rolled onto his or her left or right side.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

1. Roll the patient onto either side so that the head, shoulders, and torso move at the same time without twisting.
2. Extend the patient's lower arm and place the upper hand under his or her cheek.

For patients who have resumed spontaneous breathing after being resuscitated, the recovery position will prevent the aspiration of vomitus. However, this position is not appropriate for patients with suspected spinal, hip, or pelvic injuries or for patients who are unconscious and require ventilatory assistance. Reposition such patients to provide adequate access to the airway while maintaining appropriate spinal stabilization.

Supplemental Oxygen

Always give supplemental oxygen to patients who are hypoxic because not enough oxygen is being supplied to the tissues and cells of the body.

Some tissues and organs, such as the heart, central nervous system, lungs, kidneys, and liver, need a constant supply of oxygen to function normally. *Never withhold oxygen from any patient who might benefit from it, especially if you must assist ventilations.*

When ventilating any patient in cardiac or respiratory arrest, use high-concentration supplemental oxygen.

Supplemental Oxygen Equipment

In addition to knowing when and how to give supplemental oxygen, you must understand how oxygen is stored and the various hazards associated with its use.

Oxygen Cylinders

The oxygen that you will give to patients is usually supplied as a compressed gas in green, seamless, steel or aluminum cylinders. Some cylinders may be silver or chrome with a green area around the valve stem on top. Newer cylinders are often made of lightweight aluminum or spun steel; older cylinders are much heavier.

Check to make sure that the cylinder is labeled for medical oxygen. Look for letters and numbers stamped into the metal on the collar of the cylinder **Figure 10-28**. Of particular importance are the month and year stamps, which indicate when the cylinder was last tested. Generally, aluminum cylinders are tested every 5 years; composite cylinders are tested every 3 years.

Oxygen cylinders are available in several sizes. The two sizes that you will most often use are the D (or jumbo D) and M cylinders **Figure 10-29**. The D (or jumbo D) cylinder can be carried from your unit to the patient. The M tank remains on board your unit as a main supply tank. Other sizes that you will see are A, E, G, H, and K **Table 10-4**. Another naming system for identifying the size of the oxygen cylinder has been introduced. Per this naming convention, cylinders are labeled with M (for medical), followed by a number.

The length of time you can use an oxygen cylinder depends on the pressure in the cylinder and the flow rate. A method of calculating cylinder duration is shown in Table 10-5.

Liquid Oxygen

Like all gases, oxygen changes from a gas to a liquid when cooled. Liquid oxygen is becoming more commonly used as an alternative to compressed gas oxygen. Liquid oxygen containers tend to be more expensive than compressed oxygen tanks; however, the containers hold a large volume of oxygen and do not need to be filled as often. Liquid oxygen units also weigh less than aluminum or steel tanks. For these reasons, many people who receive long-term oxygen therapy use liquid oxygen units. Unfortunately, liquid oxygen tanks generally need to be kept upright and have special requirements for filling, large-volume storage, and cylinder transfer.

Figure 10-28 Oxygen tanks for medical use have a series of letters and numbers stamped into the metal on the collar of the cylinder.

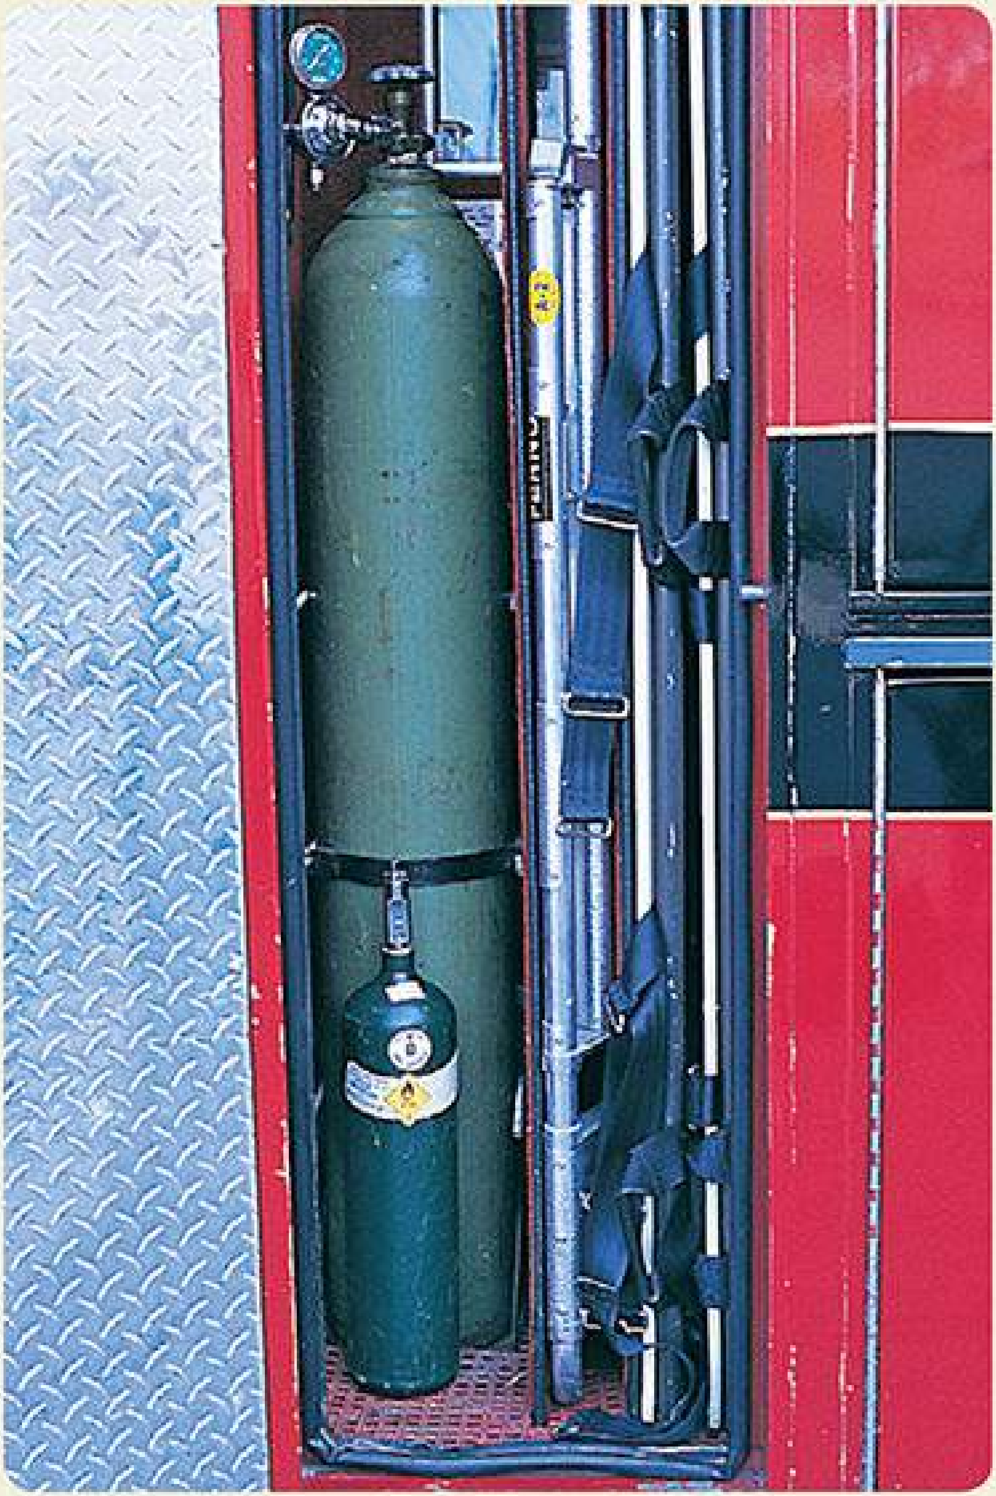


Figure 10-29 The cylinders that are most commonly found on an ambulance are the D (or jumbo D) and M size cylinders. D, Super D, and E sizes are typically portable tank systems while the M, G, H, A, and K sizes are mounted inside the ambulance.

Table 10-4 Oxygen Cylinder Sizes Carried on the Ambulance

Size	Volume, Liters
D	350
Jumbo D	500
E	625

Table 10-5 Oxygen Cylinders: Duration of Flow

Formula
$\frac{\text{(Gauge pressure in psi – Safe residual pressure)} \times \text{Cylinder constant}}{\text{Flow rate in L/min}}$ = Duration of flow in minutes
Safe residual pressure = 200 psi
Cylinder constant for a given cylinder size: A = 3.14 G = 2.41 D = 0.16 H = 3.14 E = 0.28 K = 3.14 M = 1.56
Determine the life of an M cylinder that has a pressure of 2,000 psi and a flow rate of 10 L/min.
$\frac{(2{,}000 - 200) \times 1.56}{10} = \frac{2{,}808}{10}$ = 281 min, or 4 h 41 min
psi = pounds per square inch.

Safety Considerations

Handle compressed gas cylinders carefully because their contents are under pressure. Cylinders are fitted with pressure regulators to make sure that patients receive the right amount and type of gas. Make sure that the correct pressure regulator is firmly attached before you transport the cylinders. A puncture or hole in the tank can cause the cylinder to become a deadly missile. Do not handle a cylinder by the neck assembly alone. Secure cylinders with mounting brackets when they are stored on the ambulance. Oxygen cylinders that are in use during transport should be positioned and secured to prevent the tank from falling, damaging the valve-gauge assembly, or becoming a dangerous projectile during a collision.

Pin-Indexing System

The compressed gas industry has established a **pin-indexing system** for portable cylinders to prevent an oxygen regulator from being connected to a carbon dioxide cylinder, a carbon dioxide regulator from being connected to an oxygen cylinder, and so on. In preparing to administer oxygen, always check to be sure that the pinholes on the cylinder exactly match the corresponding pins on the regulator.

The pin-indexing system features a series of pins on a yoke that must be matched with the holes on the valve stem of the gas cylinder. The arrangement of the pins and holes varies for different gases according to accepted national standards **Figure 10-30**. Other gases that are supplied in portable cylinders, such as acetylene, carbon dioxide, and nitrogen, use regulators and flowmeters that are similar to those used with oxygen. Each cylinder of a specific gas type has a given pattern and a given number of pins. These safety measures make it impossible for you to attach a cylinder of nitrous oxide to an oxygen regulator. The oxygen regulator will not fit.

The outlet valves on portable oxygen cylinders are designed to accept yoke-type pressure-reducing gauges, which conform to the pin-indexing system **Figure 10-31**.

The safety system for the large cylinders is known as the **American Standard Safety System**. In this system, oxygen cylinders are equipped with threaded gas outlet valves. The inside and outside thread sizes of these outlets vary depending on the gas in the cylinder. The cylinder will not accept a regulator valve unless it is properly threaded to fit that regulator. The purpose of these safety devices is the same as in the pin-indexing system: to prevent the accidental attachment of a regulator to a wrong cylinder.

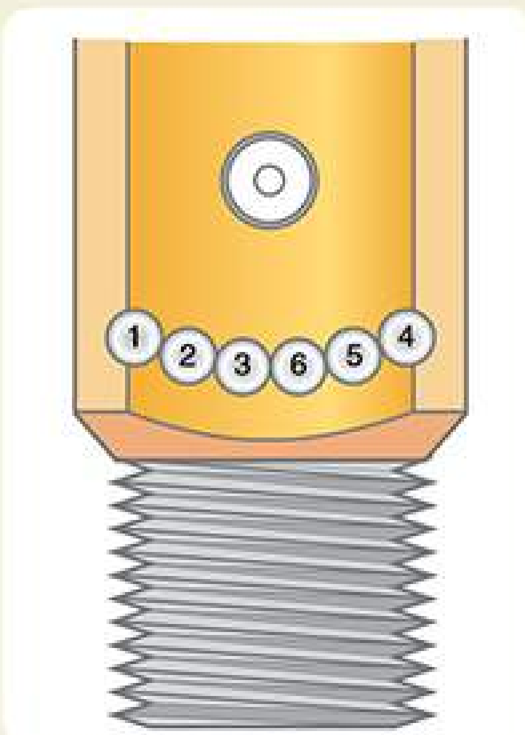

Figure 10-30 The locations of the pin-indexing safety system holes in a cylinder valve face. Each cylinder of a specific gas has a given pattern and a given number of pins.

Figure 10-31 A yoke-type pressure-reducing gauge is used with a portable oxygen cylinder.

© dream designs/ShutterStock.

Pressure Regulators

The pressure of the gas in a full oxygen cylinder is approximately 2,000 psi. This is far too much pressure to be safe or useful for your purposes. Pressure regulators reduce the pressure to a more useful range, usually 40 to 70 psi. Most pressure regulators in use today reduce the pressure in a single stage, although multi-stage regulators exist. A two-stage regulator will reduce the pressure first to 700 psi and then to 40 to 70 psi.

After the pressure is reduced to a workable level, the final attachment for delivering the gas to the patient is usually one of the following:

- A quick-connect female fitting that will accept a quick-connect male plug from a pressure hose or ventilator/resuscitator
- A flowmeter that will permit the regulated release of gas measured in liters per minute

Flowmeters

Flowmeters are usually permanently attached to pressure regulators on emergency medical equipment. The two types of flowmeters that are commonly used are pressure-compensated flowmeters and Bourdon-gauge flowmeters.

A pressure-compensated flowmeter incorporates a float ball within the tapered calibrated tube. The flow of gas is controlled by a needle valve located downstream from the float ball. This type of flowmeter is affected by gravity and must always be maintained in an upright position for an accurate flow reading **Figure 10-32**.

The Bourdon-gauge flowmeter is not affected by gravity and can be used in any position **Figure 10-33**. It is a pressure gauge that is calibrated to record flow rate. This type of flowmeter, however, is generally now considered outdated. New flowmeters incorporate a fixable setting with either a dial or a knob that sets the flow. In these regulators, a Bourdon-gauge is not necessary.

Procedures for Operating and Administering Oxygen

To place an oxygen cylinder into service and administer medical oxygen to a patient, follow the steps in **Skill Drill 10-7**:

1. Inspect the cylinder and its markings. If the cylinder was commercially filled, it will have a plastic seal around the valve stem covering the opening in the stem. Remove the seal, and inspect the opening to make sure that it is free of dirt and other debris. The valve stem should not be sealed or covered with adhesive tape or any petroleum-based substances. These can contaminate the oxygen and can contribute to combustion when mixed with pressurized oxygen.

Figure 10-32 A pressure-compensated flowmeter contains a float ball that rises or falls according to the gas flow within the tube. It must be maintained in an upright position for an accurate reading.

"Crack" the cylinder by slowly opening and then reclosing the valve to help make sure that the dirt particles and other possible contaminants do not enter the oxygen flow. Never face the tank toward yourself or others when cracking the cylinder. Open the tank by attaching a tank key (wrench) to the valve and rotating the valve counterclockwise. You should be able to hear clearly the rush of oxygen coming from the tank. Close the tank by rotating the valve clockwise **Step 1**.

2. Attach the regulator/flowmeter to the valve stem after clearing the opening. On one side of the valve stem, you will find three holes. The larger one, on top, is a true opening through which the oxygen flows. The two smaller holes below it do not extend to the inside of the tank. They provide stability to the regulator. Following the design of the pin-indexing system, these two holes are very precisely located in positions that are unique to the oxygen cylinders.

Figure 10-33 The Bourdon-gauge flowmeter is not affected by gravity and can be used in any position.

Above the pins on the inside of the collar is the actual port through which oxygen flows from the cylinder to the regulator. A metal-bound elastomeric sealing washer (also called a gasket) is placed around the oxygen port to optimize the airtight seal between the collar of the regulator and the valve stem **Step 2**. In the past, crush gaskets made of plastic and nylon were used, but are no longer recommended. If used, crush gaskets can be used only once and then they must be replaced.

3. Place the regulator collar over the cylinder valve, with the oxygen port and pin-indexing pins on the side of the valve stem that has the three holes. Open the screw bolt just enough to allow the collar to fit freely over the valve stem. Move the regulator so that the oxygen port and the pins fit into the correct holes on the valve stem. The screw bolt on the opposite side should be aligned with the dimple depression. As you hold the regulator securely against the valve stem, hand tighten the screw bolt until the regulator is firmly attached to the cylinder. At this point, you should not see any open spaces between the sides of the valve stem and the interior walls of the collar **Step 3**.

Skill Drill 10-7 Placing an Oxygen Cylinder Into Service

Step 1

Using an oxygen wrench, turn the valve counterclockwise to slowly "crack" the cylinder.

Step 2

Attach the regulator/flowmeter to the valve stem using the two pin-indexing holes and make sure that the washer is in place over the larger hole.

Step 3

Align the regulator so that the pins fit snugly into the correct holes on the valve stem, and hand tighten the regulator.

Step 4

Attach the oxygen connective tubing to the flowmeter.

4. With the regulator firmly attached, open the cylinder completely, check for air leaking from the regulator–oxygen cylinder connection, and read the pressure level on the regulator gauge. Most portable cylinders have a maximum pressure of approximately 2,000 psi. Most EMS systems consider a cylinder with less than 500 to 1,000 psi to be too low to keep in service. Learn your department's policies in this regard and follow them.

   The flowmeter will have a second gauge or a selector dial that indicates the oxygen flow rate. Several popular types of devices are widely used. Attach the selected oxygen device to the flowmeter by connecting the universal oxygen connecting tubing to the "Christmas tree" nipple on the flowmeter. Most oxygen-delivery devices come with this tubing permanently attached; however, some oxygen masks do not. You must attach this tubing to the oxygen-delivery device if it is not already attached **Step 4**.

Safety Tips

Slowly open the oxygen tank after attaching the regulator and check for leaks. Remember that although oxygen itself is not combustible, it supports combustion, and any ignition source may cause fire or an explosion in an oxygen-rich environment—especially if oxygen is being released too quickly from the cylinder at the time or if the seal between the regulator and oxygen cylinder is not secure.

Open the flowmeter to the desired flow rate. Flow rates will vary based on the oxygen-delivery device being used. Remember that you must be completely familiar with the equipment before attempting to use it on a patient. Once the oxygen is flowing at the desired rate, apply the oxygen device to the patient and make any necessary adjustments. Monitor the patient's response to the oxygen and to the oxygen device, and periodically recheck the regulator gauge to make sure there is sufficient oxygen in the cylinder. Disconnect the tubing from the flowmeter nipple and turn off the cylinder valve when oxygen therapy is complete or when the patient has been transferred to the hospital and is using the hospital's oxygen system. In a few seconds, the sound of oxygen flowing from the nipple will cease. This indicates that all the pressurized oxygen has been removed from the flowmeter. Turn off the flowmeter. The gauge on the regulator should read zero with the tank valve closed. This reading confirms that there is no pressure left above the valve stem. As long as there is a pressure reading on the regulator gauge, it is not safe to remove the regulator from the valve stem.

Hazards of Supplemental Oxygen

Combustion

Oxygen does not burn or explode. However, it does support combustion. The more oxygen is around, the faster the combustion process. A small spark, even a glowing cigarette, can become a flame in an oxygen-rich atmosphere. Therefore, you must keep any possible source of fire away from the area while oxygen is in use. Make sure the area is adequately ventilated, especially in industrial settings where hazardous materials may be present and where sparks are easily generated. Be extremely cautious in any enclosed environment in which oxygen is being administered, as an oxygen-rich environment increases the chance of fire if a spark or flame is introduced. A bystander who is smoking or sparks generated during vehicle extrication are possible sources of ignition. Never leave an oxygen cylinder standing unattended. The cylinder can be knocked over, injuring the patient or damaging the equipment.

Oxygen Toxicity

The administration of oxygen to patients is a common practice. While many patients in the prehospital environment require high concentrations of oxygen, not all patients do. Excessive supplemental oxygen can have a detrimental effect on patients with certain illnesses (ie, COPD, bronchopulmonary dysplasia).

Recent research has shown that while the administration of oxygen benefits many patients and is rarely problematic, high concentrations of oxygen are potentially harmful for a select population. **Oxygen toxicity** refers to damage to cellular tissue due to excessive oxygen levels in the blood. Years ago, high concentrations of oxygen were thought to benefit all patients in the prehospital environment. However, current evidence suggests that increased cellular oxygen levels contribute to the production of oxygen free radicals. These radicals may lead to tissue damage and cellular death in some patients.

The International Liaison Committee on Resuscitation guidelines published by the American Heart Association recognize there may be negative effects of oxygen toxicity and recommend that oxygen be administered to patients experiencing signs of a myocardial infarction when they have signs of heart failure, are short of breath, or have a room air oxygen saturation less than 94%. In addition, patients experiencing signs of shock should be placed on oxygen. Understand that hypoxemia is much worse than oxygen toxicity; when in doubt, or if unable to measure oxygen saturation reliably, supplemental oxygen should be administered.

Pulse oximetry is not always available to the EMT. When pulse oximetry is available, tailor oxygen therapy to the patient's needs, and administer the minimum amount of oxygen necessary to maintain oxygen saturation at or above 94%. Exceptions to these minimums include patients who have been exposed to carbon monoxide.

Oxygen-Delivery Equipment

In general, the oxygen-delivery equipment used in the field should be limited to nonrebreathing masks, BVMs, and nasal cannulas, depending on local protocol. However, you may encounter other devices during transports between medical facilities.

Nonrebreathing Masks

The nonrebreathing mask is the preferred way of giving oxygen in the prehospital setting to patients who are breathing adequately but are suspected of having or showing signs of hypoxia. With a good mask-to-face seal, it is capable of providing up to 90% inspired oxygen.

Words of Wisdom

Oxygen-Delivery Devices

Oxygen-Delivery Devices

Device	Flow Rate	Oxygen Delivered
Nasal cannula	1 to 6 L/min	24% to 44%
Nonrebreathing mask with reservoir	10 to 15 L/ min	Up to 95%
BVM with reservoir	15 L/min	Nearly 100%
Mouth-to-mask device	15 L/min	Nearly 55%

The nonrebreathing mask is a combination mask and reservoir bag system. Oxygen fills a reservoir bag that is attached to the mask by a one-way valve. The system is called a nonrebreathing mask because the exhaled gas escapes through flapper valve ports at the cheek areas of the mask Figure 10-34. These valves prevent the patient from rebreathing exhaled gases.

In this system, you must be sure that the reservoir bag is full before the mask is placed on the patient. Adjust the flow rate so that the bag does not fully collapse when the patient inhales, to about two-thirds of the bag volume, or 10 to 15 L/min. Make sure the bag stays inflated. Should the bag collapse when the patient inhales, increase the flow rate of oxygen. In addition, if oxygen therapy is discontinued, remove the mask from the patient's face. Leaving the mask in place while oxygen is not flowing allows the patient to rebreathe exhaled carbon dioxide. Use a pediatric nonrebreathing mask, which has a smaller reservoir bag, with infants and children, as they will inhale a smaller volume.

Figure 10-34 The nonrebreathing mask contains flapper valve ports at the cheek areas of the mask to prevent the patient from rebreathing exhaled gases.

Nasal Cannulas

A **nasal cannula** delivers oxygen through two small, tubelike prongs that fit into the patient's nostrils **Figure 10-35**. This device can provide 24% to 44% inspired oxygen when the flowmeter is set at 1 to 6 L/min. For the comfort of your patient, flow rates above 6 L/min are not recommended with the nasal cannula.

The nasal cannula delivers dry oxygen directly into the nostrils, which, over prolonged periods, can cause dryness or irritate the mucous membrane lining of the nose. Therefore, when you anticipate a long transport time, consider the use of humidification.

A nasal cannula has limited use in the prehospital setting. For example, a patient who breathes through the mouth or who has a nasal obstruction will likely get little or no benefit from a nasal cannula. Always try to give high-flow oxygen through a nonrebreathing mask if you suspect that a patient may have hypoxia, coaching the patient if necessary. If the patient will not tolerate a nonrebreathing mask, you will have to use a nasal cannula, which some patients find more comfortable. As always, a good assessment of your patient will guide your decision.

Figure 10-35 The nasal cannula delivers oxygen directly through the nostrils.

▶ Partial Rebreathing Masks

The partial rebreathing mask is similar to a nonrebreathing mask except that there is no one-way valve between the mask and the reservoir. Consequently, patients rebreathe a small amount of their exhaled air. This has some benefit when you want to increase the patient's partial pressure of carbon dioxide, which makes this the ideal mask for patients who you think are suffering from hyperventilation syndrome. The oxygen enriches the air mixture and delivers a gas mix of approximately 80% to 90% oxygen. You can easily convert a nonrebreathing mask to a partial rebreathing mask by removing the one-way valve between the mask and the reservoir bag.

▶ Venturi Masks

A Venturi mask has a number of attachments that enable you to vary the percentage of oxygen delivered to the patient while a constant flow is maintained from the regulator **Figure 10-36**. This is accomplished by the Venturi principle, which causes air to be drawn into the flow of oxygen as it passes a hole in the line. The Venturi mask is a medium-flow device that delivers 24% to 40% oxygen, depending on the manufacturer.

The main advantage of the Venturi mask is the use of its fine adjustment capabilities in the long-term management of physiologically stable patients. However, in the emergency setting, such fine adjustments are not necessary. When you need to adjust the oxygen concentration in an emergency, it is typically done by adjusting the flow rate or changing the delivery device.

▶ Tracheostomy Masks

Patients with tracheostomies do not breathe through their mouth and nose. A face mask or nasal cannula therefore cannot be used to treat them. Masks designed specifically for these patients cover the tracheostomy hole and have a strap that goes around the neck. These masks are usually available in intensive care units, where many patients have tracheostomies, and may not be available in an emergency setting. If you do not have a tracheostomy mask, you can improvise by placing a face mask over the stoma. Even though the mask is shaped to fit the face, you can usually get an adequate fit over the patient's neck by adjusting the strap Figure 10-37.

YOU are the Provider — PART 4

A rescue unit arrives at the scene to assist you and your partner. As you are preparing to load the patient onto the stretcher, you note that his level of consciousness has markedly diminished and he is making a snoring sound when he breathes. You immediately reassess him.

Recording Time: 6 Minutes	
Level of consciousness	Responsive only to pain
Respirations	10 breaths/min, shallow, snoring
Pulse	130 beats/min, weak
Skin	Cool and moist; cyanotic
Blood pressure	118/54 mm Hg
Spo_2	89% (on oxygen)

9. What should be your *most* immediate action?

10. How should you adjust your treatment of the patient?

Figure 10-36 The Venturi mask.

Figure 10-37 If you do not have a tracheostomy mask, use a face mask instead.

Humidification

Some EMS systems provide humidified oxygen to patients during extended transport or for certain conditions such as croup **Figure 10-38**. However, humidified oxygen is usually indicated only for long-term oxygen therapy. Dry oxygen is not considered harmful for short-term use. An oxygen humidifier consists of a small single-patient-use bottle of water through which the oxygen leaving the cylinder becomes moisturized before it reaches the patient. Because the humidifier must be kept in an upright position, however, it is practical only for the fixed oxygen unit in the ambulance. Therefore, many EMS systems do not use humidified oxygen in the prehospital setting. Always refer to medical control or local protocols for guidance involving patient treatment issues.

Figure 10-38 Giving humidified oxygen may be preferred with long transport times. However, the use of this type of oxygen-delivery system is not universal in all EMS systems.

Assisted and Artificial Ventilation

A patient who is not breathing needs artificial ventilation and 100% supplemental oxygen. Assisted and artificial ventilation are probably the most important skills in EMS—at any level. Too often emphasis is placed on advanced airway techniques, making the basic airway maneuvers seem ineffective. This cannot be further from the truth. Basic airway and ventilation techniques are extremely effective when administered appropriately. Mastery of these techniques at the EMT level is imperative.

Patients who are breathing inadequately are typically unable to speak in complete sentences. An irregular breathing pattern will also require artificial ventilation to assist patients in maintaining adequate minute volume. Keep in mind that fast, shallow breathing can be just as dangerous as very slow breathing. Fast, shallow breathing moves air primarily in the larger airway passages (dead air space) and does not allow for adequate exchange of air and carbon dioxide in the alveoli. Patients with inadequate breathing require assisted ventilations with some form of positive-pressure ventilation. Remember to follow standard precautions as needed when managing the patient's airway.

Words of Wisdom

Methods of Ventilation (listed in order of preference)

- Mouth-to-mask with one-way valve
- Two-person BVM with reservoir and supplemental oxygen
- Manually triggered ventilation device (flow-restricted, oxygen-powered ventilation device)
- One-person BVM with oxygen reservoir and supplemental oxygen

Note: This order of preference has been stated because research has shown that personnel who infrequently ventilate patients have great difficulty maintaining an adequate seal between the mask and the patient's face.

Assisting Ventilation in Respiratory Distress/Failure

When a patient is in severe respiratory distress or respiratory failure and not breathing adequately, you must intervene quickly to prevent further deterioration of the patient. Two treatment options are available in these situations: assisted ventilation and continuous positive airway pressure (CPAP). CPAP is discussed later in this chapter; the focus of this section will be on assisted ventilation.

The purpose of assisted ventilations is to improve the overall oxygenation and ventilatory status of the patient. Patients who require assisted ventilations are no longer able to maintain adequate oxygen levels for the body and need assistance to prevent further hypoxia.

You need to be familiar with the signs and symptoms associated with inadequate ventilation. Signs of altered mental status and inadequate minute volume are indications for assisted ventilation. In addition, excessive accessory muscle use and fatigue from labored breathing are signs of potential respiratory failure. Patients exhibiting these signs need immediate treatment.

Follow these steps to assist a patient with ventilations using a BVM:

1. Explain the procedure to the patient.
2. Place the mask over the patient's nose and mouth.
3. Squeeze the bag each time the patient breathes, maintaining the same rate as the patient.
4. After the initial 5 to 10 breaths, slowly adjust the rate and deliver an appropriate tidal volume.
5. Adjust the rate and tidal volume to maintain an adequate minute volume.

Artificial Ventilation

Patients who are in respiratory arrest need immediate treatment. Without it, they will die. However, the act of breathing for a patient, or artificial ventilation, is not a skill you should take lightly. Once you determine that a patient is not breathing, begin artificial ventilation immediately. The methods that you may use to provide artificial ventilation include the mouth-to-mask technique, a one- or two-person BVM, and the manually triggered ventilation device.

Normal Ventilation Versus Positive-Pressure Ventilation

It is important to understand that while artificial ventilations are necessary to sustain life, they are not the same as normal breathing. As discussed earlier, the act of air moving in and out of the lungs is based on pressure changes within the thoracic cavity. During normal ventilation, the diaphragm contracts and negative pressure is generated in the chest cavity. This essentially sucks air into the chest from the trachea in an attempt to equalize the pressure in the chest with the atmospheric pressure. However, positive-pressure ventilation generated by a device, such as a BVM, forces air into the chest cavity from the external environment, rather than based on pressure changes. This difference between normal ventilation and positive-pressure ventilation can create some challenges Table 10-6.

The physical act of the chest wall expanding and retracting during breathing serves to aid the circulatory system in returning blood to the heart. During normal ventilation, the chest wall movement works similar to a pump. The pressure changes in the thoracic cavity help draw venous return back to the heart. However, when positive-pressure ventilation is initiated, more air is needed to achieve the same oxygenation and ventilatory effects of normal breathing. This increase in airway wall pressure causes the walls of the chest cavity to push out of their normal anatomic shape. As a result, there is an increase in the overall intrathoracic pressure within the chest cavity. This pressure increase affects the venous return of blood back to the heart. The blood flow is decreased due to the increased pressure in the chest. This causes poor venous return to the heart, and the amount of blood pumped out of the heart is reduced. Therefore, it is imperative that you regulate the rate and volume of artificial ventilations to help prevent this drop in cardiac output. Cardiac output is a function of stroke volume and heart rate, such that cardiac output = stroke volume × heart rate. Stroke volume is the amount of blood ejected by the ventricle in one cardiac cycle. The heart rate is assessed by taking the pulse for 1 minute. The cardiac output is the amount of blood ejected by the left ventricle in 1 minute.

Words of Wisdom

Ventilation Rates*	
Adult	1 breath every 5 to 6 seconds
Child	1 breath every 3 to 5 seconds
Infant	1 breath every 3 to 5 seconds
*For apneic patients with a pulse.	

Mouth-to-Mouth and Mouth-to-Mask Ventilation

As you learned in your CPR course, mouth-to-mouth ventilations are now routinely done with a barrier device, such as a mask or face shield. A **barrier device** is a protective item that features a plastic barrier placed on a patient's face with a one-way valve to prevent the backflow of secretions, vomitus, and gases. Barrier devices provide adequate protection Figure 10-39. Mouth-to-mouth ventilations without a barrier device should be provided only in extreme situations. Performing mouth-to-mask ventilations with a pocket mask containing a one-way valve is a safer method to prevent possible disease transmission.

Table 10-6 Normal Ventilation Versus Positive-Pressure Ventilation

	Normal Ventilation	Positive-Pressure Ventilation
Air movement	Air is sucked into the lungs due to the negative intrathoracic pressure created when the diaphragm contracts.	Air is forced into the lungs through a means of mechanical ventilation.
Blood movement	Normal breathing allows blood to naturally be pulled back to the heart.	Intrathoracic pressure is increased, causing compression of the vena cava and reducing blood return to the heart. This causes the amount of blood pumped by the heart to be reduced.
Airway wall pressure	Not affected during normal breathing.	More volume is required to have the same effects as normal breathing. As a result, the walls are pushed out of their normal anatomic shape.
Esophageal opening pressure	Not affected during normal breathing.	Air is forced into the stomach, causing gastric distention that could result in vomiting and aspiration.
Overventilation	Overventilation is not typical of normal breathing.	Forcing volume and rate results in increased intrathoracic pressure, gastric distention, and decrease in cardiac output (hypotension).

Figure 10-39 Barrier devices, such as a plastic shield or a pocket mask with a one-way valve, provide adequate protection.

A mask with an oxygen inlet provides oxygen during mouth-to-mask ventilation to supplement the air from your lungs. Remember that the gas you exhale contains 16% oxygen. With the mouth-to-mask system, however, the patient gets the additional benefit of significant oxygen enrichment with inspired air. This system also frees both your hands to help keep the airway open and helps you to provide a better seal between the mask and face, thus delivering adequate tidal volume.

The mask may be shaped like a triangle or a doughnut, with the apex (top) placed across the bridge of the nose. The base (bottom) of the mask is placed in the groove between the lower lip and the chin. In the center of the mask is a chimney with a 15/22-mm connector.

Follow these steps to use mouth-to-mask ventilation **Skill Drill 10-8**:

1. Kneel at the patient's head. Open the airway using the head tilt–chin lift maneuver or the jaw-thrust maneuver if trauma is suspected. Insert an oral or nasal airway, if possible, to help maintain airway patency. Connect the one-way valve to the face mask and place the mask on the patient's face. Make sure the top is over the bridge of the nose and the bottom is in the groove between the lower lip and the chin. Hold the mask in position by placing your thumbs over the top part of the mask and your index fingers over the bottom half. Grasp the lower jaw with the remaining three fingers on each hand, making an airtight seal by pulling the lower jaw into the mask. Maintain an upward and forward pull on the lower jaw with your fingers to keep the airway open. This method of securing the mask to the patient's face is known as the EC-clamp method **Step 1**.
2. Take a deep breath and exhale through the open port of the one-way valve. Breathe slowly into the patient's mask until you observe adequate chest rise **Step 2**.
3. Remove your mouth, and watch for the patient's chest to fall during passive exhalation **Step 3**.

You know that you are providing adequate ventilations if you see the patient's color improving and the chest rise adequately and if you do not meet esistance when ventilating. You should also hear and feel air escape as the patient exhales. Make sure that you are providing the correct number of breaths per minute for the patient's age.

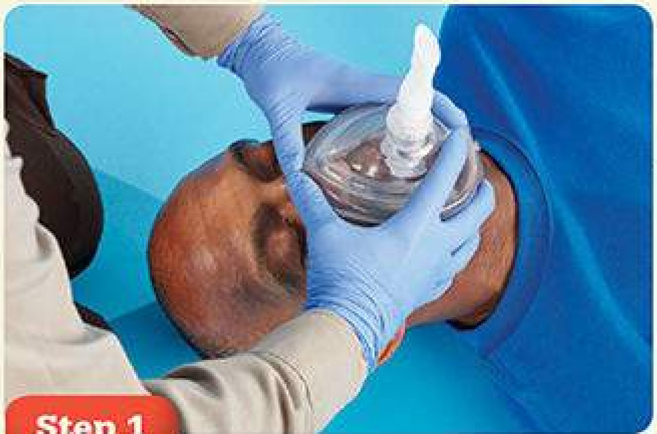
To increase the oxygen concentration, administer high-flow oxygen at 15 L/min through the oxygen inlet valve of the mask. This, when combined with your exhaled breath, will deliver approximately 55% oxygen to the patient. If supplemental oxygen is available, deliver a tidal volume of approximately 500 to 600 mL (6 to 7 mL/kg) over 1 second.

The Bag-Valve Mask

With an oxygen flow rate of 15 L/min and an adequate mask-to-face seal, a BVM with an oxygen reservoir can deliver nearly 100% oxygen **Figure 10-40**. Most BVMs on the market today include modifications or accessories (reservoirs) that permit the delivery of oxygen concentrations approaching 100%; however, the device can deliver only as much volume as you can squeeze out of the bag by hand. The BVM provides less tidal volume than mouth-to-mask ventilation; however, it delivers a much higher concentration of oxygen. The BVM is the most common method used to ventilate patients in the field. While an experienced EMT will be able to supply adequate tidal volume with a BVM, as a new EMT you should develop proficiency at ventilating airway-training manikins before using a BVM on a patient. If you have difficulty adequately ventilating a patient with a BVM, you should immediately switch to an alternative method of ventilation, such as the mouth-to-mask technique.

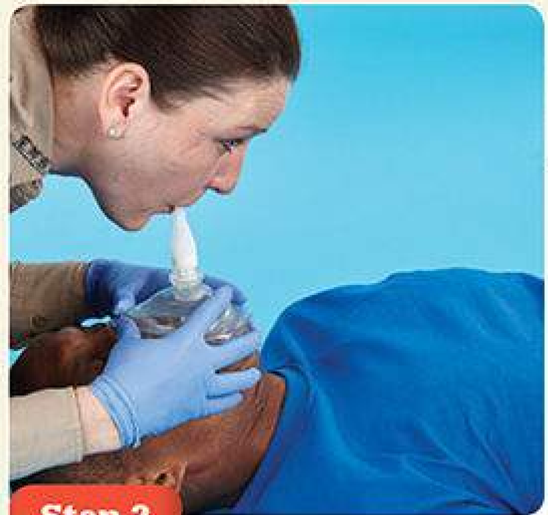
A BVM should be used when you need to deliver high concentrations of oxygen to patients who are not ventilating adequately. The device is also used for patients in respiratory arrest, cardiopulmonary arrest, and respiratory failure. The BVM may be used with or without oxygen. However, to ensure the highest concentration of delivered oxygen, you must attach supplemental oxygen and a reservoir. Use an oral or nasal airway adjunct in conjunction with the BVM.

Skill Drill 10-8 Performing Mouth-to-Mask Ventilation



Step 1

Once the patient's head is properly positioned and an airway adjunct is inserted, place the mask on the patient's face. Seal the mask to the face using both hands (EC-clamp method).



Step 2

Breathe into the one-way valve until you note visible chest rise.

Step 3

Remove your mouth and watch the patient's chest fall during exhalation.

Words of Wisdom

Volume Capabilities of the Bag-Valve Mask

Size	Amount, mL
Adult	1,200 to 1,600
Pediatric	500 to 700
Infant	150 to 240

Bag-Valve Mask Components. All adult BVMs should have the following components:

- A disposable self-refilling bag
- No pop-off valve, or if one is present, the capability of disabling the pop-off valve
- An outlet valve that is a true valve for nonrebreathing
- An oxygen reservoir that allows for delivery of high-concentration oxygen

Figure 10-40 A BVM with an oxygen reservoir can deliver nearly 100% oxygen if a good seal between the mouth and mask is achieved and if supplemental oxygen is used.

- A one-way, no-jam inlet valve system that provides an oxygen inlet flow at a maximum of 15 L/min with standard 15/22-mm fittings for face mask and endotracheal tube (or other advanced airway adjunct) connection
- A transparent face mask
- Ability to perform under extreme environmental conditions, including extreme heat or cold

The total volume in the bag of an adult BVM is usually 1,200 to 1,600 mL. The pediatric bag contains 500 to 700 mL, and the infant bag holds 150 to 240 mL.

The volume of air (oxygen) delivered to the patient is based on one key observation—chest rise and fall. This, in essence, is generally the only means of assessing tidal volume in the field. In most situations, you will be using the BVM attached to high-flow oxygen (15 L/min). When using the BVM with high-flow oxygen on an adult patient, you should squeeze the bag enough to cause a noticeable rise of the patient's chest—a volume of about 600 mL (approximately 6 to 7 mL/kg) over 1 second.

By delivering just enough tidal volume to see the chest rise, the risk of gastric distention (and associated complications of vomiting and aspiration) is reduced.

It is not practical for you to accurately measure tidal volume in milliliters per kilogram for each patient ventilated in the field. The key is to watch for good chest rise and fall—let these observations determine the appropriate amount of volume to deliver.

Bag-Valve Mask Technique. Whenever possible, you and your partner should work together to provide BVM ventilation.

One EMT can maintain a good mask seal by securing the mask to the patient's face with two hands while the other EMT squeezes the bag. Ventilation using a BVM is a challenging skill: it may be very difficult for one EMT to maintain a proper seal between the mask and the face with one hand while squeezing the bag well enough to deliver an adequate volume to the patient. This skill can be difficult to maintain if you do not have many opportunities to practice. Effective one-person BVM ventilation requires considerable experience. Also, performance of this skill depends on having enough personnel to carry out other actions that need to be done at the same time, such as chest compressions, putting the stretcher in place, or helping to lift the patient onto the stretcher.

YOU are the Provider — PART 5

You continue your treatment of the patient, load him into the ambulance, and proceed to the hospital. A member of the rescue team, who is also an EMT, accompanies you to assist with patient care. After reassessing the patient, you call in your report to the emergency department (ED).

Recording Time: 10 Minutes	
Level of consciousness	Responsive only to pain
Respirations	14 breaths/min, shallow
Pulse	100 beats/min, stronger
Skin	Warm and moist; less cyanotic
Blood pressure	124/62 mm Hg
Spo_2	92% (on oxygen)

11. Has your treatment improved the patient's condition? If so, how do you know?
12. What is the appropriate technique for ventilating an apneic adult?
13. What are the dangers of hyperventilating a patient?

Follow these steps to use the one-person BVM technique **Skill Drill 10-9**:

1. Select the proper size mask and assemble your equipment. Kneel above the patient's head. Maintain the patient's neck in an extended position unless you suspect a cervical spine injury **Step 1**. In that case, stabilize the patient's head and neck and use the jaw-thrust maneuver. Have your partner hold the head, or, if you are alone, use your knees to stabilize the head.
2. Open the patient's mouth, and suction as needed. Insert an oral or nasal airway to maintain airway patency **Step 2**.
3. Place the mask on the patient's face **Step 3**. Make sure the top is over the bridge of the nose and the bottom is in the groove between the lower lip and the chin. If the mask has a large, round cuff around the ventilation port, center the port over the patient's mouth. Inflate the collar to obtain a better fit and seal to the face if necessary.
4. Create a seal by holding your index finger over the lower part of the mask and your thumb over the upper part of the mask. Then use your remaining fingers to pull the lower jaw into the mask. This is known as the EC-clamp method and will maintain an effective face-to-mask seal.
5. Bring the lower jaw up to the mask with the last three fingers of your hand. This will help to maintain an open airway. Make sure you do not grab the fleshy part of the neck, as you may compress structures and create an airway obstruction.
6. Squeeze the bag with your other hand until you see adequate chest rise **Step 4**. Perform this in a rhythmic manner once every 5 seconds for an adult and once every 3 seconds for infants and children. In patients with ongoing CPR and an advanced airway in place, such as an endotracheal tube, a laryngeal mask airway, or a King airway, use a simplified ventilation rate of 1 breath every 6 seconds, without pausing chest compressions.

If two EMTs are available to manage the airway, have one EMT hold the mask in position by placing the thumbs over the top part of the mask and the index fingers over the bottom half. Use the last three fingers of the hands to bring the lower jaw up to the mask. This helps to seal the mask to the face and maintain an open airway. The second EMT squeezes the bag with two hands until the chest rises adequately in the same manner as the one-person technique **Figure 10-41**.

Words of Wisdom

In certain situations, you will need to perform ventilations with a BVM before supplemental oxygen is available. If you are unable initially to attach your BVM to an oxygen source, do not withhold ventilations. Provide ventilations using the standard technique and attach the BVM to an oxygen source as soon as it is available.

When using the device to assist ventilations of a patient who is breathing too slowly (hypoventilation) with reduced tidal volume, squeeze the bag as the patient tries to breathe in. Then, for the next 5 to 10 breaths, slowly adjust the rate and delivered tidal volume until an adequate minute volume is achieved.

To assist respirations of a patient who is breathing too fast (hyperventilation) with reduced tidal volume, you must first explain the procedure to the patient if the patient is coherent. Initially assist respirations at the rate at which the patient has been breathing, squeezing the bag each time the patient inhales. Then, for the next 5 to 10 breaths, slowly adjust the rate and the delivered tidal volume until an adequate minute volume is achieved.

As you are assisting ventilations with a BVM, you should evaluate the effectiveness of your delivered ventilations. You will know that artificial ventilations are not adequate if the patient's chest does not rise and fall with each ventilation, the rate at which you are ventilating is too slow or too fast, or the heart rate does not return to normal. If too much air is escaping from under the mask, reposition the mask for a better seal. If the patient's chest does not rise and fall, you may need to reposition the head or use an airway adjunct. If the patient's chest still does not rise and fall after you have made these corrections, check for an airway obstruction. If an obstruction is not present, attempt ventilations using an alternative method, such as the mouth-to-mask technique.

The BVM may also be used in conjunction with an endotracheal tube or with other advanced airway devices. Advanced airway techniques are beneficial when a good seal is difficult to maintain, the patient has a cervical spine injury, or the patient's condition warrants. These techniques are discussed later in the text.

Skill Drill 10-9 Performing One-Rescuer Bag-Valve Mask Ventilations

Step 1

Assemble your equipment and position yourself above the patient's head. Open the airway using the head tilt-chin lift or jaw-thrust maneuver.

Step 2

Open the patient's mouth and suction as necessary to clear secretions. Insert an oral or nasal airway.

Step 3

Select the appropriate mask and position it properly on the patient's face. Following the EC-clamp method, make a seal by holding your index finger over the lower part of the mask and your thumb over the upper part of the mask. Then use your remaining fingers to pull the lower jaw into the mask. Bring the lower jaw up to the mask with the last three fingers of your hand. Avoid the fleshy soft tissue of the neck.

Step 4

Squeeze the bag with your other hand until you see adequate chest rise. For adults, squeeze once every 5 seconds. For infants and children, squeeze once every 3 seconds. In patients with ongoing CPR and an advanced airway in place, use a rate of 1 breath every 6 seconds.

Figure 10-41 With two-person BVM ventilation, you hold the mask in place while your partner squeezes the bag with two hands until the patient's chest rises adequately.

Words of Wisdom

The Sellick maneuver, also known as cricoid pressure, has been used to inhibit the flow of air into the stomach (and thus reduce gastric distention) and reduce the chance of aspiration by helping block the regurgitation of gastric contents from the esophagus. In this maneuver, a rescuer applies cricoid pressure on the patient by placing the thumb and index finger on either side of the cricoid cartilage (at the inferior border of the larynx) and pressing down.

According to the International Liaison Committee on Resuscitation (ILCOR) guidelines, cricoid pressure may actually *impede* ventilation and not completely prevent aspiration. For this reason, the procedure is generally not recommended. Be sure to follow your local protocol regarding the use of the Sellick maneuver.

Gastric Distention. When using a BVM or any other ventilation device, be alert for **gastric distention**, inflation of the stomach with air. Although gastric distention most commonly affects children, it also affects adults. Gastric distention is most likely to occur when you ventilate the patient too forcefully or too rapidly with a BVM or pocket-mask. It may also occur when the airway is obstructed as a result of a foreign body or improper head position. For this reason, give slow, gentle breaths during artificial ventilation over 1 second (enough to see the chest rise) in the adult patient. As compliance decreases, you will notice it becoming increasingly difficult to squeeze the BVM to get air into the lungs. Slight gastric distention is not of concern; however, severe inflation of the stomach is dangerous because it may cause vomiting and increase the risk of aspiration during CPR. Gastric distention can also significantly reduce the lung volume by elevating the diaphragm, especially in infants and children. Gastric distention is a common complication associated with the use of manually triggered ventilation devices, a key reason why these devices are not highly recommended.

To prevent or alleviate distention, do the following: (1) ensure that the patient's airway is appropriately positioned, (2) ventilate the patient at the appropriate rate, and (3) ventilate the patient with the appropriate volume.

If the patient's stomach appears to be distending, recheck and reposition the head, and watch for rise and fall of the chest wall as you perform rescue breathing. Continue slow rescue breathing without attempting to expel the stomach contents. If gastric distention makes it impossible to ventilate the patient and an ALS provider is not available to perform orogastric tube or nasogastric tube decompression, consider applying pressure over the upper abdomen. Manual decompression should only be used as a last resort. Applying manual pressure over the patient's upper abdomen will likely result in vomiting; therefore, if vomiting occurs, turn the patient's entire body to the side, suction and/ or wipe out the mouth with your gloved hand, and return the patient back to a supine position so that you can continue rescue breathing.

Passive Ventilation

The process of expansion and contraction of the chest creates a "pump" for air movement in and out of the chest. Normally, the muscles of the chest wall are the driving force behind the expansion and contraction of the chest. However, when a patient is not breathing, the movement of the chest wall is completely dependent on the EMS providers' ability to provide artificial breathing to the patient—active ventilation.

During cardiac arrest, you are responsible for providing high-quality chest compressions to circulate blood and artificial ventilations to oxygenate the hemoglobin. Since movement of the chest wall has been shown to assist in the ventilation process, patients receiving chest compressions benefit from a process known as **passive ventilation**. This is sometimes also called passive oxygenation or apneic oxygenation. In passive ventilation, air movement in and out of the chest cavity occurs passively as a result of compressing the chest. When the chest is compressed, air is forced out of the thorax. As the chest recoils following compression, a negative pressure is created within the chest, which results in a vacuum. This leads to air being sucked into the chest cavity, similar to what occurs with muscle contraction during active inhalation.

Words of Wisdom

Indications That Artificial Ventilation Is Adequate:

- Visible and equal chest rise and fall with ventilation
- Ventilations delivered at the appropriate rate
  - 10 to 12 breaths/min for adults*
  - 12 to 20 breaths/min for infants and children*
  - In patients with ongoing CPR and an advanced airway in place, 1 breath every 6 seconds
- Heart rate returns to normal range
- Patient's color is improving (pink)

Indications That Artificial Ventilation Is Inadequate:

- Minimal or no chest rise and fall
- Ventilations are delivered too fast or too slowly for patient's age
- Heart rate does not return to normal range
- Patient's color remains cyanotic, mottled, or deteriorates

*In apneic patients with a pulse.

When you are performing chest compressions, passive ventilation can be enhanced by inserting an oropharyngeal airway and providing supplemental oxygen to the patient. You can also improve oxygenation during passive ventilation by applying supplemental oxygen with a nasal cannula or a nonrebreathing mask.

Manually Triggered Ventilation Devices

Another method of providing artificial ventilation is with a **manually triggered ventilation device** Figure 10-42. These devices, also known as flow-restricted, oxygen-powered ventilation devices, are widely available and have been used in EMS for several years. The major advantage of this device is that it allows a single rescuer to use both hands to maintain a mask-to-face seal while providing positive-pressure ventilation. It also reduces rescuer fatigue associated with using a BVM on extended transports. However, recent findings suggest that manually triggered ventilation devices are associated with difficulty in maintaining adequate ventilation without assistance and should not be used routinely because of the high incidence of gastric distention and possible damage to structures within the chest cavity. Another disadvantage is that a special unit and additional training are required when using the manually triggered ventilation device on infants and children. In addition, this device *should not* be used on patients with COPD or suspected cervical spine or chest injuries. Because the rescuer is not actively squeezing a bag, it is difficult to assess for lung compliance. As a result, the rescuer should take extra care when ventilating; the high ventilatory pressures generated by the device may damage lung tissue if not carefully monitored. Typical adult ventilation consumes 5 L/min of oxygen versus the manually triggered device at 15 to 25 L/min.

Figure 10-42 A manually triggered ventilation device can provide up to 100% oxygen.

Manually Triggered Ventilation Device Components. Manually triggered ventilation devices should have the following components:

- A peak flow rate of 100% oxygen at up to 40 L/min
- An inspiratory pressure safety release valve that opens at approximately 60 cm of water and vents any remaining volume to the atmosphere or stops the flow of oxygen
- An audible alarm that sounds whenever you exceed the relief valve pressure
- The ability to operate satisfactorily under normal and varying environmental conditions
- A trigger (or lever) positioned so that both your hands can remain on the mask to provide an airtight seal while supporting and tilting the patient's head and keeping the jaw elevated

Learning how to use these devices correctly requires proper training and considerable practice. As with BVMs, you must make sure there is an effective seal between the patient's face and mask. The amount of pressure necessary to ventilate a patient adequately will vary according to the size of the patient, the patient's lung volume, and the condition of the lungs. A patient with COPD will need greater pressure to receive adequate volume than would be necessary for a patient with normal lungs. Pressures that are too great can cause a **pneumothorax**. Always follow local medical protocols carefully when you use these devices.

Automatic Transport Ventilator/ Resuscitator

The **automatic transport ventilator (ATV)** is essentially a manually triggered ventilation device attached to a control box that allows the variables of ventilation to be set. Although the ATV lacks the sophisticated control of a hospital ventilator, it frees you to perform other tasks, such as maintaining a mask seal or ensuring continued patency of the airway. You can even perform non–airway-related tasks if the patient has an advanced airway in place and is being ventilated with the ATV. However, even though an ATV is helpful, always have a BVM and mask prepared and ready for use should a malfunction occur with the ATV.

Most models have adjustments for respiratory rate and tidal volume. In most cases, the respiratory rate is set at the midpoint or average for the patient's age. Tidal volume is usually estimated using the formula of 6 to 7 mL/kg because ATVs are oxygen-powered and provide oxygen-enriched breathing gas. The tidal volume can be adjusted based on the patient's chest rise and physiologic response. ATVs are considered volume-cycled/rate-controlled ventilators. This means that they deliver a preset volume at a preset respiratory rate, although this does not guarantee that all of the volume is being delivered to the lungs.

Like the manually triggered ventilation device, the ATV is generally oxygen-powered, although some models may require an external power source. Whereas this device does require oxygen, it generally consumes 5 L/min of oxygen, unlike a BVM that uses 15 to 25 L/min. In addition, just like the manually triggered ventilation device, the ATV has a pressure relief valve, which can lead to hypoventilation in patients with poor lung compliance, increased airway resistance, or airway obstruction. **Compliance** is the ability of the alveoli to expand when air is drawn in during inhalation. Poor lung compliance is the inability of the alveoli to fully expand during inhalation.

Whereas ATVs potentially free you to perform other tasks, constant reassessment of the patient is necessary. Barotrauma is a common complication associated with manually triggered ventilation devices and the ATV. In addition, you need to assess for full chest recoil when using an ATV. This step is not only essential with patients in respiratory arrest, but with patients in cardiac arrest receiving chest compressions as well.

Continuous Positive Airway Pressure

Continuous positive airway pressure (CPAP) is a noninvasive means of providing ventilatory support for patients experiencing respiratory distress. Many people who have been diagnosed with obstructive sleep apnea wear a CPAP unit at night to maintain their airway while they sleep **Figure 10-43**. Over the past several years, the use of CPAP in the prehospital environment has proven to be an excellent adjunct in the treatment of respiratory distress associated with obstructive pulmonary disease and acute pulmonary edema. Typically, many of the patients would be managed with advanced airway devices, such as endotracheal intubation. Research has shown that there is a significant increase in morbidity and mortality when patients with these conditions receive intubation for their condition in the field. CPAP offers an alternative means for providing ventilatory assistance to patients and helps to decrease the overall morbidity and mortality. Because of the simplicity of the device and its great benefit to the patient, CPAP is becoming widely used at the EMT level. However, not all EMTs are trained in the use of CPAP. Follow your local protocols.

Figure 10-43 Many people who have been diagnosed with obstructive sleep apnea wear a CPAP unit at night to maintain their airway while they sleep.

Mechanism

CPAP increases pressure in the lungs, opens collapsed alveoli, pushes more oxygen across the alveolar membrane, and forces interstitial fluid back into the pulmonary circulation. The therapy is typically delivered through a face mask that is held to the head with a strapping system. A good seal with minimal leakage between the face and mask is essential.

Many CPAP systems use oxygen as the driving force to deliver the positive ventilatory pressure to the patient. Frequently check the oxygen regulator when administering CPAP; depending on the flow and the patient's respiratory rate, some CPAP units can empty a D cylinder in as little as 5 to 10 minutes.

The mechanism that determines the amount of pressure delivered to the patient (such as 5 cm H_2O) varies depending on the manufacturer. In most cases, the result is similar to hanging your head out the window while driving on the highway. This results in a high inspiratory flow and the need to push a pressure valve open with exhalation. While this may appear to require a great deal of effort on the part of a patient who is already in distress, many patients make a dramatic turnaround when CPAP is applied.

Because CPAP increases pressure inside the chest, it reduces the amount of blood flow returning to the heart. As the pressure in the thorax increases, the venous flow of blood returning to the heart meets the resistance of the increased pressure in the chest. The result is a decrease in the workload of the heart and a drop in cardiac output. This is not common with lower levels of CPAP; however, caution should be used when considering CPAP in patients with low blood pressure. Continually reassess patients for sudden drops in blood pressure.

Indications

CPAP is indicated for patients experiencing respiratory distress in which their own compensatory mechanisms are not enough to keep up with their oxygen demand. Whereas most patients improve after the application of CPAP, it is important to remember that CPAP is merely treating the symptoms and not necessarily the underlying pathology.

The following are some general guidelines for CPAP candidates:

- Patient must be alert and able to follow commands
- Patient is displaying obvious signs of moderate to severe respiratory distress (eg, accessory muscle use, tripod position) from an underlying pathology, such as pulmonary edema or obstructive pulmonary disease (ie, COPD)
- Patient is breathing rapidly, such that it affects overall minute volume (greater than 26 breaths/min)
- Pulse oximetry reading is less than 90%

Whereas these guidelines should be considered when assessing the need for CPAP, it is important that you follow your local guidelines and protocols.

Contraindications

CPAP has proven to be immensely beneficial to patients experiencing respiratory distress from acute pulmonary edema or obstructive pulmonary disease; however, there are times when CPAP is not appropriate for the patient.

The following are general contraindications for CPAP use:

- A patient who is in respiratory arrest
- Signs and symptoms of a pneumothorax or chest trauma
- A patient who has a tracheostomy
- Active gastrointestinal bleeding or vomiting
- Patient is unable to follow verbal commands

In addition to these contraindications, always reassess the patient for signs of deterioration and/ or respiratory failure. CPAP is an excellent tool to improve ventilation; however, not all patients will improve with this device. Once signs of respiratory failure become apparent or the patient is no longer able to follow commands, remove CPAP from the patient, and initiate positive-pressure ventilation with a BVM attached to high-flow oxygen.

Application

Several varieties of CPAP units are available to EMS providers; however, most follow the same general guidelines for use and set up. CPAP units are generally composed of a generator, a mask, a circuit that contains corrugated tubing, a bacteria filter, and a one-way valve. The CPAP generator creates resistance throughout the respiratory cycle. This resistance creates a back pressure into the airways that pushes open the smaller airway structures, such as bronchioles and alveoli, as the patient exhales. The amount of pressure can be determined by adjusting a valve within the system or with a separate valve that can be attached to the CPAP system. A pressure of 7.0 to 10.0 cm H_2O is generally an acceptable therapeutic range for a patient on CPAP. Always consult the operations manual of a particular CPAP device for proper assembly instructions.

Since most CPAP units are powered by oxygen, it is important to have a full cylinder of oxygen when using CPAP. Some CPAP units use a continuous flow of oxygen, while others use oxygen on more of a demand basis. In either situation, continuously monitor the amount of available oxygen in your cylinder. A typical CPAP unit will deplete a full D cylinder of oxygen in 15 to 30 minutes, depending on the fraction of inspired oxygen (FIO_2) setting. Therefore, proper planning for oxygen consumption is necessary when considering applying CPAP. In addition, some of the newer CPAP devices allow the provider to adjust the FIO_2. Some CPAP devices are set to deliver a fixed FIO_2 of 30% to 35%; however, some can deliver as high as 95%.

Over the past several years, new disposable CPAP devices have become available to the EMS provider. These devices typically have a mask that is secured to the face, similar to standard CPAP devices. However, these devices run entirely off the oxygen system and do not require the adjustment of a valve. Depending on the manufacturer, a valve in either the tubing or the mask creates the pressure needed for the system. Pressure is controlled by changing the oxygen flow. The higher the oxygen flow rate, the higher the pressure. These devices are gaining in popularity as they are lightweight and relatively easy to operate.

Follow the steps in **Skill Drill 10-10** to use CPAP:

1. Take standard precautions. Confirm blood pressure. Check your equipment, then connect the circuit to the CPAP generator. Make sure your generator is connected to an oxygen source and/or a power source if required **Step 1**.
2. Connect the face mask to the circuit tubing **Step 2**. Once the system is connected, check to see if there is an on/off button. Some of the newer models have this feature. Make sure the device is set in the "on" position before you apply CPAP to the patient.
3. Connect the tubing to the oxygen tank **Step 3**.
4. Confirm the device is working, and place the mask over the patient's mouth and nose, creating as much of an airtight seal as possible. This can be a rather difficult task depending on your patient. Many patients will resist the application of a mask to their face while in severe respiratory distress. Explain the application to the patient and coach him or her through the application of the mask. Allowing the patient to hold the mask to his or her face initially may actually be beneficial in alleviating some of the stress associated with CPAP application **Step 4**.
5. Once the mask is on the face, use the strapping mechanism to secure it to the patient's head, making sure the seal between the mask and face remains. Consult the manufacturer's guidelines for specific strapping instructions **Step 5**.
6. Adjust the pressure valve and the FIO_2 accordingly to maintain adequate oxygenation and ventilation. With CPAP in place, the patient's oxygenation should improve and the work of breathing should decrease. Constant reassessment of patients for signs of deterioration is essential **Step 6**.

Complications

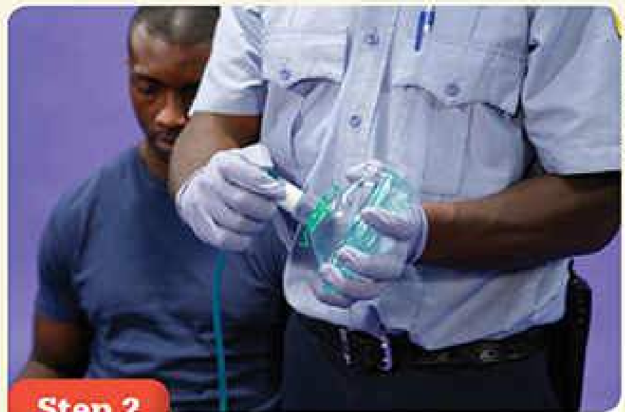
The application and administration of CPAP is a relatively easy process. However, some patients may find CPAP claustrophobic and will resist the application. As patients become more hypoxic, the application of a mask to their face is sometimes perceived as suffocation, rather than helping them breathe. In any event, it is important to explain the application to patients and coach them through the process. Do not force the mask on patients. This will create a higher level of anxiety and increase their oxygen demand. Coach patients through the application of CPAP, allowing them to adjust to the situation. Coaching patients is not always an easy task; it takes practice and a willingness to work closely with your patient during a difficult time.

Due to the high volume of pressure generated by CPAP, there is the possibility of causing a pneumothorax. Whereas some literature suggests this is not likely, you should be aware of this risk and continually assess your patients for signs and symptoms of a pneumothorax.

Skill Drill 10-10 Using CPAP

Step 1

Take standard precautions. Confirm blood pressure. Check your equipment, then connect the circuit to the CPAP generator.



Step 2

Connect the face mask to the circuit tubing.

Step 3

Connect the tubing to the oxygen tank.

Step 4

Confirm that the device is on before you apply it to the patient's face. Place the mask over the patient's mouth or nose or allow the patient to hold it to his or her mouth and nose.

Step 5

Use the strapping mechanism to secure the CPAP to the patient's head. Make sure there is a tight seal.

Step 6

Adjust the pressure valve and the FIO_2, according to the manufacturer's recommendations to maintain adequate oxygenation and ventilation. Reassess the patient.

In addition to a pneumothorax, high pressure in the chest can lower a patient's blood pressure. As the intrathoracic pressure increases, venous blood returning to the heart meets resistance from the increased pressure in the chest. This can result in a sudden drop in blood pressure. While this is not common with lower levels of CPAP, continuous monitoring of blood pressure is necessary.

CPAP has shown positive results consistently with patients experiencing moderate and severe respiratory distress; however, there are still cases in which patients deteriorate. It is important that you reassess the patient for signs of deterioration. If the patient is no longer able to follow verbal commands and/or goes into respiratory failure/arrest, you must act quickly to remove CPAP and begin positive-pressure ventilation using a BVM attached to high-flow oxygen.

Special Considerations

Stomas and Tracheostomy Tubes

BVM ventilation may also need to be used for patients who have had a laryngectomy (surgical removal of the larynx). These patients have a permanent tracheal stoma (an opening in the neck that connects the trachea directly to the skin) **Figure 10-44**. This type of stoma, known as the **tracheostomy**, is an opening at the center front and base of the neck. Many patients who have had a laryngectomy will have other openings in the neck, according to the type of operation performed. You should ignore any opening other than the midline tracheal stoma. The midline opening is the only one that can be used to put air into the patient's lungs.

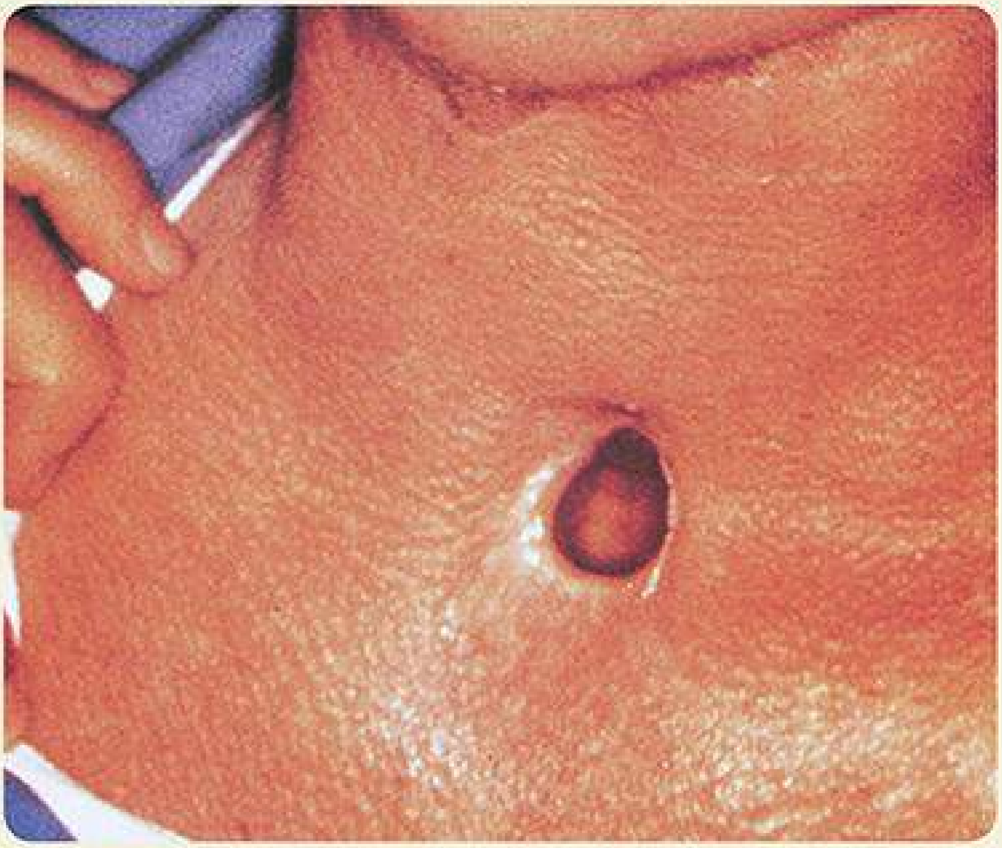


Figure 10-44 A tracheal stoma typically lies in the midline of the neck. The midline opening is the only one that can be used to deliver oxygen to the patient's lungs.

YOU are the Provider PART 6

On arrival at the ED, your reassessment reveals that the patient's condition has improved significantly. His eyes are open, he responds to verbal stimuli, and his breathing, although still somewhat labored, has improved.

Recording Time: 17 Minutes	
Level of consciousness	Eyes open; responsive to verbal stimuli
Respirations	16 breaths/min, slightly labored, adequate depth
Pulse	88 beats/min, strong and regular
Skin	Pink, warm, and moist
Blood pressure	132/72 mm Hg
Spo_2	97% (on oxygen)

You transfer care of the patient to the ED physician, who tells you that he believes the patient is experiencing acute exacerbation of his congestive heart failure. After further treatment in the ED, the patient is admitted to the intensive care unit.

14. How does respiratory failure differ from respiratory arrest?
15. Was your patient experiencing respiratory failure or respiratory arrest?

Neither the head tilt–chin lift nor the jaw-thrust maneuver is required for ventilating a patient with a stoma. If the patient has a tracheostomy tube, ventilate through the tube with a BVM (the standard 15/22-mm adapter on the BVM will fit onto the tube in the tracheal stoma) and 100% oxygen attached directly to the BVM. If the patient has a stoma and no tube is in place, use an infant or child mask with your BVM to make a seal over the stoma. Seal the patient's mouth and nose with one hand to prevent a leak of air through the upper airway when you ventilate through a stoma. Release the seal of the patient's mouth and nose for exhalation. This allows the air to exhale through the upper airway.

If you are unable to ventilate a patient who has a stoma, try suctioning the stoma and the mouth with a French or soft-tip catheter before giving the patient artificial ventilation through the mouth and nose. If you seal the stoma during mouth-to-mouth ventilation, the ability to ventilate the patient may be improved, or it may help to clear any obstructions.

Foreign Body Airway Obstruction

A foreign body that *completely* blocks the airway in a patient is a true emergency that will result in death if not treated immediately. In an adult, sudden foreign body airway obstruction usually occurs during a meal. In a child, it occurs while eating, playing with small toys, or crawling around the house. An otherwise healthy child who has sudden difficulty breathing has probably aspirated a foreign object.

By far, the most common airway obstruction in an unconscious patient is the tongue, which relaxes and falls back into the throat. There are other causes of airway obstruction that do not involve foreign bodies in the airway. These include swelling (from infection or acute allergic reaction) and trauma (tissue damage from injury). With airway obstruction from medical conditions such as infection and acute allergic reactions, repeated attempts to clear the airway as if there were a foreign body will be unsuccessful and potentially dangerous. These patients require specific emergency medical care for their condition; therefore, rapid transport to the hospital is critical.

Recognition

Early recognition of airway obstruction is crucial for you to be able to provide emergency medical care effectively. Obstruction from a foreign body can result in a **mild airway obstruction** or a **severe airway obstruction**.

Patients with a mild airway obstruction are still able to exchange air but will have varying degrees of respiratory distress. Great care must be taken to prevent a mild airway obstruction from becoming a severe airway obstruction. The patient will usually have noisy breathing and may be coughing. Assess the patient and determine whether the patient has **good air exchange** or **poor air exchange**.

With good air exchange, the patient can cough forcefully, although you may hear **wheezing** (the production of whistling sounds during respiration) between coughs. Wheezing is usually indicative of a mild lower airway obstruction. As long as the patient can breathe, cough forcefully, or talk, you should not interfere with the patient's efforts to expel the foreign object on his or her own. Continue to monitor the patient closely and encourage the patient to continue coughing. Abdominal thrusts are usually not effective for dislodging a partial obstruction. Attempts to remove the object manually could force the object farther down into the airway and cause a severe airway obstruction. Continually reassess the patient's condition and be prepared to provide treatment if the air exchange becomes poor or a mild obstruction becomes a severe obstruction.

With poor air exchange, the patient has a weak, ineffective (not forceful) cough and may have increased difficulty breathing, **stridor** (a high-pitched noise heard primarily on inspiration), and cyanosis. Stridor is an indication of a mild upper airway obstruction. You must quickly recognize this situation and provide immediate care.

For patients with mild airway obstruction with poor air exchange, treat immediately as if there is a severe airway obstruction.

Patients with a severe airway obstruction cannot breathe, talk, or cough. One sure sign of a severe obstruction is the sudden inability to speak or cough during or immediately after eating. The person may clutch or grasp his or her throat (universal distress signal), begin to turn cyanotic, and have extreme difficulty breathing **Figure 10-45**. There is little or no air movement. Ask the conscious patient, "Are you choking?" If the patient nods "yes," provide immediate treatment. If the obstruction is not cleared quickly, the amount of oxygen in the patient's blood will decrease dramatically. If not treated, the patient will become unconscious and die.

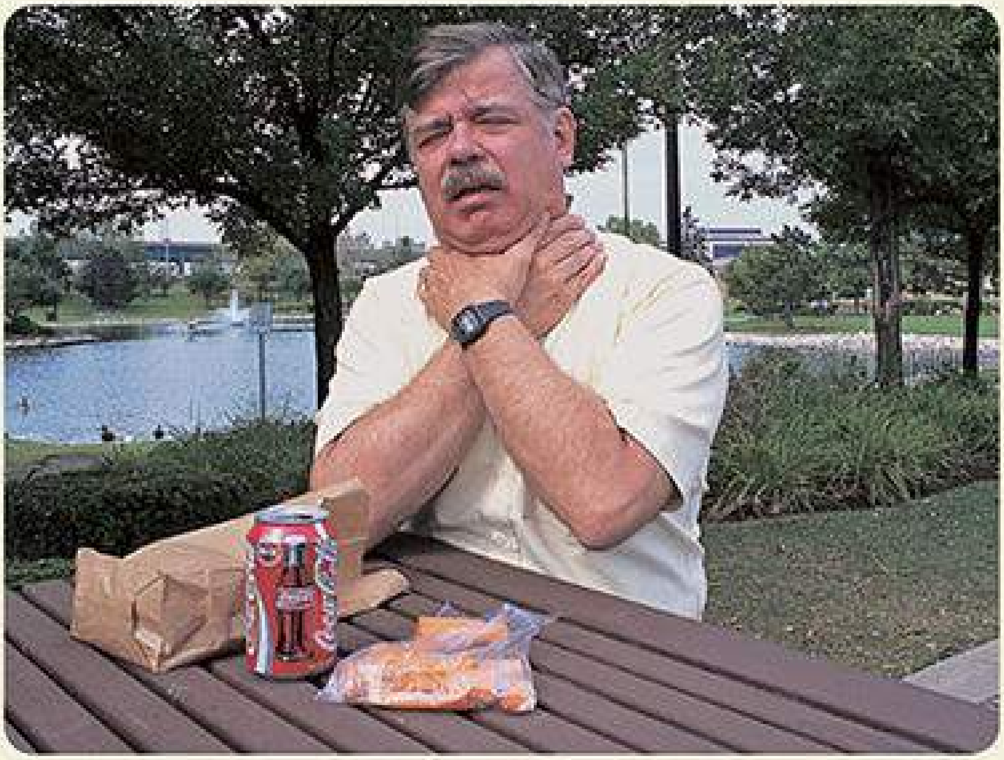

Figure 10-45 The universal sign of choking is a person who grasps his or her throat and has difficulty breathing.

Figure 10-46 When you open the airway and attempt ventilations, it will be obvious to you if the airway is still blocked.

Some patients with a severe airway obstruction will be unconscious as you form your general impression. You may not know that an airway obstruction is the cause of their condition. There are many other causes of unconsciousness and respiratory failure, including stroke, heart attack, trauma, seizures, and drug overdoses. A complete and thorough patient assessment by you, therefore, is essential to providing appropriate emergency medical care.

If the patient is found unresponsive, does not appear to be breathing, and does not have a pulse, begin CPR with high-quality chest compressions. When you open the airway and attempt two ventilations following chest compressions, it will be obvious to you if the airway is blocked **Figure 10-46**. The compressions may have been enough to clear the airway; however, if you are unable to ventilate the patient after several attempts (no chest rise and fall) or you feel resistance while ventilating, consider the possibility of an airway obstruction. Resistance to ventilation can also be due to poor lung compliance. As discussed, compliance is the ability of the alveoli to expand when air is drawn in during inhalation; poor lung compliance is the inability of the alveoli to fully expand during inhalation.

Emergency Medical Care for Foreign Body Airway Obstruction

Perform the head tilt–chin lift maneuver to clear an obstruction that has been caused by the tongue and throat muscles relaxing back into the airway in any person who is found unconscious. This should be performed on unresponsive patients with adequate or inadequate breathing who are not suspected of having spinal trauma. If spinal trauma is suspected, open the airway with a jaw-thrust maneuver. Large pieces of vomited food, mucus, loose dentures, or blood clots in the mouth should be swept forward and out of the mouth with your gloved index finger. When available, use suction to maintain a clear airway.

Abdominal thrusts are the most effective method of dislodging and forcing an object out of the airway of a conscious adult or child. Residual air, which is always present in the lungs, is compressed upward and used to expel the object. Use abdominal thrusts until the object dislodges or the patient becomes unconscious.

For the unresponsive patient with a severe foreign body airway obstruction, reassess to confirm apnea and inability to ventilate. Begin chest compression just as you would for CPR, following the 30 compressions to 2 breaths ratio. At the completion of the 30 compressions, perform a tongue-jaw lift by grasping the jaw with your thumb and index finger. Place your thumb onto the tip of the patient's lower teeth and tongue while placing your index finger under the bony portion of the chin. Be careful not to compress the soft tissues under the chin. Pull the jaw/mouth open and look at the back of the oropharynx for any foreign objects. If an object is observed, remove it with a gloved index finger or suction. Only attempt to remove an object if it is visible during examination of the open mouth; blind sweeps of the back of the oropharynx may push an object farther down in the airway, making the obstruction worse. Once the object(s) is removed or if no object was seen during the tongue-jaw lift, attempt to ventilate. If you are still unable to ventilate, repeat the process.

If you are unable to clear a severe airway obstruction with your initial attempts, begin rapid transport and continue your efforts to relieve the obstruction with abdominal thrusts (chest compressions in the unresponsive patient) on the way to the hospital.

Remember to treat patients with a mild airway obstruction with poor air exchange as if they have a severe airway obstruction.

Patients with a mild airway obstruction and good air exchange should be monitored closely for deterioration of their condition. If the patient is unable to clear the obstruction and remains conscious, support (or let the patient control) the airway position that is most efficient and comfortable. Provide supplemental oxygen, and transport to the hospital.

Words of Wisdom

If spinal trauma is suspected, open the airway using the jaw-thrust maneuver.

Dental Appliances

Many dental appliances can cause an airway obstruction. If a dental appliance, such as a crown or bridge, dentures, or even a piece or sections of braces, has become loose, manually remove it before providing ventilations. Simple manual removal may relieve the obstruction and allow the patient to breathe on his or her own.

Providing BVM or mouth-to-mask ventilation is usually much easier when dentures can be left in place. Leaving the dentures in place provides more structure to the face and will generally assist you in being able to provide a good face-to-mask seal, thus delivering adequate tidal volume. However, loose dentures make it difficult to perform artificial ventilation by any method and can easily obstruct the airway. Therefore, dentures and dental appliances that do not stay in place should be removed. Dentures and appliances may become loose or be completely out of place following an accident or as you are providing care. Periodically reassess the patient's airway to make sure these devices are firmly in place. If dentures become dislodged, if possible, place them in a container and transport with the patient.

Facial Bleeding

Airway problems can be especially challenging in patients with serious facial injuries **Figure 10-47**. Because the blood supply to the face is so rich, injuries to the face can result in severe tissue swelling and bleeding into the airway. Control bleeding with direct pressure and suction as necessary.

Figure 10-47 Airway problems can be especially challenging in patients with serious facial injuries.

YOU are the Provider — SUMMARY

1. What is the function of the respiratory system?

The function (physiology) of the respiratory system, as critical as it is, is quite simple: to bring oxygen into the lungs and remove carbon dioxide from the lungs. Failure of the respiratory system will compromise oxygenation—the loading of oxygen onto the hemoglobin molecule—and cause carbon dioxide to accumulate in the blood. This results in the buildup of dangerous acids in the bloodstream.

2. What is the difference between ventilation and respiration?

Ventilation is the movement of air into and out of the lungs. Normal, unassisted breathing occurs through a process called negative-pressure ventilation. When the diaphragm and intercostal muscles contract, the thorax enlarges and pressure within it falls; this creates a slight vacuum, which pulls air into the lungs. By contrast, positive-pressure ventilation occurs when air is pushed into the lungs, such as when performing artificial ventilation with a BVM or pocket face mask.

Respiration is the process of exchanging oxygen and carbon dioxide. Pulmonary (external) respiration is the exchange of oxygen and carbon dioxide between the blood and alveoli in the lungs. Cellular (internal) respiration is the exchange of oxygen and carbon dioxide between the blood and the body's cells. Adequate cellular respiration relies on adequate ventilation, oxygenation, and pulmonary respiration.

3. How often should you assess a patient's airway and breathing status?

Assessment of a patient's airway and breathing status should be an ongoing process, from the time you initially encounter the patient until he or she is delivered to the ED. A patient's airway may be patent and his or her breathing may be adequate initially; however, this can change quickly. Frequent assessments allow you to detect airway or breathing problems and correct them immediately.

4. Is this patient's airway patent?

A patent airway is one that is open and free of secretions or foreign bodies. At the present time, the patient's airway is patent. However, a patent airway does not mean that the patient is breathing adequately. Carefully assess your patient!

5. Is he breathing adequately? Why or why not?

A patient who is breathing adequately is able to move enough air into and out of the lungs to adequately oxygenate the blood. Adequate breathing in the adult is characterized by a respiratory rate of between 12 and 20 breaths/min; adequate depth (tidal volume); the ability to speak in complete sentences; a regular pattern of inhalation and exhalation; skin that is pink, warm, and dry; pink mucous membranes; and a normal mental status.

The patient in this scenario is not breathing adequately. His respirations are severely labored, he can only speak in two-word sentences, and his mental status is decreased (ie, he is "sleepy"). An altered mental status in a patient with respiratory distress indicates that the brain is hypoxic—that is, it is not receiving enough oxygen.

6. How should you manage his present airway and breathing status?

If a patient is unable to draw enough air into the lungs on his own through the process of negative-pressure ventilation, you must provide some form of positive-pressure ventilation. In a conscious or semiconscious patient, this involves applying a BVM to the patient's face and advising him or her that each time he or she takes a breath, you will squeeze the bag.

Continuous positive airway pressure (CPAP) may also be beneficial to this patient. CPAP delivers positive pressure to the spontaneously breathing patient during the respiratory cycle. It is especially useful in treating patients with breathing difficulty secondary to congestive heart failure and pulmonary edema. With CPAP, the patient breathes against positive pressure that is delivered through a tight-fitting mask. This helps prevent atelectasis (alveolar collapse), forces fluid from the alveoli, and improves gas exchange in the lungs.

Left untreated, inadequate breathing will cause the patient to continue to deteriorate—potentially to the point where he stops breathing completely. If the patient's level of consciousness decreases further, manually keep his airway open and consider inserting an airway adjunct (eg, oral or nasal airway).

7. What is cyanosis? What does it indicate?

Cyanosis is a dark blue or purple color of the skin; it indicates hypoxemia—a deficiency of oxygen in the blood. Highly oxygenated blood is bright red, which gives the patient's skin a pink appearance. If the blood is poorly oxygenated, as with inadequate breathing, it assumes a dark red or purple color. Cyanosis is commonly seen on the face, nail beds, and mucous membranes. It is important to note that cyanosis is a later sign of hypoxemia, so its absence does not rule out an airway or breathing problem.

8. What does the patient's oxygen saturation indicate?

Oxygen saturation (Spo_2) refers to the percentage of hemoglobin (the iron-containing portion of the red blood cell to which oxygen attaches) that is bound to oxygen. Oxygen saturation is measured with a pulse oximeter—a device that sends a beam of light through the capillary bed and measures the density of the blood. Pulse oximetry values normally range between 95% and 100%. An Spo_2 of between 90% and 94% indicates mild to moderate hypoxemia, while an Spo_2 of less than 90% indicates significant hypoxemia. Your patient's Spo_2 of 85% indicates that a significant portion of his blood is not being oxygenated. You must correct this immediately by ensuring that he receives high-flow oxygen. Pulse oximetry is a useful tool for assessing oxygenation provided you remember that it is only a tool, not a substitute for a good assessment.

9. What should be your *most* immediate action?

Snoring respirations indicate that the patient's tongue has fallen back into his throat and is partially blocking his airway. In fact, the tongue is the most common cause of upper airway obstruction in semiconscious and unconscious patients. Your patient's airway is no longer patent, and you must take immediate corrective action. Opening the patient's airway with the head tilt–chin lift maneuver is the quickest, most effective way of accomplishing this. Since his level of consciousness has decreased, an airway adjunct should also be inserted to help maintain his airway. In this case, a nasopharyngeal airway would be the best choice. Although his level of consciousness has significantly decreased, he is not completely unconscious and likely has a gag reflex. Inserting an oropharyngeal airway may result in vomiting and aspiration.

10. How should you adjust your treatment of the patient?

If you weren't already assisting the patient's ventilations, you certainly need to now! Ventilate the patient with 100% oxygen, ensure a good mask-to-face seal, and observe for visible chest rise during each ventilation. His decreased level of consciousness; slow, shallow breathing; and profoundly low oxygen saturation make it clear that he is rapidly progressing toward respiratory arrest. This is likely because he is fatigued from laboring to breathe for a prolonged period. If a patient cannot bring enough oxygen into the lungs, hypoxia will develop. Hypoxia—a dangerous condition in which the tissues and cells of the body are deprived of oxygen—can rapidly cause death unless promptly treated.

11. Has your treatment improved the patient's condition? If so, how do you know?

Compared with earlier assessments, the patient's condition has improved. His skin color and condition are improving, his oxygen saturation is increasing, his heart rate and quality are improving, and his respiratory rate (unassisted), although still shallow, has increased. He still requires assisted ventilation; however, if you continue to ventilate him adequately with high-flow oxygen, you can keep him stable until his underlying problem can be evaluated and definitively treated by a physician. Do not let your guard down, however, because his condition could just as easily deteriorate again.

12. What is the appropriate technique for ventilating an apneic adult?

When ventilating an apneic adult, you should deliver each breath over a period of 1 second—just enough to produce visible chest rise—at a rate of 10 to 12 breaths/min (one breath every 5 to 6 seconds).

13. What are the dangers of hyperventilating a patient?

Hyperventilation (ventilating too fast or with too much force) can have several negative effects on the patient and should be avoided. Hyperventilation increases the incidence of gastric distention, thus increasing the threat of aspiration if regurgitation occurs. Hyperventilation also hyperinflates the lungs; this effect may reduce the amount of blood that returns to the heart and cause cardiac output to fall. Proper ventilation involves delivering each breath over a period of 1 second—just enough to cause visible chest rise—at the appropriate rate (10 to 12 breaths/min for adults; 12 to 20 breaths/min for infants and children).

14. How does respiratory failure differ from respiratory arrest?

Respiratory failure is just that—failure of the respiratory system to bring oxygen into the lungs and remove carbon dioxide. The patient is breathing; however, it is inadequate and requires ventilation assistance. If not promptly treated, respiratory failure can rapidly deteriorate to respiratory arrest. In respiratory arrest, the patient is no longer breathing; he or she is apneic (cessation of breathing). Patients with respiratory arrest need immediate artificial ventilation; otherwise, cellular death will occur and cause cardiopulmonary arrest.

15. Was your patient experiencing respiratory failure or respiratory arrest?

Initially, the patient was experiencing respiratory distress; however, his condition deteriorated to respiratory failure. This was evidenced by a decrease in his level of consciousness, slowing of his respirations, and falling oxygen saturation. Because he was treated promptly and appropriately, he never experienced respiratory arrest (he never stopped spontaneously breathing).

Narrative

9-1-1 dispatch for a male patient with "breathing problems." Arrived on scene to find the patient, a 55-year-old man, in obvious respiratory distress. He was conscious, but appeared sleepy. Skin was cool, pale, and moist. Began assisting patient's breathing with a BVM and high-flow oxygen secondary to poor respiratory effort and signs of hypoxemia. Vital signs obtained and noted above. According to the patient's wife, he began reporting shortness of breath the day before, but it worsened today. His past medical history is significant for CHF and HTN. As preparations were being made to transport, reassessment revealed that patient's LOC had markedly decreased (responsive only to pain), his respiratory rate (unassisted) had decreased, his oxygen saturation decreased, and cyanosis to his facial area developed. Manually opened airway, inserted nasal airway device, and continued to assist breathing. Began transport to emergency department and continued treatment en route. Assessment of assisted ventilation revealed that breath sounds were audible bilaterally with a stethoscope and chest rise was visible with each ventilation. On arrival at the emergency department, the patient's LOC had improved; he was conscious and responded to verbal stimuli, and his oxygen saturation and skin condition had markedly improved. Patient was resistant to assisted ventilation; therefore, high-flow oxygen was continued via nonrebreathing mask. Delivered patient to hospital staff and gave verbal report to attending physician.**End of report**

Prep Kit

Ready for Review

- The upper airway includes the nose, mouth, jaw, oral cavity, pharynx, and larynx. Its function is to warm, filter, and humidify air as it enters the nose and mouth.
- The lower airway includes the trachea and lungs and its function is to exchange oxygen and carbon dioxide.
- Adequate breathing for an adult features a normal rate of 12 to 20 breaths/min, a regular pattern of inhalation and exhalation, adequate depth, bilaterally clear and equal lung sounds, and regular and equal chest rise and fall.
- Inadequate breathing for an adult features a respiratory rate of fewer than 12 breaths/min or more than 20 breaths/min, shallow depth (reduced tidal volume), an irregular pattern of inhalation and exhalation, and breath sounds that are diminished, absent, or noisy.
- Patients who are breathing inadequately show signs of hypoxia, a dangerous condition in which the body's tissues and cells do not have enough oxygen.
- Patients with inadequate breathing need to be treated immediately. Emergency medical care includes airway management, supplemental oxygen, and ventilatory support.
- Basic techniques for opening the airway include the head tilt–chin lift maneuver or, if trauma is suspected, the jaw-thrust maneuver.
- One basic airway adjunct is the oropharyngeal or oral airway, which keeps the tongue from blocking the airway in unconscious patients with no gag reflex. If the oral airway is not the proper size or is inserted incorrectly, it can actually cause an obstruction.
- Another basic airway adjunct is the nasopharyngeal or nasal airway, which is usually used with patients who have a gag reflex and is better tolerated than the oral airway.
- Suctioning is the next priority after opening the airway. Rigid tonsil-tip catheters are the best catheters to use when suctioning the pharynx; soft plastic catheters are used to suction the nose and liquid secretions in the back of the mouth.
- The recovery position is used to help maintain the airway in patients without traumatic injuries who are unconscious and breathing adequately.
- You must provide immediate artificial ventilations with supplemental oxygen to patients who are not breathing on their own. Patients with inadequate breathing may also require artificial ventilations to maintain effective tidal volume.
- Excessive supplemental oxygen can have a detrimental effect on patients with certain illnesses. Patients who require oxygen include: (1) patients with signs of dyspnea, (2) patients with signs of shock, and (3) patients experiencing signs of a myocardial infarction with an oxygen saturation level equal to or lower than 94%. Use pulse oximetry, when available, to tailor oxygen administration to the patient's needs.
- Handle compressed gas cylinders carefully; their contents are under pressure. Always make sure the correct pressure regulator is firmly attached before transporting a cylinder. The pin-indexing safety system features a series of pins on a yoke that must be matched with the holes on the valve stem of the gas cylinder. Pressure regulators reduce the pressure of gas in an oxygen cylinder to between 40 and 70 psi. Pressure-compensated flowmeters and Bourdon-gauge flowmeters permit the regulated release of gas measured in liters per minute.
- When oxygen therapy is complete, disconnect the tubing from the flowmeter nipple and turn off the cylinder valve, then turn off the flowmeter. As long as there is a pressure reading on the regulator gauge, it is not safe to remove the regulator from the valve stem. Keep any possible source of fire away from the area while oxygen is in use.
- Nasal cannulas and nonrebreathing masks are used most often to deliver oxygen in the field. The nonrebreathing mask is the delivery device of choice for providing supplemental oxygen to patients who are breathing adequately but are suspected of having or are showing signs of hypoxia. With a flow rate set at 15 L/min and the reservoir bag preinflated, the nonrebreathing mask can provide more than 90% inspired oxygen. If the patient will not tolerate a nonrebreathing mask, apply a nasal cannula.
- The methods of providing artificial ventilation include mouth-to-mask ventilation, two-person BVM ventilation, a manually triggered ventilation device, and one-person BVM ventilation. The manually triggered ventilation device is not a recommended ventilation device by most standards. Combined with your own exhaled breath, mouth-to-mask ventilation will give your patient up to 55% oxygen; a BVM with an oxygen reservoir and supplemental oxygen can deliver nearly 100% oxygen.
- CPAP is a noninvasive method of providing ventilatory support for patients in respiratory distress or suffering from sleep apnea.
- When you are providing artificial ventilation, remember that ventilating too forcefully can cause gastric distention. Slow, gentle breaths during artificial ventilation can help to prevent gastric distention. Patients who have a tracheal stoma or a tracheostomy tube need to be ventilated through the tube or the stoma.
- Foreign body airway obstruction usually occurs during a meal in an adult or while a child is eating, playing with small objects, or crawling about the house. The earlier you recognize an airway obstruction, the better. You must learn to

recognize the difference between airway obstruction caused by a foreign object and that caused by a medical condition.

- Foreign body airway obstructions are classified as being mild or severe. Patients with a mild airway obstruction are able to move adequate amounts of air and should be left alone. Patients with a severe airway obstruction cannot move any air at all and require immediate treatment. Perform abdominal thrusts on conscious adults and children with a severe airway obstruction. If the patient becomes unconscious, open the airway and look in the mouth (do not perform blind finger sweeps), attempt to ventilate the patient, and perform chest compressions if ventilations are unsuccessful.
- Check for loose dental appliances in a patient before assisting ventilations. Loose appliances should be removed to prevent them from obstructing the airway. Tight-fitting appliances should be left in place.

Vital Vocabulary

aerobic metabolism Metabolism that can proceed only in the presence of oxygen.

agonal gasps Occasional, gasping breaths that occur after the heart has stopped.

airway The upper airway tract or the passage above the larynx, which includes the nose, mouth, and throat.

alveolar minute volume The volume of air moved through the lungs in 1 minute minus the dead space; calculated by multiplying tidal volume (minus dead space) and respiratory rate.

alveolar ventilation The volume of air that reaches the alveoli. It is determined by subtracting the amount of dead space air from the tidal volume.

American Standard Safety System A safety system for large oxygen cylinders, designed to prevent the accidental attachment of a regulator to a cylinder containing the wrong type of gas.

anaerobic metabolism The metabolism that takes place in the absence of oxygen; the principal product is lactic acid.

apnea Absence of spontaneous breathing.

aspiration In the context of airway, the introduction of vomitus or other foreign material into the lungs.

ataxic respirations Irregular, ineffective respirations that may or may not have an identifiable pattern.

automatic transport ventilator (ATV) A ventilation device attached to a control box that allows the variables of ventilation to be set. It frees the EMT to perform other tasks while the patient is being ventilated.

bag-valve mask (BVM) A device with a one-way valve and a face mask attached to a ventilation bag; when attached to a reservoir and connected to oxygen, it delivers more than 90% supplemental oxygen.

barrier device A protective item, such as a pocket mask with a valve, that limits exposure to a patient's body fluids.

bilateral A body part or condition that appears on both sides of the midline.

bronchioles Subdivision of the smaller bronchi in the lungs; made of smooth muscle and dilate or constrict in response to various stimuli.

capnography A noninvasive method to quickly and efficiently provide information on a patient's ventilatory status, circulation, and metabolism. Effectively measures the concentration of carbon dioxide in expired air over time.

capnometry The use of a capnometer, a device that measures the amount of expired carbon dioxide.

carina Point at which the trachea bifurcates (divides) into the left and right mainstem bronchi.

chemoreceptors Monitor the levels of O_2, CO_2, and the pH of the cerebrospinal fluid and then provide feedback to the respiratory centers to modify the rate and depth of breathing based on the body's needs at any given time.

compliance The ability of the alveoli to expand when air is drawn in during inhalation.

continuous positive airway pressure (CPAP) A method of ventilation used primarily in the treatment of critically ill patients with respiratory distress; can prevent the need for endotracheal intubation.

dead space The portion of the tidal volume that does not reach the alveoli and thus does not participate in gas exchange.

diffusion A process in which molecules move from an area of higher concentration to an area of lower concentration.

dyspnea Shortness of breath.

end-tidal CO_2 The amount of carbon dioxide present at the end of an exhaled breath.

exhalation The passive part of the breathing process in which the diaphragm and the intercostal muscles relax, forcing air out of the lungs.

external respiration The exchange of gases between the lungs and the blood cells in the pulmonary capillaries; also called pulmonary respiration.

gag reflex A normal reflex mechanism that causes retching; activated by touching the soft palate or the back of the throat.

gastric distention A condition in which air fills the stomach, often as a result of high volume and pressure during artificial ventilation.

glottis The space in between the vocal cords that is the narrowest portion of the adult's airway; also called the glottic opening.

good air exchange A term used to distinguish the degree of distress in a patient with a mild airway obstruction. With good air exchange, the patient is still conscious and able to cough forcefully, although wheezing may be heard.

head tilt–chin lift maneuver A combination of two movements to open the airway by tilting the forehead back and lifting the chin; not used for trauma patients.

hypercarbia Increased carbon dioxide level in the bloodstream.

hypoxia A dangerous condition in which the body tissues and cells do not have enough oxygen.

hypoxic drive A condition in which chronically low levels of oxygen in the blood stimulate the respiratory drive; seen in patients with chronic lung diseases.

inhalation The active, muscular part of breathing that draws air into the airway and lungs.

internal respiration The exchange of gases between the blood cells and the tissues.

intrapulmonary shunting Bypassing of oxygen-poor blood past nonfunctional alveoli to the left side of the heart.

jaw-thrust maneuver Technique to open the airway by placing the fingers behind the angle of the jaw and bringing the jaw forward; used for patients who may have a cervical spine injury.

labored breathing Breathing that requires greater than normal effort; may be slower or faster than normal and usually requires the use of accessory muscles.

larynx A complex structure formed by many independent cartilaginous structures that all work together; where the upper airway ends and the lower airway begins; also called the voice box.

manually triggered ventilation device A fixed flow rate ventilation device that delivers a breath every time its button is pushed; also referred to as a flow-restricted, oxygen-powered ventilation device.

mediastinum Space within the chest that contains the heart, major blood vessels, vagus nerve, trachea, major bronchi, and esophagus; located between the two lungs.

metabolism (cellular respiration) The biochemical processes that result in production of energy from nutrients within the cells.

mild airway obstruction Occurs when a foreign body partially obstructs the patient's airway. The patient is able to move adequate amounts of air, but also experiences some degree of respiratory distress.

minute volume The volume of air moved through the lungs in 1 minute; calculated by multiplying tidal volume and respiratory rate; also referred to as minute ventilation.

nasal cannula An oxygen-delivery device in which oxygen flows through two small, tubelike prongs that fit into the patient's nostrils; delivers 24% to 44% supplemental oxygen, depending on the flow rate.

nasopharyngeal (nasal) airway Airway adjunct inserted into the nostril of an unresponsive patient or a patient with an altered level of consciousness who is unable to maintain airway patency independently.

nasopharynx The nasal cavity; formed by the union of facial bones and protects the respiratory tract from contaminants.

nonrebreathing mask A combination mask and reservoir bag system that is the preferred way to give oxygen in the prehospital setting; delivers up to 90% inspired oxygen and prevents inhaling the exhaled gases (carbon dioxide).

oropharyngeal (oral) airway Airway adjunct inserted into the mouth of an unresponsive patient to keep the tongue from blocking the upper airway and to facilitate suctioning the airway, if necessary.

oropharynx Forms the posterior portion of the oral cavity, which is bordered superiorly by the hard and soft palates, laterally by the cheeks, and inferiorly by the tongue.

oxygenation The process of delivering oxygen to the blood by diffusion from the alveoli following inhalation into the lungs.

oxygen toxicity A condition of excessive oxygen consumption resulting in cellular and tissue damage.

parietal pleura Thin membrane that lines the chest cavity.

partial pressure The term used to describe the amount of gas in air or dissolved in fluid, such as blood.

passive ventilation The act of air moving in and out of the lungs during chest compressions.

patent Open, clear of obstruction.

phrenic nerve Nerve that innervates the diaphragm; necessary for adequate breathing to occur.

pin-indexing system A system established for portable cylinders to ensure that a regulator is not connected to a cylinder containing the wrong type of gas.

pneumothorax A partial or complete accumulation of air in the pleural space.

poor air exchange A term used to describe the degree of distress in a patient with a mild airway obstruction. With poor air exchange, the patient often has a weak, ineffective cough, increased difficulty breathing, or possible cyanosis and may produce a high-pitched noise during inhalation (stridor).

pulse oximetry An assessment tool that measures oxygen saturation of hemoglobin in the capillary beds.

recovery position A side-lying position used to maintain a clear airway in unconscious patients without injuries who are breathing adequately.

residual volume The air that remains in the lungs after maximal expiration.

respiration The process of exchanging oxygen and carbon dioxide.

retractions Movements in which the skin pulls in around the ribs during inspiration.

severe airway obstruction Occurs when a foreign body completely obstructs the patient's airway. The patient cannot breathe, talk, or cough.

stoma An opening through the skin and into an organ or other structure; a stoma in the neck connects the trachea directly to the skin.

stridor A high-pitched noise heard primarily on inspiration.

suction catheter A hollow, cylindrical device used to remove fluid from the patient's airway.

surfactant A liquid protein substance that coats the alveoli in the lungs, decreases alveolar surface tension, and keeps the alveoli expanded; a low level in a premature infant contributes to respiratory distress syndrome.

tension pneumothorax A life-threatening collection of air within the pleural space; the volume and pressure have both collapsed the involved lung and caused a shift of the mediastinal structures to the opposite side.

tidal volume The amount of air (in mL) that is moved in or out of the lungs during one breath.

tonsil tips Large, semirigid suction tips recommended for suctioning the pharynx; also called Yankauer tips.

tracheostomy Surgical opening into the trachea.

ventilation Exchange of air between the lungs and the environment, spontaneously by the patient or with assistance from another person, such as an EMT.

visceral pleura Thin membrane that covers the lungs.

vital capacity The amount of air that can be forcibly expelled from the lungs after breathing in as deeply as possible.

vocal cords Thin white bands of tough muscular tissue that are lateral borders of the glottis and serve as the primary center for speech production.

wheezing The production of whistling sounds during expiration such as occurs in asthma and bronchiolitis.

Assessment *in Action*

You and your partner arrive at a local restaurant where you find an unresponsive 62-year-old man lying on the floor. Witnesses report the patient collapsed to the ground without any warning. You perform a primary assessment and note the patient has a carotid pulse, but is unresponsive and not breathing. He appears cyanotic and there are no signs of traumatic injury.

1. What is the first intervention that should take place?

   A. Apply oxygen with a nonrebreathing mask and assess vital signs.
   B. Prepare for immediate transport to a hospital.
   C. Insert an oral airway and begin ventilations with a BVM.
   D. Check the patient for any medical alert tags.

2. You attempt to ventilate the patient with a BVM and notice resistance. The chest does not rise during your ventilation. What should you do?

   A. Reposition the airway by hyperextending the head to allow for better anatomic position, then attempt to ventilate.
   B. Assume there is a foreign body airway obstruction and immediately begin chest compressions.
   C. Assume there is a foreign body airway obstruction and provide forceful ventilations.
   D. Reposition the airway by bringing the head back to a neutral position, then reopen the airway and attempt to ventilate.

3. Which of the following indicates that your artificial ventilations are inadequate?

   A. Minimal or no chest rise and fall
   B. Increased levels on pulse oximetry

C. Heart rate returning to normal range
D. Warm, pink skin

4. How can gastric distention be prevented when performing artificial ventilations?

   A. Provide rapid, forceful breaths during artificial ventilation over 1 second.
   B. Provide slow, gentle breaths during artificial ventilation over 1 second.
   C. Provide rapid, forceful breaths during artificial ventilation over 3 seconds.
   D. Provide slow, gentle breaths during artificial ventilation over 3 seconds.

5. Which of the following is contraindicated in a patient who has sustained a head injury?

   A. Insertion of an oral airway
   B. Jaw-thrust maneuver
   C. Mouth-to-mask ventilation
   D. Insertion of a nasal airway

6. While you are performing artificial ventilations on this patient, he vomits. What should you do?

   A. Roll the patient onto his side to allow for drainage of emesis.
   B. Continue ventilations with increased force to prevent aspiration.
   C. Immediately stop ventilations and begin chest compressions.
   D. Stop ventilations and wait for advanced life support to arrive.

7. Your partner applies a pulse oximeter to the patient. While ventilating, you note adequate chest rise and fall and improved skin color; however, the oxygen saturation reads 88%. Which of the following is a potential cause of an inaccurate pulse oximetry reading?

   A. Hypertension
   B. Peripheral vasoconstriction
   C. Jaundice
   D. Diabetes

8. Explain the effects of hypoxia on cellular metabolism.

9. You are providing artificial ventilations to your patient with a BVM attached to oxygen. What is the difference between ventilation and oxygenation?

10. While en route to the hospital, the patient begins shallow breathing at a rate of 6 breaths/min. He remains unresponsive. What should you do?

Pharmacology

11 Principles of Pharmacology

CHAPTER 11

Principles of Pharmacology

National EMS Education Standard Competencies

Pharmacology

Applies fundamental knowledge of the medications that the EMT may assist/administer to a patient during an emergency.

Principles of Pharmacology

› Medication safety (pp 461–463)
› Kinds of medications used during an emergency (pp 464–475)

Medication Administration

› Self-administer medication (pp 463–464)
› Peer-administer medication (pp 463–464)
› Assist/administer medications to a patient (pp 463–464)

Emergency Medications

› Names (p 456)
› Effects (pp 455–456)
› Actions (p 455)
› Indications (p 456)
› Contraindications (p 456)
› Complications (p 456)
› Routes of administration (pp 456–458)
› Side effects (p 456)
› Interactions (pp 465–466, 475–476)
› Dosages for the medications administered (pp 455, 462, 465–466)

Knowledge Objectives

1. Define the terms pharmacodynamics, therapeutic effects, indications, side effects, unintended effects, and untoward effects. (pp 455–456)
2. Explain medication contraindications; include an example. (p 456)
3. Explain the differences between a generic medication name and a trade medication name; provide an example of each. (p 456)
4. Differentiate enteral and parenteral routes of medication administration. (p 456)
5. Describe rectal, oral, intravenous, intraosseous, subcutaneous, intramuscular, inhalation, sublingual, and transcutaneous routes of medication administration; include the rates of absorption. (pp 457–458)
6. Explain the solid, liquid, and gas forms of medication and the routes of administration; provide examples of each. (pp 459–461)
7. List the "six rights" of medication administration; include how each one relates to EMS. (pp 461–463)
8. Explain the difference between direct orders (online) and standing orders (off-line) and the role of medical control. (p 463)
9. Discuss the medication administration circumstances involving peer-assisted medication, patient-assisted medication, and EMT-administered medication. (pp 463–464)
10. Know the generic and trade names, actions, indications, contraindications, routes of administration, side effects, interactions, and doses of 10 medications that may be administered by an EMT in an emergency as dictated by state protocols and local medical direction. (pp 463–475)
11. Describe the medication administration considerations related to special populations, including pediatric, geriatric, and pregnant patients. (pp 464, 472–473)
12. State the steps to follow when dispensing medications to a patient using an auto-injector. (p 471)
13. Explain why determining what prescription and over-the-counter medications a patient is taking is a critical aspect of patient assessment during an emergency. (pp 475–476)
14. State the steps to take if a medication error occurs. (p 477)

Skills Objectives

1. Apply the six rights of medication administration. (pp 461–463)
2. Demonstrate how to administer oral medication to a patient. (pp 464, 467–468)
3. Demonstrate how to administer aspirin to a patient with chest pain. (p 468)
4. Demonstrate how to administer oral glucose to a patient with hypoglycemia. (p 468)
5. Demonstrate how to assist a patient with the sublingual administration of a medication. (p 468)
6. Demonstrate how to administer a medication by auto-injector. (p 471)
7. Demonstrate how to administer an intranasal medication. (pp 471–472)

Introduction

Medications are an important intervention available to you as an EMT. You must understand the medications within your scope of practice, just as paramedics and nurses must understand the medications they administer. Used appropriately, a medication may alleviate pain and improve a patient's condition. Failure to administer medications safely and competently can lead to serious consequences for the patient, including death. Therefore, it is essential that you have the knowledge and skills to administer or assist in administration of these medications.

This chapter describes the various forms of medications, the different ways in which they can be administered, and how they work. It then takes a close look at each of the seven forms of medications you may be asked to administer or help patients to self-administer. It will also explain when it is dangerous to administer these medications.

How Medications Work

Pharmacology is the science of drugs, including their ingredients, preparation, uses, and actions on the body. Although the terms *drugs* and *medications* are often used interchangeably, the term drugs may make some people think of narcotics or illegal substances. For this reason, you should use the word *medications*, especially when interviewing patients and families. In general terms, a **medication** is a substance that is used to treat or prevent disease or relieve pain.

Pharmacodynamics is the process by which a medication works on the body. Different types of receptors are located throughout the body. Receptors are sites on cells where medications or chemicals produced in the body can bind and produce an effect. When medications are given, they bind to these sites and either stimulate the receptors to produce an effect or block the receptors to prevent other chemicals or medications from binding. Thus, a medication can either increase or decrease a normal function of the body. Medications that cause stimulation of receptors are called **agonists**. Medications that bind to a receptor and block other medications or chemicals from attaching are called **antagonists**, or blockers.

Words of Wisdom

It is important for you to become familiar with the "street" names of commonly used and abused drugs. Most users will not tell you they took methylenedioxy-methamphetamine; most likely you will hear terms like ecstasy, XTC, Molly, rolling, or popping. Research these street names using a reliable source, such as the National Institutes of Health (NIH) or the Centers for Disease Control and Prevention (CDC).

The **dose** is the amount of the medication that is given. The dose often depends on the patient's weight or age. The dose also depends on the desired action of the medication. The **action** is the intended **therapeutic effect** that a medication is expected to have on the body. The therapeutic effect is also referred to as the desired or intended effect. These factors, among others, can help to explain why one dose of medication works quickly and efficiently on one patient and the same dose has little effect on another patient. Doses of medications may need to be decreased for infants because they have small bodies. Doses may also need to be decreased for older adults because they cannot process medications as efficiently as younger people.

YOU are the Provider — PART 1

You and your partner are dispatched to a residence at 4864 Project Avenue for an older woman with "diabetic problems." The time is 0600 hours, the weather is clear, the traffic is light, and your response time to the scene is approximately 5 minutes.

1. What is pharmacology?
2. Why is knowledge of pharmacology important to patient care?

Indications are the reasons or conditions for which a particular medication is given. For example, nitroglycerin relaxes the walls of all blood vessels, both veins and arteries. This increases the blood flow and the supply of oxygen to the heart muscle. In this way, nitroglycerin may relieve the discomfort that can occur with the cardiac condition called angina. Therefore, nitroglycerin is indicated for chest pain associated with angina.

There are times when you should not give a medication, even if it usually is indicated for that person's condition. Such situations are called **contraindications**. A medication is contraindicated when it would harm the patient or have no positive effect on the patient's condition. For example, the administration of activated charcoal may be indicated when a patient has swallowed a poison. Generally, activated charcoal, premixed with water, is used to prevent the body from absorbing a poison. However, activated charcoal would be contraindicated if the patient were unconscious and could not swallow. Some contraindications are "absolute," meaning the medication should never be given if the contraindication is present. For example, severe hypotension is an absolute contraindication for nitroglycerin. Some contraindications are "relative," meaning the benefits of administering the drug may outweigh the risks. For example, glaucoma (a condition of increased pressure within the eye) is a relative contraindication for many drugs. Consider a patient with anaphylaxis and a history of glaucoma. It would likely be more dangerous to withhold epinephrine from this patient than to administer it.

Side effects are any actions of a medication other than the desired ones. There are two types of side effects: unintended effects and untoward effects. **Unintended effects** are the effects that are undesirable but pose little risk to the patient, such as a slight headache after taking nitroglycerin. **Untoward effects** are the effects that can be harmful to the patient, such as hypotension after taking nitroglycerin.

Consider diphenhydramine (Benadryl). People take this medication for allergic reactions (indication). The medication is supposed to block the effects of histamine (intended effect). Its side effects include dry mouth and drowsiness (unintended effect) and it can increase the pressure of the fluid within the eye (untoward effect). Asthma is a relative contraindication for diphenhydramine because it can worsen lower airway constriction.

Medication Names

Medications usually have two names. The **generic name** (such as ibuprofen) is a simple, clear, nonproprietary name. The generic name is not capitalized. Sometimes a medication is called by its generic name more often than by any of its trade names. For example, you may hear "nitroglycerin" used more often than the trade names Nitromist and Nitrostat. All medications that are licensed for use in the United States are listed by their generic names in the *United States Pharmacopoeia and the National Formulary (USP-NF)*.

A **trade name** is the brand name that a manufacturer gives to a medication, such as Tylenol (acetaminophen). As a proper noun, a trade name begins with a capital letter. Trade names are used in every aspect of our daily lives, not just in medications. Well-known examples include Jell-O, Band-Aid, Kleenex, and Coke. A medication may have many different trade names, depending on how many companies manufacture it. Advil, Nuprin, and Motrin all are trade names for the generic medication ibuprofen. A trade name sometimes is also designated by a raised registered symbol; that is, Advil®.

Medications may be **prescription medications** or **over-the-counter (OTC) medications**. Prescription medications are distributed to patients only by pharmacists according to a physician's order. OTC medications may be purchased directly, without a prescription. In recent years, many medications previously available only by prescription have become available in OTC form, such as Nasacort, Nexium, and Flonase.

You may come into contact with patients who have taken recreational drugs such as heroin or cocaine. Other patients may take herbal remedies, enhancement drugs, vitamin supplements, or alternative medicines. As we have discussed, the body's cells are configured to operate using chemical reactions; they cannot discern between safe and unsafe pharmacologic agents. Any medication that a patient takes can be pharmacologically active and can cause an effect. As an EMT, you need to ask patients about any and all medications they take.

Routes of Administration

Medications can enter the body through a variety of routes. To simplify this topic, the routes of medication administration are divided into two categories: enteral and parenteral. **Enteral medications** enter the body through the digestive system. Typically, the form of the medication will be a pill or a liquid such as cough medicine. Medications administered via this route tend to absorb slowly and are therefore not commonly used in an emergency setting. **Parenteral medications** enter the body by a route other than the digestive tract, the skin, or the mucous membranes. Parenteral medications are often in a liquid form and are generally administered using syringes and needles. These medications are absorbed much more quickly and offer a more predictable and measurable response.

Regardless of the route of administration of a medication, the end goal is to get that medication into the bloodstream. **Absorption** is the process by which medications travel through body tissues until they reach the bloodstream. Often the rate at which a medication is absorbed into the bloodstream depends on its route of administration. **Table 11-1** lists common routes of medication administration and rates of absorption.

- **Per rectum (PR)**. Per rectum means by rectum. This route of delivery is most commonly used with children because of easier administration and more reliable absorption. (Children often regurgitate some or all of a medication.) For similar reasons, many medications that are used for nausea and vomiting come in a rectal suppository form. Some medications to control seizures are administered PR when it is impossible to administer them intravenously. The PR route also is used to give some medications when the patient cannot swallow or is unconscious.
- **Oral**. Many medications are taken by mouth, or **per os (PO)**, and enter the bloodstream through the digestive system. This process often takes as long as 1 hour. One of the advantages of using this route is that it is noninvasive. Patients are often much happier to take a pill than to have a needle stuck in them. It is also less expensive to use enteral medications than to use parenteral. The main disadvantage of this administration route is the unpredictability of medication absorption. If the patient has vomiting or diarrhea, the amount of medication that is absorbed will be altered. Some medications, referred to as orally disintegrating tablets (ODTs), are put directly onto the tongue, where they dissolve. This is an alternative administration form for patients who may have difficulty swallowing. Some forms of medications are adversely affected by stomach acids, so dissolving them directly on the tongue avoids breakdown by gastric acids. An example of this type of medication is ondansetron (Zofran), which is used to treat nausea and vomiting.

Table 11-1 Routes of Administration and Rates of Absorption

Route	Rate
Enteral	
Sublingual (SL)	Rapid
Per rectum (PR)	Rapid
By mouth (PO)	Slow
Parenteral	
Intravenous (IV)	Immediate
Intraosseous (IO)	Immediate
Inhalation	Rapid
Intranasal (IN)	Rapid
Intramuscular (IM)	Moderate
Subcutaneous (SC)	Slow
Transcutaneous	Slow

- **Intravenous (IV) injection**. Intravenous means into the vein. Medications that need to enter the bloodstream immediately may be injected directly into a vein. This is the fastest way to deliver a chemical substance, but the IV route cannot be used for all chemicals. For example, aspirin, oxygen, and charcoal cannot be given by the IV route.
- **Intraosseous (IO) injection**. Intraosseous means into the bone. Medications that are given by this route reach the bloodstream through the bone marrow. Giving a medication by the IO route, into the marrow, requires drilling a needle into the outer layer of the bone. Because this is painful, the IO route is used most often in patients who are unconscious as a result of cardiac arrest or extreme shock. Often, the IO route is used for children who have fewer available (or difficult to access) IV sites.
- **Subcutaneous (SC) injection**. Subcutaneous means under the skin. A SC injection is given into the fatty tissue between the skin and the muscle. Because there is less blood here than in the muscles, medications that are given by this route are generally absorbed more slowly, and their effects last longer. A SC injection is a useful way to give medications that cannot be taken by mouth, as long as they do not irritate or damage the tissue. Daily insulin injections for patients with

diabetes are given by the SC route. Some forms of epinephrine can be given by the SC route.

- **Intramuscular (IM) injection**. Intramuscular means into the muscle. Usually, medications that are administered by IM injection are absorbed quickly because muscles have a lot of blood vessels. However, not all medications can be administered by the IM route. Possible problems with IM injections are damage to muscle tissue and uneven, unreliable absorption, especially in people with decreased tissue perfusion or who are in shock.

  You will typically use the IM route of medication administration with an auto-injector. These devices deliver a predetermined amount of medication into the patient when pressed firmly into the thigh. Examples of this delivery method would be the EpiPen auto-injector, which is used for anaphylactic reactions (see Chapter 20, *Immunologic Emergencies*), and the DuoDote Auto-Injector or the Antidote Treatment-Nerve Agent Auto-Injector (ATNAA), which are used for nerve agent exposure (see Chapter 40, *Terrorism Response and Disaster Management*).
- **Inhalation**. Some medications are inhaled into the lungs so that they can be absorbed into the bloodstream more quickly. Others are inhaled because they work in the lungs. Generally, inhalation helps minimize the effects of the medication in other body tissues. Such medications come in the form of aerosols, fine powders, and sprays.
- **Sublingual (SL)**. Sublingual means under the tongue. Medications given by the SL route, such as nitroglycerin tablets, enter through the oral mucosa under the tongue and are absorbed into the bloodstream within minutes. This route is faster than the oral route, and it protects medications from chemicals in the digestive system, such as acids that can weaken or inactivate them.
- **Transcutaneous (transdermal)**. Transcutaneous means through the skin. Some medications can be absorbed transcutaneously, such as the nicotine in patches used by people who are trying to quit smoking. On occasion, a medication that also comes in another form is administered transcutaneously to achieve a longer-lasting effect. An example is an adhesive patch containing nitroglycerin.
- **Intranasal (IN)**. Intranasal is a relatively new format for the delivery of some medications. In this route a liquid medication is pushed through a specialized device called a **mucosal atomizer device (MAD)**. The liquid medication is aerosolized and is administered into a nostril. The head and face are very vascular; therefore, absorption is rather quick with this route. The flu vaccine and naloxone (Narcan), a reversal agent for opioid overdose that will be discussed later in this chapter, are examples of medications that can be administered intranasally.

Table 11-2 lists the words that are used for routes of medication delivery, along with their meanings.

Table 11-2 Routes of Administration: Words and Their Meanings

This Word...	From These Latin Words...	Means
Inhalation	*inhalatio* (drawing air into the lungs)	inhaling or breathing in
Intramuscular (IM)	*intra* (into) and *muscularis* (of the muscles)	into muscle
Intraosseous (IO)	*intra* (into) and *osse* (bone)	into bone
Intravenous (IV)	*intra* (into) and *venosus* (of the veins)	into vein
Per os (PO)	*per* (by) and *os* (mouth)	by mouth
Per rectum (PR)	*per* (by) and *rectum* (rectum)	by rectum
Subcutaneous (SC)	*sub* (under) and *cutis* (skin)	under the skin
Sublingual (SL)	*sub* (under) and *lingua* (relating to the tongue)	under the tongue
Transcutaneous (transdermal)	*trans* (through) and *cutis* (skin)	through the skin
Intranasal	*intra* (into) and *nasal* (nose)	into the nose

Safety Tips

Make absolutely certain you follow standard precautions when administering any medication, particularly topical drugs. If the medication can be absorbed into the patient's skin, it can be absorbed into yours as well.

Medication Forms

The form of a medication usually dictates the route of administration. For example, a tablet or a spray cannot be given through a needle. The manufacturer chooses the form to ensure the proper route of administration, the timing of its release into the bloodstream, and its effects on the target organs or body systems. As an EMT, you should be familiar with the following seven medication forms.

Tablets and Capsules

Most medications that are given by mouth to adult patients are in tablet or capsule form. Capsules are gelatin shells filled with powdered or liquid medication. If the capsule contains liquid, the shell is sealed and usually soft. If the capsule contains powder, the shell can usually be pulled apart. In tablets, the medication is compressed under high pressure. Tablets often contain other materials that are mixed with the medication.

Some tablets are designed to dissolve very quickly in small amounts of liquid so that they can be given sublingually (under the tongue) and absorbed rapidly. An example is the sublingual nitroglycerin tablet used to treat chest pain in patients with cardiac conditions. These medications are especially useful in emergency situations, because medications that must be swallowed and then digested provide a slower route of delivery. For example, an oral pain medication is less useful than an IV pain medication when pain relief is needed immediately.

Solutions and Suspensions

A **solution** is a liquid mixture of one or more substances that cannot be separated by filtering or allowing the mixture to stand. Solutions can be given by almost any route. When given by mouth, solutions may be absorbed from the stomach fairly quickly because the medication is already dissolved. Many solutions can be given as an IV, IM, or SC injection. If a patient has an anaphylactic reaction, you may help him or her to self-administer a solution of epinephrine using an auto-injector (EpiPen).

YOU are the Provider — PART 2

You arrive at the scene and find the patient, a 68-year-old woman, sitting in a recliner in her living room. Her son, who called 9-1-1, tells you that she is not "acting right." He also tells you that she has taken her medications today, but is not sure when she last ate. You assess the patient as your partner opens the jump kit and prepares to begin treatment.

Recording Time: 0 Minutes	
Appearance	Confused; diaphoretic; pale
Level of consciousness	Conscious but confused
Airway	Open; clear of secretions or foreign bodies
Breathing	Increased rate; shallow depth
Circulation	Radial pulses, rapid and weak; skin, pale and diaphoretic

As your partner gives the patient high-flow oxygen via nonrebreathing mask, her son tells you that she has diabetes, heart disease, and depression. Her medication list includes eight different prescription medications, including glimepiride (Amaryl), nitroglycerin (Nitrostat), and sertraline (Zoloft). You assess her blood glucose level, which reads 36 mg/dL. The patient is disoriented to place and time but able to speak and follow simple commands.

3. Other than oxygen, what other medication does this patient require, and why?
4. What are the "six rights" of medication administration and why are they important?
5. Why is it significant to know the patient took her medications on an empty stomach?

Many substances do not dissolve well in liquids. Some of these can be ground into fine particles and evenly distributed throughout a liquid by shaking or stirring. This type of mixture is called a **suspension**. An example is activated charcoal, which you may give to patients who have taken overdoses of certain medications or ingested certain poisons.

Suspensions separate if they stand or are filtered. It is very important that you shake or swirl a suspension before administering it to ensure that the patient receives the right amount of medication. For example, if you are a parent, you may have had to shake a suspension of oral antibiotic before giving it to your child.

Suspensions usually are administered by mouth but sometimes are given rectally. Occasionally, suspensions are applied directly to the skin to treat skin problems. You may have used calamine lotion in this way. Injectable suspensions are given via IM or SC injection only. Certain hormone shots or vaccinations are given this way because of the suspended particles. They cannot be given by IV injection because the suspended particles do not remain dissolved.

Metered-Dose Inhalers

If liquids or solids are broken into small enough droplets or particles, they can be inhaled. A **metered-dose inhaler (MDI)** is a miniature spray canister used to direct such substances through the mouth and into the lungs **Figure 11-1** and is often used by a patient with a respiratory illness such as asthma or emphysema. An MDI delivers the same amount of medication each time it is used. Because an inhaled medication usually is suspended in a propellant, the MDI must be shaken vigorously before the medication is administered. Many patients who use MDI medications also self-administer medications with a nebulizer. Use of MDIs and nebulizers will be discussed later in this chapter.

Topical Medications

Lotions, creams, and ointments are **topical medications**; that is, they are applied to the surface of the skin and affect only that area. Lotions contain the most water, and ointments contain the least. Lotions (such as calamine lotion) are absorbed the most rapidly, and ointments (such as triple antibiotic ointment [Neosporin]) the most slowly. Hydrocortisone cream, to diminish skin itching, is an example of a medical cream that can also be given in ointment form.

Figure 11-1 Some medications are inhaled into the lungs with a metered-dose inhaler so that they can be absorbed into the bloodstream near the site of desired action more quickly.

Transcutaneous Medications

Transdermal medications are designed to be absorbed through the skin, or transcutaneously. Medications such as nitroglycerin paste usually have properties or delivery systems that help to dilate the blood vessels in the skin and, thus, speed absorption into the bloodstream. In contrast with most topical medicines, which work directly on the application site, transdermal medications are usually intended for systemic (whole-body) effects. A note of caution: If you touch such a medication with your bare skin while administering it, you will absorb it just as readily as the patient will. This can be very dangerous. For example, if you absorb nitroglycerin paste, your blood pressure may drop and cause you to faint while driving the ambulance to the hospital.

One delivery system for transcutaneous medications is the adhesive patch. Patches attach to the skin and allow even absorption of a medication for many hours **Figure 11-2**. Prescription and OTC medications come in this form. Common examples are nitroglycerin, nicotine, some pain medications, and some oral contraceptives.

Gels

A **gel** is a semiliquid substance that is administered orally in capsule form or through plastic tubes. Gels usually have the consistency of pastes or creams but are transparent (clear). "Gelatinous" means thick and sticky, like gelatin. Depending on your local medical directives, as an EMT, you may give oral glucose in gel form to a patient with diabetes **Figure 11-3**.

Figure 11-2 Some medications are transcutaneous, or administered through the skin, such as the nitroglycerin patch shown.

Figure 11-3 Oral glucose, used in diabetic emergencies, is available in gel and tablet forms.

Gases for Inhalation

Gaseous medications are neither solid nor liquid. The medication most commonly used in gas form is oxygen. You might not think of oxygen as a medication; however, in its concentrated form, it is a potent medication that has systemic effects. You will deliver this gas through a nonrebreathing mask, nasal cannula, or bag-valve mask (BVM). Current guidelines and potential risks of oxygen administration will be discussed in Chapter 10, *Airway Management*.

Words of Wisdom

When you document the use of oxygen, include the liter flow rate, the time oxygen was delivered (usually recorded in military time), and the type of device used. For example, "0915—Nonrebreathing mask at 15 L/min. Patient states shortness of breath has improved." Always remember to document the patient's response to oxygen administration.

General Steps in Administering Medication

As an EMT, you may only administer medications for which you have an order from medical control. Medical control may be provided online or offline based on local protocol. You must be familiar with the six general steps of administering any medication to a patient. These steps are the "six rights" of medication administration Table 11-3. Medication errors, which will be discussed later in this chapter, are disturbingly common and almost always result from failure to follow these six rights. After the medication has been administered, you will need to reassess the patient to see if it worked. You should look for side effects and then be prepared to document your findings and your actions.

When administering or assisting with the administration of patient medications, you must have an order from medical control to do so. If this order is given to you directly through online medical control, it is important that you repeat the order back to the physician. This is referred to as the echo technique and it is done to ensure that you heard the order correctly.

Table 11-3 The "Six Rights" of Medication Administration

Right patient
Right medication
Right dose
Right route
Right time
Right documentation

The following example illustrates the correct way to acknowledge orders for medications. EMT Johnson is talking on the radio to medical control. She has already given the physician all of the patient assessment information and vital signs. She now asks, "Do you have any orders?" Dr. Ortez says, "Yes, please assist the patient with one nitroglycerin tablet. Make sure the tablet is administered sublingually. Reassess the patient's pain and blood pressure and contact me for further orders if needed." EMT Johnson should reply, "Dr. Ortez, I copy one nitroglycerin tablet sublingual, reassess the patient's pain and blood pressure, and contact you again if needed." Dr. Ortez says, "That is correct. ABC Hospital clear."

If at any point while you are receiving an order for a medication you are confused or unclear about what to do, you should tell medical control. It is very important that you understand what the physician wants you to do. With all of the noise on a hectic scene, or in the back of an ambulance, it is important to err on the cautious side. If you are not sure what to do, say so and ask for the order to be clarified. If you believe a medication order may be harmful to the patient, it is your responsibility to address your concerns with the ordering physician.

The other way to receive orders to administer or assist with medications is through indirect or off-line medical control. Protocols are documents that contain standing orders for the administration of certain medications. For example, your system may use a protocol that describes how the medical director wants you to deal with a patient who is having respiratory difficulties. Part of this protocol may direct you to use a nonrebreathing mask to deliver oxygen at 15 L/min. You may do this without calling online medical control if the patient meets the criteria of the protocol.

The "six rights" of medication administration are as follows:

1. **Right patient.** For EMS, this safety check may seem unneeded if there is only one patient; however, there will be times when you will be working with more than one patient. Consider the following scenario. You respond to a patient with chest pain and discover that the patient is preparing to self-administer one nitroglycerin tablet sublingually. You check the bottle prior to administration and discover that the medication was actually prescribed for his wife. Depending on local protocols, administering a medication that was prescribed for a different patient may represent a violation.

2. **Right medication.** Verify the proper medication and prescription, if applicable. Once received, confirm the medication order and determine that the patient is still a candidate for the medication. Make sure the patient does not have any contraindications for the medication. It is always a good idea to have your partner confirm the medication before you administer it. Carefully read the label. If it is the patient's own prescription, the bottle may show the trade name or the generic name. If you have any questions, contact online medical control. Make sure that the medication is the patient's own and does not belong to a friend or relative. You should never give a medication to a patient who has been prescribed for someone else.
3. **Right dose.** Verify the form and dose of the medication. Once you have confirmed the order and verified that the medication is the correct one to give, you must make sure that the form of the medication and the dose are correct. This is where it is important to pay very close attention to detail. If you are ordered to give 324 mg of aspirin, you will need to read the bottle to determine how many milligrams are in each tablet. If aspirin is available in 81-mg tablets, how many will you need to give the patient? Again, it is always a good idea to have your partner confirm the dosage before administering it.
4. **Right route.** Verify the route of the medication. Now you must make sure the route matches the order you received. For example, suppose you are told to give the patient a sublingual nitroglycerin tablet. The patient's nitroglycerin tablet bottle is empty, but he has another bottle of nitroglycerin capsules. These are to be swallowed four times a day. The medication is the same, even the dose may be the same, but the route of delivery is different from the order given. You may not substitute the capsules for the tablets without specific orders from medical control.
5. **Right time.** Check the expiration date and condition of the medication. The last step before administering a medication is to make sure the expiration date has not passed. Prescription and OTC medications have an expiration date. Check the label. If no date can be found, you should examine the medication with suspicion. If you find discoloration, cloudiness, or particles in a liquid medication, you should not use it. If a patient with asthma gives you an MDI and the expiration date on it is smudged, you should not use it. After the medication is administered, you will need to reassess the patient to see if it has worked. Does the patient still have the same complaint as before you administered the medication? Has it changed? Is the patient experiencing any side effects? You should reassess the vital signs, especially heart rate and blood pressure, at least every 5 minutes if the patient's condition changes. If the medication is being administered to help reduce pain (such as oxygen), you should ask the patient to rate his or her pain both before and after medication administration. A 0 to 10 scale, or the Wong-Baker pain scale, is often used to help patients quantify their pain level. In addition, if the physician orders you to repeat the medication, it is important to do so at the right time. For example, if you are advised to repeat administration of nitroglycerin in 10 minutes if the patient's pain is unresolved, you should not wait 15 minutes.
6. **Right documentation.** Remember the EMS rule: The work is not done until the paperwork is done. Once the medication has been given, you must document your actions and the patient's response. This includes the time you gave the medication and the name, dose, and route of administration. Did the patient's condition improve, worsen, or not change? Were there any side effects? A second EMS rule says, "If you did not write it down, it did not happen." Should your performance ever be questioned, accurate documentation is your best defense.

Medication Administration and the EMT

There are several medications that may be carried on the EMS unit, including oxygen, oral glucose, activated charcoal, aspirin, and epinephrine. When used wisely, each can be a powerful tool. Keep in mind, however, that you may give these medications only according to standing orders in a protocol (off-line medical control) or a direct order (online medical control). Along with the several different medications that can be given by EMTs, there are several different routes of administration that will be used to deliver these medications to the patient.

Before specific medications are discussed, the circumstances surrounding the administration of the medications need to be discussed. Over the years, EMTs have been allowed increasing responsibility to work with medications, but this growth has come with some degree of confusion and worry. Many departments throughout the United States have strict controls on when an EMT is allowed to administer a medication. The circumstances are:

- **Peer-assisted medication**
- **Patient-assisted medication**
- **EMT-administered medication**

In peer-assisted medication administration, you are administering medication to yourself or your partner. At times it may be necessary for an EMS crew to receive medications because they were exposed to a toxic nerve agent, such as during a terrorism incident. In this case, you would first treat yourself and then your partner. Typically, nerve agent antidotes are administered via an auto-injector (see Chapter 40, *Terrorism Response and Disaster Management*, for more information).

In patient-assisted medication administration, you are assisting the patient with the administration of his or her own medication, such as an EpiPen, an MDI bronchodilator, or nitroglycerin. Perhaps the patient cannot find his or her medication. Maybe the patient is so upset that he or she cannot open the pill bottle or hold the MDI steady. In this circumstance, the patient is trying to administer the medication, but you need to offer some help so the task can be completed.

The last circumstance is EMT-administered medications. Here you are directly administering the medication to the patient. It can certainly be difficult to find the exact point where "assisting" a patient ends and actually administering a medication begins. The patient may be severely confused or unable to understand the need for the medication. Common medications that you will administer in this circumstance are oxygen, oral glucose, activated charcoal, nitroglycerin, and aspirin.

It is important for you to understand that the medication itself does not necessarily dictate whether or not you will be assisting or directly administering. Medical control, state guidelines, and local protocols will be the determining factors that define the role of the EMT. The EpiPen has often been an example of a medication that is both patient-assisted and EMT-administered. Refer to your local standards to obtain a listing of how and when EMTs can administer medications.

Words of Wisdom

The following is a list of medications that, depending on local protocol, may be administered by EMTs. Keep in mind that this list is ultimately set by the state in which you will be delivering patient care and the medical director of your agency.

- Oxygen
- Activated charcoal
- Oral glucose
- Aspirin
- Epinephrine
- Metered-dose inhaler (MDI) medications
- Nitroglycerin
- Naloxone

You may administer or help to administer medications only under the following conditions:

- Medical control gives you a direct order to administer a medication and/or the local medical protocols under which you are working permit you to administer that medication.
- The local medical protocols, developed by a medical physician under whom you are working, include standing orders for the use of a medication in defined situations.

It is imperative that you do not give or help patients take any other medications under any other circumstances.

Special Populations

Pediatric and geriatric patients often have slower absorption and elimination times, necessitating modification of the doses administered. Pregnant patients are limited in the medications they can take because of the risk to the fetus.

Medications Used by EMTs

The following is a discussion of medications that may be administered by EMTs. Again, your state, department, and medical director will ultimately define what medications are carried on your ambulance. Table 11-4 provides an excellent overview of these medications and their actions, indications, contraindications, routes of administration, side effects, interactions, and doses.

The 2009 National EMS Education Standards recognize that some regions of the country may need their EMTs involved in the administration of additional medications aside from oxygen, oral glucose, activated charcoal, aspirin, and epinephrine. The exact list of medications that you will be allowed to manage is ultimately controlled by the state and medical director of your agency.

Oral Medications

There are several medications you may be asked to administer or to assist with administration. Activated charcoal, oral glucose, aspirin, and several OTC medications can be administered by this route. As discussed, the advantages of this route are its ease of access and comfort level for the patient. One of the disadvantages of administering medications orally is that the digestive tract can be easily affected by foods, stress, and illness. The speed of movement of food through the tract dramatically changes the speed of absorption. As with all medications, you need to start with the six rights. Follow these steps to perform oral medication administration:

1. Take standard precautions.
2. Confirm the medication is not expired.
3. Obtain medical direction per local protocol.
4. Confirm that the patient has a patent airway and is able to swallow, then instruct the patient to swallow or chew the medication **Figure 11-4**.
5. Monitor the patient's condition and document.

Activated Charcoal

Many poisoning emergencies involve overdoses of medications taken by mouth. Many medications bind with activated charcoal, reducing the amount of medication that can be absorbed by the body. **Adsorption** means to bind to or stick to a surface, while absorption is the process by which medications travel through body tissues until they reach the bloodstream. **Activated charcoal** is ground into a very fine powder to provide the greatest possible surface area for binding. You will probably carry a container with a premixed suspension of activated charcoal powder and water in the EMS unit, if allowed by local protocol **Figure 11-5**. The usual dose is 1 to 2 g/kg of body weight. To convert pounds to kilograms, remember that 1 kg is equal to 2.2 lb. One method is to divide the patient's weight (in lb) by 2.2 to calculate his or her approximate weight in kg. For example, a 200 lb man weighs approximately 90.9 kg. You should use a method of calculating a patient's weight consistent with and accepted by local protocol.

Table 11-4 EMT Medication Overview

Medications EMTs Administer or May Assist in Administering								
Generic/Trade	Action	Indications	Contraindications	Routes	Side Effects	Interactions	Adult Dose	Administration Concerns
Activated charcoal (Actidose with Sorbitol)	Adsorbs toxic substances in the digestive tract	Most oral poisonings; overdose	Decreased level of consciousness; overdose of corrosives, caustics, or petroleum substances	PO	Nausea, vomiting, constipation, black stools	Bonds with and inactivates most medications/substances in the digestive tract	1 to 2 g/kg	Stains (protect patient and provider clothing); do not give when giving other PO medications
Aspirin (Bayer)	Anti- inflammatory agent and anti-fever agent; prevents platelets from clumping, thereby decreasing formation of new clots	Relief of mild pain, headache, muscle aches; chest pain of cardiac origin	Hypersensitivity; recent bleeding	PO	Nausea, vomiting, stomach pain, bleeding, allergic reactions	Caution should be used in patient who are taking anticoagulants	160 to 325 mg; 160- to 325-mg chewable tablets for chest pain	Do not administer for pain caused by trauma or for fevers in children; patients with chest pain must be able to chew tablets
Common fast-acting MDI medications (albuterol [Proventil, Ventolin])	Stimulates nervous system, causing bronchodilation	Asthma/difficulty breathing with wheezing	Hypersensitivity; tachycardia (relative); chest pain of cardiac origin	Inhalation	Hypertension, tachycardia, anxiety, restlessness	Increases effects of other nervous system stimulants	1 to 2 inhalations; wait 5 minutes before repeating dose	Patient must inhale all medication in one breath; coach patient to hold breath for 5 seconds after inhalation
Epinephrine (EpiPen)	Stimulates nervous system, causing bronchodilation	Anaphylactic reaction	Chest pain of cardiac origin; hypothermia; hypertension	IM	Hypertension, tachycardia, anxiety, restlessness	Increases effects of other nervous system stimulants	0.3 mg for adult; 0.15 mg for children	Medication will last approximately 5 minutes; do not repeat dose; ensure ALS is en route for continuing treatment
Naloxone (Narcan, EVZIO auto-injector)	Reverses respiratory depression secondary to opioid overdose	Opioid poisoning	Hypersensitivity	IM, IN	Nausea, vomiting	Additional doses may be required for severe opioid overdoses	0.4 mg auto-injector; 2 mg IN	Patients may wake up combative

Medications EMTs Administer or May Assist in Administering								
Generic/ Trade	**Action**	**Indications**	**Contraindications**	**Routes**	**Side Effects**	**Interactions**	**Adult Dose**	**Administration Concerns**
Nitroglycerin (Nitrostat, Nitromist)	Dilates blood vessels	Chest pain of cardiac origin	Hypotension; use of sildenafil (Viagra) or another treatment for erectile dysfunction within the previous 24 hours; head injury	SL tablet or spray	Headache, burning under tongue, hypotension, nausea	Increases dilating effects of other blood vessel–dilating medications	0.3 to 0.4 mg SL; 0.4 mg spray	Ensure ALS is en route
Oral glucose (Glutose)	When absorbed, provides glucose for cell use	Low blood glucose (hypoglycemia)	Decreased level of consciousness; nausea; vomiting	PO	Nausea, vomiting	None	1/2 to 1 tube	Patient must be awake, have control of airway, and be able to follow commands
Oxygen (no trade name)	Reverses hypoxia; provides oxygen to be absorbed by lungs	Hypoxia or suspected hypoxia	Very rarely used in patients with COPD; do not use near open flames, as oxygen will support combustion	Inhalation	Decreased respiratory effort in rare cases in patients with COPD	Can support combustion	Use oxygen delivery devices to administer 28% to 100% oxygen.	No open flames nearby; do not withhold oxygen from patients in respiratory distress
Common Over-the-Counter (OTC) Medications								
Acetaminophen (Tylenol)	Analgesic and fever reducer	Relief of mild pain or fever, headache, muscle aches	Hypersensitivity	PO	Allergic reaction	Take caution to avoid potential overdosing. Many OTC medications contain acetaminophen	500 to 1,000 mg every 4 hours as needed; dose is weight-based for children	Weight of child is more important than age
Diphenhydramine (Benadryl)	Antihistamine (blocks histamine)	Mild allergic reactions	Asthma; glaucoma; pregnancy; hypertension; infants	PO	Sleepiness (although can stimulate children), dry mouth and throat	Do not take with alcohol or MAO inhibitors (a type of psychiatric medication)	25 to 50 mg	Can use in severe allergic reaction; however, epinephrine is administered first
Ibuprofen (Advil, Motrin, Nuprin)	Nonsteroidal anti-inflammatory drug that reduces inflammation and fever; analgesic	Mild pain or fever, headache, muscle aches	Hypersensitivity	PO	Nausea, vomiting, stomach pain, bleeding, allergic reactions	Do not take with aspirin	200 to 400 mg every 4 to 6 hours; dose is weight-based in children	Do not take for pain caused by trauma; weight of child is more important than age

Figure 11-4 Instruct the patient to chew (eg, baby aspirin) or swallow (eg, activated charcoal) the medication.

The bond between medication and charcoal is not permanent. The medication may break free and be absorbed into the bloodstream if activated charcoal remains in the digestive system throughout a normal day. As a result, charcoal is frequently suspended with another medication called sorbitol (a complex sugar). This suspension has a laxative effect that causes the entire mixture, including the medication, to move quickly through the digestive system. The sorbitol additive increases the risk of dehydration due to diarrhea. This can be especially dangerous with pediatric patients. Consult local protocol regarding which form of activated charcoal you can administer.

Activated charcoal is given by mouth. Although sorbitol sweetens the suspension, the black charcoal makes it look unappealing. For this reason, you should use a covered container and ask the patient to drink the fluid through a straw. Also, it is important to have a layer of protective clothing, such as a gown, over your uniform. Activated charcoal stains clothing, so protect yourself and the patient's clothes when administering it. This medication should not be given to anyone with an altered level of consciousness because of the risk of aspiration. Activated charcoal is not indicated for patients who have ingested an acid, an alkali, or a petroleum product.

Figure 11-5

Activated charcoal is a suspension that is sometimes used for patients who have taken a medication overdose or swallowed a poison.

YOU are the Provider PART 3

After administering 15 g of oral glucose to the patient, you reassess her and note that her condition has improved. She is conscious and alert and asks you what happened. As you explain what happened to her, your partner takes her vital signs.

Recording Time: 5 Minutes	
Respirations	22 breaths/min; regular and adequate
Pulse	112 beats/min; strong and regular
Skin	Pink; slightly moist
Blood pressure	122/72 mm Hg
Oxygen saturation (Spo_2)	98% (on oxygen)
Blood glucose	70 mg/dL

6. What medications are typically carried on an EMT ambulance?
7. As an EMT, what medications can you assist the patient to self-administer?

Oral Glucose

Glucose is a sugar that our cells use as fuel. Although some cells can use other sugars, brain cells must have glucose. If the level of glucose in the blood gets too low, a person can suffer a loss of consciousness, have seizures, and ultimately die.

The medical term for an extremely low blood glucose level is **hypoglycemia**. Hypoglycemia can be caused by an excess of insulin, which is taken to control blood glucose levels. Patients with diabetes who use insulin regularly usually understand the effects of this medication on the body. The **oral glucose** that is carried in the EMS unit, as well as glucose tablets, can counteract the effects of hypoglycemia in the same way as a caloric beverage such as juice or a non-diet soda, but faster. This is because common table sugar (sucrose) and fruit sugars (fructose) are complex sugars and must be broken down before they can be absorbed. Glucose is a simple sugar that is readily absorbed by the bloodstream.

As an EMT, you can give glucose only by mouth. Hospital personnel and advanced providers (AEMTs and paramedics) can also give a form of glucose (dextrose) intravenously. Glucose is available as a gel designed to be spread on the mucous membranes between the cheek and gum; however, absorption through this route is not as quick as with injection. Because the patient may be conscious one moment and unconscious the next, you must be very careful when administering oral glucose. Never administer oral medications to an unconscious patient or to one who is unable to swallow or protect the airway. See Chapter 19, *Endocrine and Hematologic Emergencies*, for more information on the administration of oral glucose.

Safety Tips

Never attempt to give anything by mouth to a patient with a decreased level of consciousness. Remember, an altered LOC may be an indication for a medication such as oral glucose; however, a decreased LOC can be a contraindication for oral medications, due to the potential for airway compromise.

Aspirin

Aspirin (acetylsalicylic acid or ASA) is an antipyretic (reduces fever), analgesic (reduces pain), and anti-inflammatory (reduces inflammation) medication that inhibits platelet aggregation (clumping). This last property makes it one of the most used medications today. Research has shown that the aggregation of platelets in the coronary arteries under certain conditions is one of the direct causes of heart attack. Patients at risk for coronary artery disease are often prescribed one or two "baby" (or children's) aspirins a day. During a potential heart attack, aspirin may be lifesaving.

Contraindications for aspirin include documented hypersensitivity to aspirin (absolute), preexisting liver damage (absolute), bleeding disorders (relative), and asthma (relative). Because of the association of aspirin with Reye syndrome (a rare but serious condition that causes swelling in the brain and liver), it should not be given to children.

Sublingual Medications

The sublingual route of administration has many advantages. Assuming the patient is awake, alert, and able to follow commands, it is easy to talk with the patient and advise him or her to place a pill under his or her tongue. The head and face receive large amounts of blood flow, so absorption rates are relatively quick. Be aware, however, that any medication placed in the mouth requires constant evaluation of the airway. You must also be alert to any signs of choking on the pill. If the patient is uncooperative or unconscious, this route of medication administration should not be used.

Nitroglycerin

Many patients with cardiac conditions carry some form of fast-acting nitroglycerin to relieve the pain of angina. **Nitroglycerin** has been used medically since the 1800s. Nitroglycerin is typically the only medication that you will help to administer sublingually **Figure 11-6**.

If you have ever run for a prolonged period, you probably remember your muscles developed a painful, heavy, burning sensation. This is because the demand for oxygen by the muscles exceeded the supply. When a similar pain develops in heart muscle, it is called angina pectoris. The cause is the same—not enough oxygen. In this case the pain is due to a blockage or narrowing in the blood vessels that supply the heart. Occasionally, the cause is a spasm in these blood vessels. Unlike a runner with sore legs, the heart muscle cannot stop and rest until the pain goes away.

The purpose of nitroglycerin is to increase blood flow by relieving the spasms or causing the arteries to dilate. It does this by relaxing the muscular walls of the coronary arteries and veins. Nitroglycerin also relaxes veins throughout the body, so less blood is returned to the heart and the heart does not have to work as hard each time it contracts. In short, blood pressure is decreased. Because of this, it is important that you always take the patient's blood pressure before administering nitroglycerin. If the systolic blood pressure is less than 100 mm Hg, the nitroglycerin may have the harmful effect of lowering the blood flow to the heart's own blood vessels. Even a patient who has adequate blood pressure should sit or lie down with the head elevated before taking this medication. If the patient is standing, he or she may faint when blood flow to the brain is reduced as the nitroglycerin starts to work. If a significant drop in the patient's blood pressure (15 to 20 mm Hg) occurs and the patient suddenly feels dizzy or sick, have the patient lay down.

Figure 11-6 Nitroglycerin, which is prescribed for chest pain, can be given sublingually as a spray **(A)** or tablet **(B)**.

A: Courtesy of Shionogi Pharma, Inc.; B: © Jones & Bartlett Learning.

During a heart attack (myocardial infarction, or MI), a narrowing or blockage in a coronary artery blocks the blood flow to a section of the heart muscle (myocardium). If the blockage is not cleared in time, that section of the heart muscle beyond the clot will die. If nitroglycerin no longer brings relief to a person in whom it has previously worked, the person may be experiencing an MI instead of an angina attack. Therefore, it is important to know how much nitroglycerin a patient has needed in the past to relieve chest pain and how much has been taken during the current emergency, including the use of nitroglycerin patches. Always report this information to medical control. Remember, you cannot administer this medication without clearance from medical control or standing orders.

There are important interactions to consider when administering nitroglycerin. Erectile dysfunction medications, such as sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra), can have potentially fatal interactions with nitroglycerin. When taken together, nitroglycerin and sildenafil can cause a dramatic drop in blood pressure. Always ask a patient who has been prescribed nitroglycerin if he or she has used any medication for the treatment of erectile dysfunction within the previous 24 hours. If he or she has, do not administer the nitroglycerin and report this to medical control. Keep in mind that drugs for erectile dysfunction may be used by both men and women; do not assume women have not taken erectile dysfunction drugs.

Nitroglycerin has the following effects:

- Relaxes the muscular walls of coronary arteries and veins
- Results in less blood returning to the heart
- Decreases blood pressure
- Relaxes arteries throughout the body
- Often causes a mild headache and/or burning under the tongue after administration

Administering Nitroglycerin by Tablet. Nitroglycerin is usually taken sublingually. The patient places a tiny tablet under the tongue, where it dissolves. The tablet should create a slight tingling or burning sensation under the tongue. Exposure to light, heat, or air may degrade the strength of the medication. If the nitroglycerin does not produce the typical burning sensation, it may have lost potency because of aging or improper storage. If you notice any signs of improper storage, be sure to include that information in the patient's medical history. In addition, be sure to check the expiration date on the bottle.

Sublingual nitroglycerin tablets should be stored in their original glass container with the cap screwed on tightly. Note that what looks like cotton in the container is actually rayon. If real cotton is placed in the container, it can absorb nitroglycerin, thus reducing the potency of the tablets. Other medications placed in the container can likewise rob nitroglycerin of its power.

Administering Nitroglycerin by Metered-Dose Spray. Some patients who take nitroglycerin use a metered-dose spray, which deposits medication on or under the tongue. Each spray is equivalent to one tablet. To ensure direct, proper dosing on the bottom of the tongue, do not use a spacer with the metered-dose canister when giving nitroglycerin by this method.

Whether using the tablets or the metered-dose spray, you should wait 5 minutes for a response before repeating the dose. Closely monitor the patient's vital signs, particularly the blood pressure. Give repeated doses per medical control and/or local protocol. Remember, always wear gloves when handling nitroglycerin tablets or spray since this medication can be absorbed by your skin.

Next, you must reconfirm that the medication is still indicated for the patient. For example, suppose you have received and verified the order to give one sublingual nitroglycerin tablet to a patient with a cardiac condition. While you were getting the order, however, the patient begins to sweat more and becomes less responsive. Reassessment of the blood pressure reveals a pressure of 80/60 mm Hg. Using your knowledge of nitroglycerin, you recognize the contraindication and decide not to give the medication. Instead, you notify medical control of the changes in the patient's condition and seek new orders.

Knowing and understanding the local protocols under which you will be working are absolutely essential, as is a thorough knowledge of the medications within your scope of practice. Refer back to Table 11-4 for a review of all of the medications and the important information needed for their administration. See Chapter 16, *Cardiovascular Emergencies*, for more information on how to administer nitroglycerin.

Words of Wisdom

General Steps in Administering Medication

1. Obtain an order from medical control.
2. Verify the proper medication and prescription.
3. Verify the form, dose, and route of the medication.
4. Check the expiration date and condition of the medication.
5. Reassess the vital signs, especially heart rate and blood pressure, at least every 5 minutes or as the patient's condition changes.
6. Document your actions and the patient's response.

Intramuscular Medications

The intramuscular (IM) route of administration provides quick and easy access to the circulatory system without the need for placing a needle within a vein. Blood flow to the muscles is relatively stable, even during circumstances of severe illness or injury. This advantage makes the IM route an efficient means to deliver some medications. A disadvantage for this route is the use of a needle and the subsequent pain it can cause. Patients may be reluctant for you to use the needle for fear of pain or injury. With proper technique, you can administer medications via the IM route and limit the amount of pain delivered to the patient.

Epinephrine

Epinephrine is the main hormone that controls the body's fight-or-flight response and is the primary medication that you will be administering IM. Epinephrine is a sympathomimetic. A sympathomimetic mimics the effect of the sympathetic nervous system. The body releases epinephrine when there is sudden stress, such as during exercise or when the patient is suddenly scared. Because epinephrine is secreted by the adrenal glands, it is also known as adrenaline. Epinephrine has different effects on different body tissues and is used as a medication in several forms. Generally, epinephrine will increase the heart rate and blood pressure and dilate passages in the lungs. It can ease breathing problems caused by the bronchial spasms common in asthma and allergic reactions. In a person who is close to anaphylactic shock as a result of an allergic reaction, epinephrine may also help to maintain the patient's blood pressure. However, epinephrine is not indicated for patients who do not show signs of airway obstruction or wheezing due to an allergic reaction. This medication should also not be given to patients with hypertension, hypothermia, or if you believe the patient may be having a myocardial infarction.

Epinephrine has the following characteristics:

- Secreted naturally by the adrenal glands
- Dilates passages in the lungs
- Constricts blood vessels, causing increased blood pressure
- Increases heart rate and blood pressure

Refer back to Chapter 6, *The Human Body,* for more information on epinephrine.

Administering Epinephrine by Injection. Some states and EMS agencies now authorize the use of epinephrine by EMTs for the treatment of life-threatening anaphylaxis. In certain patients, insect venom or other allergens cause the body to over-release histamine, which lowers blood pressure by relaxing the small blood vessels and allowing them to leak. The over-release of histamine may also cause wheezing from bronchial spasms and swelling of the airway tissues (edema), which make it difficult for the patient to breathe. Epinephrine acts as a specific antidote to reverse the effects of histamines, countering both of these harmful effects. It constricts the blood vessels, allowing blood pressure to rise and reducing the swelling. In the lungs, it has the opposite effect; it dilates the air passages, so the flow of air is less restricted.

Epinephrine may be dispensed from an auto-injector, which automatically delivers a preset amount of the medication **Figure 11-7**. This is usually 0.3 mg of epinephrine. This is the method that you will most likely use.

Some areas may allow epinephrine to be administered by intramuscular injection using a vial of 1:1,000 concentration with a needle and syringe, as discussed in Chapter 20, *Immunologic Emergencies.*

Be sure to familiarize yourself with the procedures for using the auto-injector on your unit. Some manufacturers of auto-injectors include verbal instructions for administration. The general procedure is as follows:

1. Grasp unit with the tip pointing downward.
2. Form a fist around the unit. Do *not* place your thumb over either end of the unit.
3. With the other hand, pull off the activation cap.
4. Hold the tip near the outer part of the patient's thigh.
5. Insert firmly into the outer thigh so that the unit is perpendicular (at a 90-degree angle) to the thigh. Do not allow the unit to bounce.

Figure 11-7 An EpiPen auto-injector may be used to administer a preset dose of epinephrine.

© Jones & Bartlett Learning.

6. Hold firmly in the thigh for several seconds.
7. Immediately place the unit in an appropriate sharps container after administration.

Epinephrine causes a burning sensation where it is injected, and the patient's heart rate will increase after the injection, so be prepared for these side effects. Some services do not permit EMTs to carry epinephrine but do allow them to assist patients in administering their own epinephrine in life-threatening anaphylactic reactions.

Administering Naloxone by Injection. The US Food and Drug Administration (FDA) has approved an auto-injector device that delivers an IM or subcutaneous injection of naloxone (Narcan) to reverse the effects of an opioid overdose. This medication can be administered by family members or caregivers to help reverse dangerous side effects of opioid overdose, such as life-threatening respiratory depression. One version of auto-injectable naloxone, called EVZIO, provides verbal instructions for administration similar to those provided by AEDs. There are several important considerations for EMTs related to auto-injectable naloxone:

- Consult medical direction to determine if EMTs are allowed to administer naloxone in your region. As always, follow local protocol. Consider requesting assistance from ALS personnel if available for any suspected opioid overdose.
- Find out if naloxone has been administered by a bystander prior to your arrival.
- Be aware that the effects of naloxone may not last as long as opioids. Repeat doses of naloxone may be needed.
- Administration of naloxone to opioid-dependent patients can cause severe withdrawal symptoms, including seizures and cardiac arrest.
- You must consider your safety, as patients may become violent following naloxone administration.

Begin by administering naloxone in increments of 0.4 mg, then gradually increase based on the patient response, or lack thereof, to achieve the desired effect of restoring respirations while avoiding withdrawal symptoms and associated complications.

Intranasal Medications

Naloxone

Not all EMS departments will use naloxone auto-injectors, due to their expense. The most common technique for naloxone administration is via the intranasal route. Other common routes of administration include intravenous and intramuscular. All of the same considerations described for administering injectable naloxone apply when administering naloxone in any another form.

Follow these steps to administer a medication intranasally:

1. Obtain medical direction per local protocol.
2. Confirm correct medication and expiration date.
3. Attempt to determine if the patient is allergic to any medications.
4. Prepare the medication and attach the atomizer. *Never* use a needle.
5. Place the atomizer in one nostril, pointing up and slightly outward **Figure 11-8**.
6. Administer a half dose (1 mL maximum) into each nostril.
7. Reassess the patient and document appropriately.

If you do not have naloxone available, note that BVM ventilations provide necessary treatment to opioid overdose patients until definitive treatment can be reached.

Figure 11-8 Some EMTs may administer naloxone intranasally to treat an opioid overdose.

Words of Wisdom

When documenting a medication, include the name of the medication, dose and route, and vital signs before and after administration. For example: 1030 hours—vital signs: pulse, 88 beats/min; respirations, 18 breaths/min; blood pressure, 128/68 mm Hg; nitroglycerin, 0.4 mg SL. 1035 hours —vital signs: pulse, 80 beats/min; respirations, 18 breaths/min; blood pressure, 124/60 mm Hg.

Special Populations

Geriatric patients often take many medications. They might also save medications left over from previous medical conditions. Make every effort to identify which medications are current and the conditions they are being used to treat. Ask family members to help distinguish current from outdated medications, or look at the expiration dates on the medication labels. If possible, bring the medications with you to the emergency department.

Geriatric patients can become confused about their medication regimen. Uncertainty about whether they missed a dose may cause a patient to repeat the medication, possibly leading to an overdose. If you think an overdose has occurred, contact medical control.

Remember, medications can interact with each other, creating potentially harmful conditions. Even though a medication may be indicated for a special condition, it might be contraindicated in the presence of another medication. For example, if the patient is taking the heart medication propranolol (Inderal) and has an acute episode of shortness of breath, some asthma treatments might be made less effective by the heart medication.

Although medications help people to recover from acute conditions and adjust to chronic diseases, they can pose serious problems for geriatric patients. You should distinguish current from previous medications, suspect accidental or intentional overdoses, and be prepared for potentially lethal medication interactions. Document all findings, and inform medical control.

Inhalation Medications

Oxygen

Oxygen is, by far, the most commonly administered medication in the prehospital setting. All cells need **oxygen** to function properly. The heart and brain, especially, cannot function for long if oxygen levels decrease, which is why oxygen is an onboard medication for EMS units. If a patient is not breathing or is having trouble getting air into the lungs, you should administer supplemental oxygen. In general, you will be giving oxygen via a nonrebreathing mask at 10 to 15 L/min (or via nasal cannula at 2 to 6 L/min if the patient cannot tolerate a nonrebreathing mask). However, if the patient is not breathing adequately, you must also provide artificial ventilations, so you will need to use a BVM. Oxygen is usually delivered at 15 L/min with this technique.

Outside a hospital, the nonrebreathing mask is the preferred method of giving oxygen to patients who are experiencing significant respiratory difficulties or shock. With a good mask-to-face seal, this mask can provide up to 90% inspired oxygen. With a nasal cannula, oxygen flows through two small, tube-like prongs that fit into the patient's nostrils. This device can provide up to 44% inspired oxygen if the flowmeter is set at 6 L/min.

Remember that, although oxygen itself does not burn, it is a catalyst for combustion. If there is extra oxygen in the air, objects will burn more easily. So make sure there are no open flames, lit cigarettes, or sparks in the area in which you are administering oxygen.

Words of Wisdom

Oxygen is not helpful, and may be harmful, in patients who are having a heart attack or stroke when breathing is normal and the oxygen saturation is 94% or greater.

Special Populations

Children are not small adults, especially when it comes to the administration of medications. The approach to children differs from that for adults. First, doses of medications are different. Most of the assisted medications will be smaller doses. Children may not have the coordination needed to use an MDI. It will be easier if a spacer device is added to the inhaler to ensure the child receives the full benefit of the medicine. The second and most important issue in medication administration in children is affective. Children are not cognitively or emotionally the same as adults. Therefore, a little more time and effort may be required to explain each procedure. It is also in your best interest to tell the child the truth. It is very important to gain the trust of the child in the short time you have to bond with him or her.

YOU are the Provider — PART 4

The patient is placed onto the stretcher and loaded into the ambulance. She remains conscious and alert. Her son tells you that he has to retrieve some items from her house and will follow the ambulance in his car. Shortly before departing the scene, you reassess the patient's vital signs.

Recording Time: 13 Minutes	
Level of consciousness	Conscious and alert
Respirations	18 breaths/min; regular and adequate
Pulse	84 beats/min; strong and regular

Skin	Pink, warm, and slightly moist
Blood pressure	128/74 mm Hg
Spo_2	99% (on oxygen)
Blood glucose	94 mg/dL

The patient tells you that she thinks she may have accidentally taken too much of her Amaryl. You reassess her blood glucose level and note that it is 94 mg/dL.

8. You are unfamiliar with the medication Amaryl. What should you do?

9. If you were unable to obtain a blood glucose reading on this patient, would you still administer oral glucose? Why or why not?

Metered-Dose Inhalers and Nebulizers

MDIs and small volume nebulizers (SVNs) are used to administer liquid medications that have been turned into a fine mist by a flow of air or oxygen **Figure 11-9**. With the medication atomized, it is breathed into the lungs and delivered to the alveoli. Blood flow to the alveoli is very high and absorption rates are very close to those found with IV medications. This route is fast and relatively easy to access. MDIs are commonly used because of their convenience and portability. The major disadvantage of an MDI is that the patient needs to be cooperative and control his or her breathing. If the patient is unconscious, an MDI cannot be used, although you could use a nebulizer. Nebulizers are often used for more severe problems.

Medications Administered Using a Metered-Dose Inhaler or Small Volume Nebulizer

Sometimes, a respiratory condition such as asthma is not severe enough to require the use of epinephrine. In such cases, patients may use one of the chemical "cousins" of epinephrine that are more narrowly focused on the lungs. These medications are delivered with an MDI or SVN. Proper use of an MDI requires a great deal of coordination, something that may be difficult to achieve when a person is having trouble breathing. Patients must aim properly and spray just as they start to inhale. If administered improperly, most of the medication ends up on the roof of the patient's mouth. An adapter, called a "spacer," fits over the inhaler like a sleeve and can be used to avoid misdirecting the spray **Figure 11-10**. The patient sprays the prescribed dose into the chamber and then breathes in and out of the mouthpiece until the mist is completely inhaled. Spacer devices are especially useful with young children who have difficulty using an MDI.

Figure 11-9 Metered-dose inhalers and small volume nebulizers (shown here) convert liquid medications into a fine mist.

SVNs are much easier to use than MDIs; however, they take longer to deliver the medication and require an external air or oxygen source. An SVN can be more effective than an MDI in moderate to severe respiratory distress. An SVN can also be used while a patient is on CPAP and during BVM ventilation. An SVN can easily be adapted to a nonrebreathing mask for patients unable to hold an SVN. This can be especially helpful with children.

Assisting a patient with an SVN involves placing the medication into the nebulizer and then running a flow of oxygen through the device, which will atomize the liquid and allow the patient to breathe in the medication **Figure 11-11**. You will typically use an oxygen tank to deliver an SVN treatment; however, many respiratory patients have a portable SVN machine at home that can also be used. Consult local protocol to determine if use of an SVN is within the EMT scope of practice for your agency.

Follow the below steps to administer a medication via SVN. See Chapter 15, *Respiratory Emergencies*, for more information on steps for using MDIs and SVNs.

1. Obtain medical direction per local protocol.
2. Confirm correct medication and expiration date.

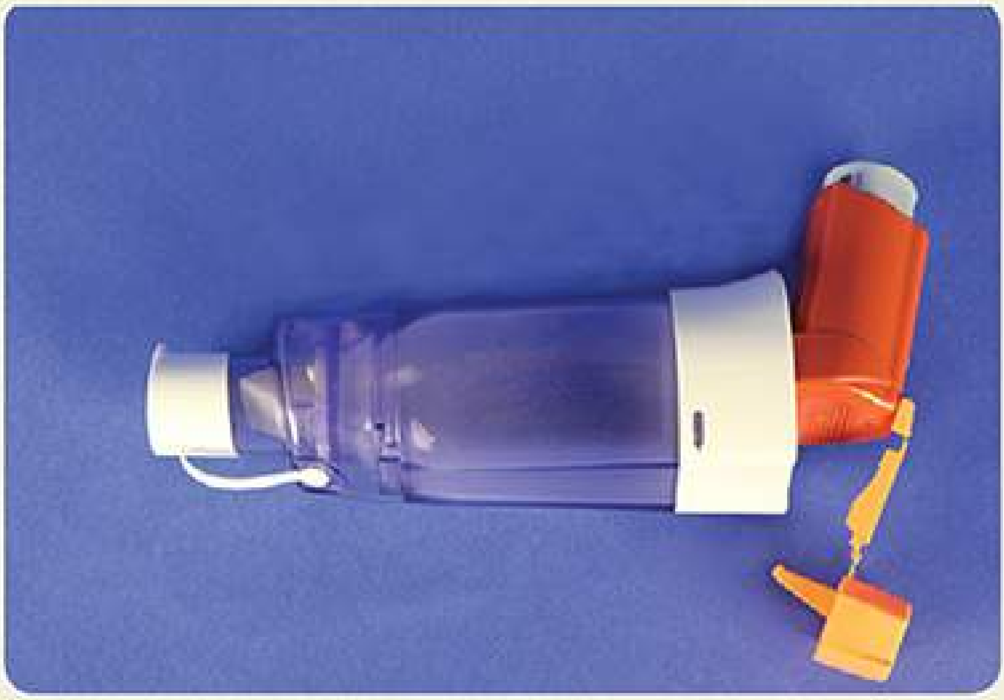

Figure 11-10 Some inhalers have spacer devices to better direct the medication spray.

Figure 11-11 With a small volume nebulizer, liquid medication is atomized by the flow of oxygen. The patient then breathes in the medication.

3. Confirm that the patient is *not* allergic to the medication.
4. Add the appropriate medication and dose to the nebulizer reservoir and assemble according to the manufacturer's instructions.
5. Connect to the nebulizer machine (often in the patient's home) or oxygen tank at 6 to 8 L/min.
6. Place the nebulizer in the patient's mouth and instruct the patient to breathe until the medication is gone (usually about 5 minutes).
7. Reassess the patient and document appropriately.

Note: some nebulizers come preconnected to an oxygen mask for easier administration for patients who are unable to hold the nebulizer.

You can activate the spray by pressing the canister into the adapter just as the patient starts to inhale. If relief is not achieved, wait 3 to 5 minutes and repeat this sequence according to the patient's prescription. Above all, it is important to ensure that the patient inhales all the medication in a single-sprayed dose.

Asthma, also known as "reactive airway disease," can be a life-threatening condition. Therefore, some patients use "rescue inhaler" MDIs to relieve bronchial spasms quickly. Just a few of the more common over-the-counter MDIs include Primatene Mist, Bronitin Mist, and Bronkaid Mist. Each of these MDIs contains epinephrine and can cause significant side effects, such as tachycardia, hypertension, and restlessness. Therefore, as mentioned earlier, most patients with asthma use certain chemical "cousins" of epinephrine that produce fewer side effects and act more specifically on the bronchi of the lungs. Common prescription MDIs include Metaproterenol (Alupent, Metaprel) and albuterol (Proventil, Ventolin). Another type of MDI used by respiratory patients is the maintenance or controller inhaler. These MDIs are slow acting and are meant to be taken regularly in order to be effective. Maintenance inhalers are *not* useful for a patient suffering acute respiratory distress and in need of immediate relief. Common maintenance inhalers include fluticasone propionate (Flovent Diskus), budesonide (Pulmicort), mometasone furoate (Asmanex Twisthaler), beclomethasone dipropionate (Qvar), and ciclesonide (Alvesco).

There are dozens of different MDIs on the market, and often patients may be prescribed several of them at once. The only medication that will be effective during an acute attack of shortness of breath will be the fast-acting rescue inhalers, such as albuterol (Proventil, Ventolin). Whether you are assisting the patient with an MDI or an SVN medication, be sure you have the right medication for a patient with acute respiratory distress.

Patient Medications

Part of your patient assessment includes finding out what medications your patient is currently taking. This information may provide vital clues to your patient's condition that may help guide your treatment or be extremely useful to the emergency department (ED) physician. Often, knowing what medications a patient takes may be the only way you can determine what chronic or underlying conditions your patient may have, such as when a patient is unable to relate his medical history to you. The patient may be unresponsive, confused, not knowledgeable about his or her medical history, uncooperative, or unable to communicate. Discovering what the patient takes and transporting the medications or a list of medications with you to the ED can be crucial in assessing your patient's needs.

In addition to prescription medications, patients often take nonprescription OTC medications, herbal medications, or other supplements. Many times, they do not consider these substances "medications" and will not report them to you unless you ask about them specifically. Yet, they may be as potent as prescription medications and can have interactions and effects on a patient's health and condition that are just as important. Be sure to ask specifically about these also. Several of the most commonly prescribed drugs for adults in the United States are used to treat cardiovascular disease and high cholesterol. **Table 11-5** lists 20 of the most prescribed medications and their uses. There are also excellent mobile apps that can help you quickly look up unfamiliar medications.

Patients are naturally reluctant to tell you about any illegal drugs or medications they may have taken. It is important to ask, and you can assure them that your only interest in asking is to be able to treat them appropriately.

Special Populations

Polypharmacy is a term referring to the use of multiple medications by one person. It is not uncommon today to find patients, especially older patients, taking many medications on a regular basis. Often, the prescription regimens can be complex and confusing. The medications may be prescribed by multiple physicians. The person may also be taking nonprescription and herbal medicines. Add to this the possibility of failing memory and confusion, and the potential for overdosing, underdosing, and harmful interactions increases exponentially.

Table 11-5 Commonly Prescribed Medications in the United States

Generic Name (Trade Name)	Use
adalimumab (Humira)	Treats arthritis
alprazolam (Xanax)	Treats anxiety disorders
amlodipine (Norvasc)	Treats high blood pressure or cardiac conditions
amoxicillin (Moxatag)	Treats infection caused by bacteria
aripiprazole (Abilify)	Treats depression
atorvastatin (Lipitor)	Treats high cholesterol
azithromycin (Zithromax)	Treats infection caused by bacteria
duloxetine (Cymbalta)	Treats depression and anxiety disorders
esomeprazole (Nexium)	Treats gastric reflux, heartburn
furosemide (Lasix)	Diuretic; treats hypertension, heart failure
metformin (Glucophage)	Treats diabetes
hydrochlorothiazide (Microzide)	Diuretic; treats hypertension, heart failure
hydrocodone (Vicodin)	Narcotic analgesic; pain reliever
levothyroxine (Synthroid)	Treats hypothyroidism
lisinopril (Zestril)	Angiotensin-converting enzyme (ACE) inhibitor; treats hypertension
metoprolol (Lopressor)	Diuretic; treats hypertension, heart failure
omeprazole (Prilosec)	Treats gastric reflux, heartburn
rosuvastatin (Crestor)	Treats high cholesterol
salmeterol (Advair)	Steroid maintenance inhaler; prevents asthma attacks, COPD
simvastatin (Zocor)	Treats high cholesterol

Medication Errors

As discussed earlier, **medication errors** are common. A medication error is inappropriate use of a medication that could lead to patient harm. For example, this could include incorrect communication of a dose or administration of an incorrect dose. According to The National Academies, over 4,100 people in the United States are harmed every day due to medication errors in hospitals, extended care facilities, and outpatient clinics. There are about 200 deaths daily just in US hospitals due to medication errors. EMS professionals are not immune to committing medication errors. Medication errors are preventable, so you must be extremely vigilant any time medications are administered to a patient.

As discussed in Chapter 1, *EMS Systems*, errors can stem from different causes. Administration of a medication that is outside one's scope of practice is a rules-based error. Choosing the wrong medication to administer is a knowledge-based error. Using incorrect equipment or an incorrect procedure for administering a medication is an example of a skills-based error.

If the circumstances of the errors are understood, it may be possible to minimize them. Ensure that the environment does not contribute to errors—ensure that lighting is sufficient, that equipment is organized, and that distractions are limited as much as possible. Consider using a “cheat sheet” to help yourself remember all crucial steps to medication administration. Finally, before administering a medication, stop to ask yourself “Why am I doing this?” Pausing for a moment allows you to sharpen your focus and ensure that you are doing what is correct.

If a medication error does take place, take the following steps. First, rapidly provide any appropriate patient care that is required. Second, notify medical control as quickly as possible. Third, follow your local protocols and document the incident thoroughly, accurately, and honestly. Additionally, talk with your partner, supervisor, or medical director. This is an opportunity for you to learn how to prevent such errors in the future. These discussions can also help identify areas for your agency to target during quality improvement.

YOU are the Provider — PART 5

The patient’s condition remains stable during transport. You transport in non-emergency mode, reassess her vital signs, and then call in your radio report to the hospital, which you will arrive at in approximately 8 minutes.

Recording Time: 19 Minutes	
Level of consciousness	Conscious and alert
Respirations	18 breaths/min; regular and adequate
Pulse	74 beats/min; strong and regular
Skin	Pink, warm, and dry
Blood pressure	126/72 mm Hg
Spo_2	98% (on oxygen)
Blood glucose	94 mg/dL

You arrive at the hospital and give your verbal report to the charge nurse. The patient’s son arrives shortly thereafter and presents the nurse with a plastic bag containing seven medications, including those that you have already noted. After further assessment, treatment, and observation in the emergency department, the patient is discharged home with modification of her medication regimen and instructions to follow-up closely with her primary care provider.

10. What does the term “polypharmacy” mean and why is it important?

YOU are the Provider — SUMMARY

1. What is pharmacology?

Pharmacology is the study of medications, including their therapeutic uses and actions on the body. Several terms are used when discussing pharmacology. The *dose* is the amount of medication that is given to the patient. The *action* is the therapeutic effect that the medication is expected to have on the body. *Indications* are the reasons or conditions for which a particular medication is given. *Contraindications* are the reasons or conditions for which a particular medication should not be given because it may cause further harm. *Side effects* are any actions of a medication other than the desired effects.

2. Why is knowledge of pharmacology important to patient care?

Giving a medication to a patient without understanding how it will affect him or her is dangerous. Prior to administering *any* medication—including oxygen—you must understand what effect(s) it will have on the patient. In addition, you must perform a careful and accurate assessment to determine if medication therapy is even indicated.

The patient may have a condition for which a particular drug is indicated; however, various factors that are unique to the patient (eg, known allergy to the drug, unstable vital signs) may otherwise make it contraindicated. The only way you will be able to determine this is through a careful assessment.

It is easy enough to memorize the indications, contra-indications, doses, and side effects of the drugs that you may administer as an EMT, but if you do not know how the drug will affect the patient’s body, you should not be giving it.

Once you give it, you cannot take it back!

3. Other than oxygen, what other medication does this patient require, and why?

This patient is a candidate for oral glucose. A normal blood glucose level is 80 to 120 mg/dL. This patient's glucose level is 36 mg/dL, which is critically low (hypoglycemia) and would explain the patient's present mental status.

Oral glucose is available as a gel or as tablets. If authorized by medical control, you should administer oral glucose to any patient with a decreased level of consciousness, an ability to protect his or her own airway, and a history of diabetes. The only contraindications to oral glucose are an inability to swallow and unconsciousness, because of the risk of aspiration.

4. What are the "six rights" of medication administration and why are they important?

Prior to assisting a patient with his or her prescribed medication, as well as administering a drug from your ambulance, you should review the six rights of medication administration, a tool used to promote safe and accurate medication administration. Most medication errors are almost always result from failure to follow these six rights.

- **Right patient:** Look at the medication label to ensure that it reads the same name as your patient.
- **Right drug:** Check the medication label to make sure it is the right medication for the patient's condition.
- **Right dose:** Check the medication label and take note of the dose. The dosing information should be on the medication container. If it is not, contact medical control.
- **Right route:** A medication given by the wrong route, even if it is the correct medication, may be ineffective or may even cause harm to the patient.
- **Right time:** Medications that can be repeated must be given at the correct time intervals. After administering the medication, document the time. After the proper time has passed, contact medical control again if the drug needs to be readministered.
- **Right documentation:** After administering any medication to any patient, you must document the drug, dose, route, time(s) of administration, and reassessment findings after the medication has been given. Proper documentation will ensure that the receiving facility is aware of the medications the patient received in the field.

5. Why is it significant to know the patient took her medication on an empty stomach?

If a patient with diabetes takes his or her medication but does not eat, there is a significant risk of symptomatic hypoglycemia developing. If the blood glucose level becomes too low, a person can suffer a loss of consciousness, experience seizures, and ultimately die.

6. What medications are typically carried on an EMT ambulance?

There are five medications typically carried on an ambulance that is staffed by EMTs: oxygen, aspirin, oral glucose, activated charcoal, and epinephrine. Depending on local protocol, other medications may be carried on the ambulance, including naloxone, nitroglycerin, and metered-dose inhaler (MDI) medications.

It is important to note that, just because these medications are carried on the ambulance, you cannot administer them at will. They may be given only on the direct order of a physician (online medical control) or according to standing orders in your local protocol (off-line medical control).

7. As an EMT, what medications can you assist the patient to self-administer?

You may be asked to help patients self-administer certain prescription medications, including epinephrine auto-injectors (EpiPens), metered-dose inhaler medications (ie, albuterol [Proventil, Ventolin], metaproterenol [Alupent]), and nitroglycerin (Nitrostat).

First, perform a careful assessment of your patient to determine if medication therapy is indicated. Just because the patient is prescribed a particular medication does not mean that it is indicated. For example, nitroglycerin—a vasodilator drug—is contraindicated if the patient's systolic blood pressure is less than 100 mm Hg. By dilating the patient's blood vessels, nitroglycerin may cause a dangerous drop in his or her blood pressure.

8. You are unfamiliar with the medication Amaryl. What should you do?

The simplest and most obvious way of determining the purpose of a medication is to ask the patient. She is conscious and will likely be able to answer your question. If the patient is unsure what it is used for, you should refer to an EMT field guide, drug reference text or mobile app, or contact medical control. In this case, Glimepiride (Amaryl) is an oral hypoglycemic; it is commonly used by patients with type 2 diabetes mellitus to help lower their blood glucose level.

As an EMT, you will often encounter patients who take numerous medications. Just because it is not one that you carry on the ambulance or are authorized to assist the patient in taking does not mean that you should not determine its use. Much information about a patient's medical history can be obtained by looking at the medications she is taking.

9. If you were unable to obtain a blood glucose reading on this patient, would you still administer oral glucose? Why or why not?

Patients with hypoglycemia can suffer a rapid loss of consciousness, experience seizures, and even die. Withholding glucose from a patient who needs it is far more dangerous than administering it to a patient who does not. Be sure to follow local protocol regarding administration of any medication.

10. What does the term "polypharmacy" mean and why is it important?

Polypharmacy refers to the use of multiple medications by the same patient. It is not uncommon to find patients, especially older patients, taking multiple prescribed medications, over the counter medications, and herbal remedies on a regular basis; this often makes a patient's medication regimen complex and confusing.

The potential for inadvertent underdosing and overdosing and harmful drug interactions increases in patients who take multiple medications. Furthermore, the patient's primary problem may be the result of one or more of the medications he or she is taking.

You should carry a field guide or similar reference that lists common prescription and nonprescription medications. In cases where the patient is unable to communicate with you and a reliable source (eg, family member, caregiver) is not available to answer your questions, the patient's medications can give you important clues as to his or her medical history.

EMS Patient Care Report (PCR)

Date: 7-5-16	**Incident No.:** 220109	**Nature of Call:** Diabetic complications		**Location:** 4864 Project Ave.	
Dispatched: 0600	**En Route:** 0601	**At Scene:** 0606	**Transport:** 0622	**At Hospital:** 0630	**In Service:** 0636

Narrative

Dispatched to a residence for a 68-year-old woman with "diabetic problems." Arrived on scene to find the patient sitting in a recliner in her living room. She was conscious, but confused. Her airway was patent and her breathing, although increased in rate, was producing adequate tidal volume. The patient was disoriented to place and time but able to speak and follow simple commands. The patient's son, who called 9-1-1, advised that his mother has type 2 diabetes, and he is not sure when she last ate. Further past medical history includes heart disease and depression. Further assessment of patient revealed that her skin was cool, clammy, and pale. She was in no obvious respiratory distress and did not appear to be experiencing any pain. Applied oxygen at 15 L/min via nonrebreathing mask and obtained initial vital signs. Blood glucose level was assessed and read 36 mg/dL. After ensuring that the patient was able to swallow, administered one tube (15 g) of oral glucose. Placed patient onto stretcher, loaded her into the ambulance, and reassessed her status. Her level of consciousness had improved and her vital signs were stable. Began transport to the hospital and closely monitored the patient en route. Her airway and breathing remained adequate and her skin color and condition improved. The patient stated that she could not remember when she had eaten last. She further stated that she thinks that she may have accidentally taken too much of her Amaryl. Reassessed her blood glucose level, which read 94 mg/dL. Delivered patient to the emergency department without incident, gave verbal report to the charge nurse, and returned to service.**End of report**

Prep Kit

Ready for Review

- Pharmacology is the science of drugs, including their ingredients, preparation, uses, and actions on the body.
- Medications may be administered through the following routes: intravenous, intramuscular, or subcutaneous injection; intranasal; oral; sublingual; intraosseous; transcutaneous; by inhalation; and by rectum.
- These routes of administration often determine the speed with which the medication takes effect.
- Medications come in seven forms: tablets and capsules, solutions and suspensions, metered-dose inhalers (MDIs), topical medications, and transdermal medications, gels, and gases.
- The administration of any medication requires approval by medical control, through direct orders given online or standing orders that are part of the local protocols.
- Once an order from medical control has been obtained, follow these steps in administering medications: Verify the patient, verify the proper medication, verify the dose, verify the route, and verify the time. Once the medication has been administered, reassess vital signs and document the patient's history, assessment, treatment, and response findings.
- Five medications are typically carried on an EMT ambulance: oxygen, aspirin, oral glucose, activated charcoal, and epinephrine. Depending on local protocol, some EMS units may carry naloxone, nitroglycerin, and metered-dose inhaler (MDI) medications.
- There are three medications that you may assist the patient to patient self-administer, including epinephrine auto-injectors (EpiPens), metered-dose inhaler medications (eg, albuterol [Proventil, Ventolin], metaproterenol [Alupent]), and nitroglycerin (Nitrostat). Remember, medications may differ depending on local protocol.
- Knowing what medications a patient takes may be the only way you can determine what chronic or underlying conditions your patient may have.
- You must be extremely vigilant when administering medications. If a medication error occurs, provide any appropriate patient care required, notify medical control as soon as possible, and document the incident.

Vital Vocabulary

absorption The process by which medications travel through body tissues until they reach the bloodstream.

action The therapeutic effect of a medication on the body.

activated charcoal An oral medication that binds and adsorbs ingested toxins in the gastrointestinal tract for treatment of some poisonings and medication overdoses. Charcoal is ground into a very fine powder that provides the greatest possible surface area for binding medications that have been taken by mouth; it is carried on the EMS unit.

adsorption The process of binding or sticking to a surface.

agonist A medication that causes stimulation of receptors.

antagonist A medication that binds to a receptor and blocks other medications.

aspirin (acetylsalicylic acid or ASA) A medication that is an antipyretic (reduces fever), analgesic (reduces pain), anti-inflammatory (reduces inflammation), and a potent inhibitor of platelet aggregation (clumping).

contraindications Conditions that make a particular medication or treatment inappropriate because it would not help, or may actually harm, a patient.

dose The amount of medication given on the basis of the patient's size and age.

EMT-administered medication Administration of a medication by the EMT directly to the patient.

enteral medications Medications that enter the body through the digestive system.

epinephrine A medication that increases heart rate and blood pressure but also eases breathing problems by decreasing muscle tone of the bronchiole tree.

gel A semiliquid substance that is administered orally in capsule form or through plastic tubes.

generic name The original chemical name of a medication (in contrast with one of its proprietary or "trade" names); the name is not capitalized.

hypoglycemia An abnormally low blood glucose level.

indications The therapeutic uses for a specific medication.

inhalation Breathing into the lungs; a medication delivery route.

intramuscular (IM) injection An injection into a muscle; a medication delivery route.

intranasal (IN) A delivery route in which a medication is pushed through a specialized atomizer device called a mucosal atomizer device (MAD) into the naris.

intraosseous (IO) injection An injection into the bone; a medication delivery route.

intravenous (IV) injection An injection directly into a vein; a medication delivery route.

medication A substance that is used to treat or prevent disease or relieve pain.

medication error Inappropriate use of a medication that could lead to patient harm.

metered-dose inhaler (MDI) A miniature spray canister through which droplets or particles of medication may be inhaled.

mucosal atomizer device (MAD) A device that is used to change a liquid medication into a spray and push it into a nostril.

nitroglycerin A medication that increases cardiac perfusion by causing blood vessels to dilate; EMTs may be allowed to assist the patient to self-administer the medication.

oral By mouth; a medication delivery route.

oral glucose A simple sugar that is readily absorbed by the bloodstream; it is carried on the EMS unit.

over-the-counter (OTC) medications Medications that may be purchased directly by a patient without a prescription.

oxygen A gas that all cells need for metabolism; the heart and brain, especially, cannot function without oxygen.

parenteral medications Medications that enter the body by a route other than the digestive tract, skin, or mucous membranes.

patient-assisted medication When the EMT assists the patient with the administration of his or her own medication.

peer-assisted medication When the EMT administers medication to him or herself or to a partner.

per os (PO) Through the mouth; a medication delivery route; same as oral.

per rectum (PR) Through the rectum; a medication delivery route.

pharmacodynamics The process by which a medication works on the body.

pharmacology The study of the properties and effects of medications.

polypharmacy The use of multiple medications on a regular basis.

prescription medications Medications that are distributed to patients only by pharmacists according to a physician’s order.

side effects Any effects of a medication other than the desired ones.

solution A liquid mixture that cannot be separated by filtering or allowing the mixture to stand.

subcutaneous (SC) injection Injection into the fatty tissue between the skin and muscle; a medication delivery route.

sublingual (SL) Under the tongue; a medication delivery route.

suspension A mixture of ground particles that are distributed evenly throughout a liquid but do not dissolve.

therapeutic effect The desired or intended effect a medication is expected to have on the body.

topical medications Lotions, creams, and ointments that are applied to the surface of the skin and affect only that area; a medication delivery route.

trade name The brand name that a manufacturer gives a medication; the name is capitalized.

transcutaneous (transdermal) Through the skin; a medication delivery route.

unintended effects Actions that are undesirable but pose little risk to the patient.

untoward effects Actions that can be harmful to the patient.

Assessment

You respond to Nathan Lane for a 50-year-old man who reports feeling weak and dizzy. You are greeted at the front door by the patient's neighbor. You find the patient seated on the couch. His skin looks pale, but he does not appear to be in any distress. He tells you that he has recently switched to two new medications for anxiety and hypertension. He states he took his first dose of both medications this morning.

1. The patient tells you he takes glimepiride. This name is an example of a(n):

   A. trade name.
   B. generic name.
   C. chemical name.
   D. official name.

2. The patient was prescribed alprazolam (Xanax) for his anxiety. In this case, anxiety would be considered a(n):

   A. indication.
   B. contraindication.
   C. side effect.
   D. intended effect.

3. The unintended effects that occur after the patient takes his medications are called:

   A. indications.
   B. contraindications.
   C. side effects.
   D. therapeutic effects.

4. What information should you include on your PCR related to the patient's medications?

A. Document the medication names and dosages.
B. Document the medication names and expiration dates.
C. The trade name and the generic name of each medication.
D. Do not document the medication names; these will be determined at the hospital.

5. If your patient takes insulin for diabetes, what route of administration does he use?

A. Oral
B. Sublingual
C. Injection
D. Inhaled

6. Your patient tells you he takes eight different prescription and over-the-counter medications every day. Which of the following statements indicates why this is important information?

A. Patients who take multiple medications rarely have problems if the medications are taken as prescribed.
B. It is unlikely that the patient's chief complaint is related to the medications he takes.
C. Patients are never prescribed medications that are not compatible.
D. Drug interaction is a concern if the patient takes multiple medications.

7. If you placed this patient on supplemental oxygen, what type of medication delivery would this be?

A. Self-administered
B. EMT-administered
C. Patient-assisted
D. Medical director-assisted

8. Which of the following is an advantage of MDI drug administration over SVN drug administration?

A. The MDI route does *not* require an external oxygen source.
B. The patient does not need to be conscious for MDI drug administration.
C. MDI medications have no side effects.
D. MDI medications do not expire.

9. What route of medication administration has the fastest onset of action? Why?

10. Why is it important to ask patients if they take any over-the-counter medications, vitamins, or herbal remedies, in addition to prescription medications?

National EMS Education Standard Competencies

Shock and Resuscitation

Applies a fundamental knowledge of the causes, pathophysiology, and management of shock, respiratory failure or arrest, cardiac failure or arrest, and post resuscitation management.

Pathophysiology

Applies fundamental knowledge of the pathophysiology of respiration and perfusion to patient assessment and management.

Knowledge Objectives

1. Describe the pathophysiology of shock (hypoperfusion). (pp 487–490)
2. Identify the causes of shock. (p 490)
3. Differentiate among the various types of shock. (pp 491–496)
4. Describe the signs and symptoms of shock including compensated and decompensated. (pp 496–497)
5. Discuss key components of patient assessment for shock. (pp 497–499)
6. Describe the steps to follow in the emergency care of the patient with various types of shock. (pp 499–505)

Skills Objectives

1. Demonstrate how to control shock. (pp 499–504)
2. Demonstrate how to complete an EMS patient care report for a patient with shock. (p 508)

Introduction

Shock has a number of meanings. For example, it is often said that a person who has been frightened or received bad news is in shock. An electric current passing through the body delivers a shock. In this chapter, **shock** (hypoperfusion) describes a state of collapse and failure of the cardiovascular system. When the circulation of blood in the body becomes inadequate, the oxygen and nutrient needs of the cells cannot be met. In the early stages of shock, the body will attempt to compensate by maintaining **homeostasis** (a balance of all systems of the body); however, as shock progresses, blood circulation slows and eventually ceases. This abnormal state of inadequate oxygen and nutrient delivery to the cells of the body causes organs and then organ systems to fail. If not treated promptly, shock can be fatal.

Shock can occur because of several medical or traumatic events such as a heart attack, severe allergic reaction, a motor vehicle crash, or a gunshot wound. As an EMT, you will respond to these different types of emergencies to provide care and transportation for these patients. Therefore, you must be constantly alert to the signs and symptoms of shock.

This chapter begins with a close-up look at perfusion, the function that fails in shock. Next it looks at the physiologic causes of shock and describes each of its major forms. Finally, it discusses the emergency treatment of shock in general and of each kind of shock in particular. See Chapter 13, *BLS Resuscitation*, for resuscitation techniques.

Pathophysiology

Perfusion

Perfusion is the circulation of blood within an organ or tissue in adequate amounts to meet the cells' current needs for oxygen, nutrients, and waste removal. The body is perfused via the circulatory system. The circulatory system is a complex arrangement of connected tubes, including the arteries, arterioles, capillaries, venules, and veins. There are two circuits in the body: the systemic circulation in the body and the pulmonary circulation in the lungs. The systemic circulation carries oxygen-rich blood from the left ventricle through the body and back to the right atrium. In the systemic circulation, as blood passes through the tissues and organs, it delivers oxygen and nutrients. Adequate perfusion is also important for the removal of waste products such as carbon dioxide, which is picked up from cells as blood circulates through the organs and returns to the heart and lungs.

Organs, tissues, and cells must have adequate oxygenation or they may die. Each time you take a breath, the alveoli, which are microscopic, thin-walled air sacs, receive a supply of oxygen-rich air. Oxygen diffuses through the walls of the alveoli into the bloodstream and attaches to hemoglobin circulating on red blood cells. If this oxygenated blood is not properly circulated, cell death may occur.

Oxygen and carbon dioxide pass rapidly across the thin walls of the alveoli by the process of diffusion. Diffusion is a passive process in which molecules move from an area with a higher concentration of molecules to an area of lower concentration. There are more oxygen molecules in the alveoli than in the blood. Therefore, the oxygen molecules move from the alveoli into the blood. Because there are more carbon dioxide molecules in the blood than in the inhaled air, carbon dioxide moves out of the blood into the alveoli.

Whereas the majority of oxygen is carried to the tissues attached to hemoglobin, carbon dioxide can be transported in the blood from tissues back to the lungs in three ways: dissolved in the plasma, combined with water in the form of bicarbonate, or attached to hemoglobin. Carbon dioxide waste products released from cells can combine with water in the bloodstream to form bicarbonate. Bicarbonate concentrations become higher as more carbon dioxide is produced and blood moves back toward the lungs. Once it reaches the lungs, the bicarbonate breaks back down into carbon dioxide and water and the carbon dioxide is exhaled. In cases of poor perfusion (shock), the transportation of carbon dioxide out of the tissues will become impaired, resulting in a dangerous buildup of waste products, which may cause cellular damage.

YOU are the Provider **PART 1**

At 2022 hours, your alert tones sound, "Medic 4, respond to the Cedar Hills Urgent Care Clinic at 1111 Cedar Hills Drive for a 39-year-old woman who is going into shock." You and your partner proceed to the clinic, which is approximately 9 minutes from your station. It is cloudy outside, the temperature is 66°F (18.9°C), and the traffic is light.

1. What additional information should you attempt to gather about the patient while en route to the clinic?
2. What is shock and how does it relate to perfusion?

Shock, or hypoperfusion, refers to a state of collapse and failure of the cardiovascular system that leads to inadequate circulation. Like internal bleeding, shock is an unseen underlying life threat caused by a medical disorder or traumatic injury. To protect vital organs, the body attempts to compensate by directing blood flow from organs that are more tolerant of low flow (such as the skin and intestines) to organs that cannot tolerate low blood flow (such as the heart, brain, and lungs). If the conditions causing shock are not promptly addressed, death may soon occur. By recognizing the signs and symptoms of shock early, you can minimize organ damage and save lives. Shock is life threatening and requires immediate recognition and rapid treatment.

As described in Chapter 6, *The Human Body*, the cardiovascular system consists of three parts: a pump (the heart), a set of pipes (the blood vessels or arteries that act as the container), and the contents of the container (the blood) **Figure 12-1**. These three parts can be referred to as the “perfusion triangle” **Figure 12-2**. When a patient is in shock, one or more of the three parts is not working properly.

Blood is the vehicle for carrying oxygen and nutrients through the vessels to the capillary beds and tissue cells, where they are exchanged for waste products. For this process to happen, the vessels (container) must be intact. Blood contains red blood cells, white blood cells, platelets, and a liquid called plasma. As discussed in Chapter 6, *The Human Body*, red blood cells are responsible for transporting oxygen to the cells and carbon dioxide (a waste product of cellular metabolism) away from the cells to the lungs where it is exhaled and removed from the body. White blood cells help the body fight infection. Platelets assist in forming blood clots. In the body, a blood clot forms depending on one of the following principles: retention of blood due to blockage in blood circulation (blood stasis), changes in the vessel wall (such as a wound), and the blood’s ability to clot (as the result of a disease process or medication). When injury occurs to tissues in the body, platelets begin to collect at the site of injury; this causes the red blood cells to become sticky and clump together. As the red blood cells begin to clump, another substance in the body called fibrinogen reinforces the red blood cells. This is the final step in the formation of a blood clot.

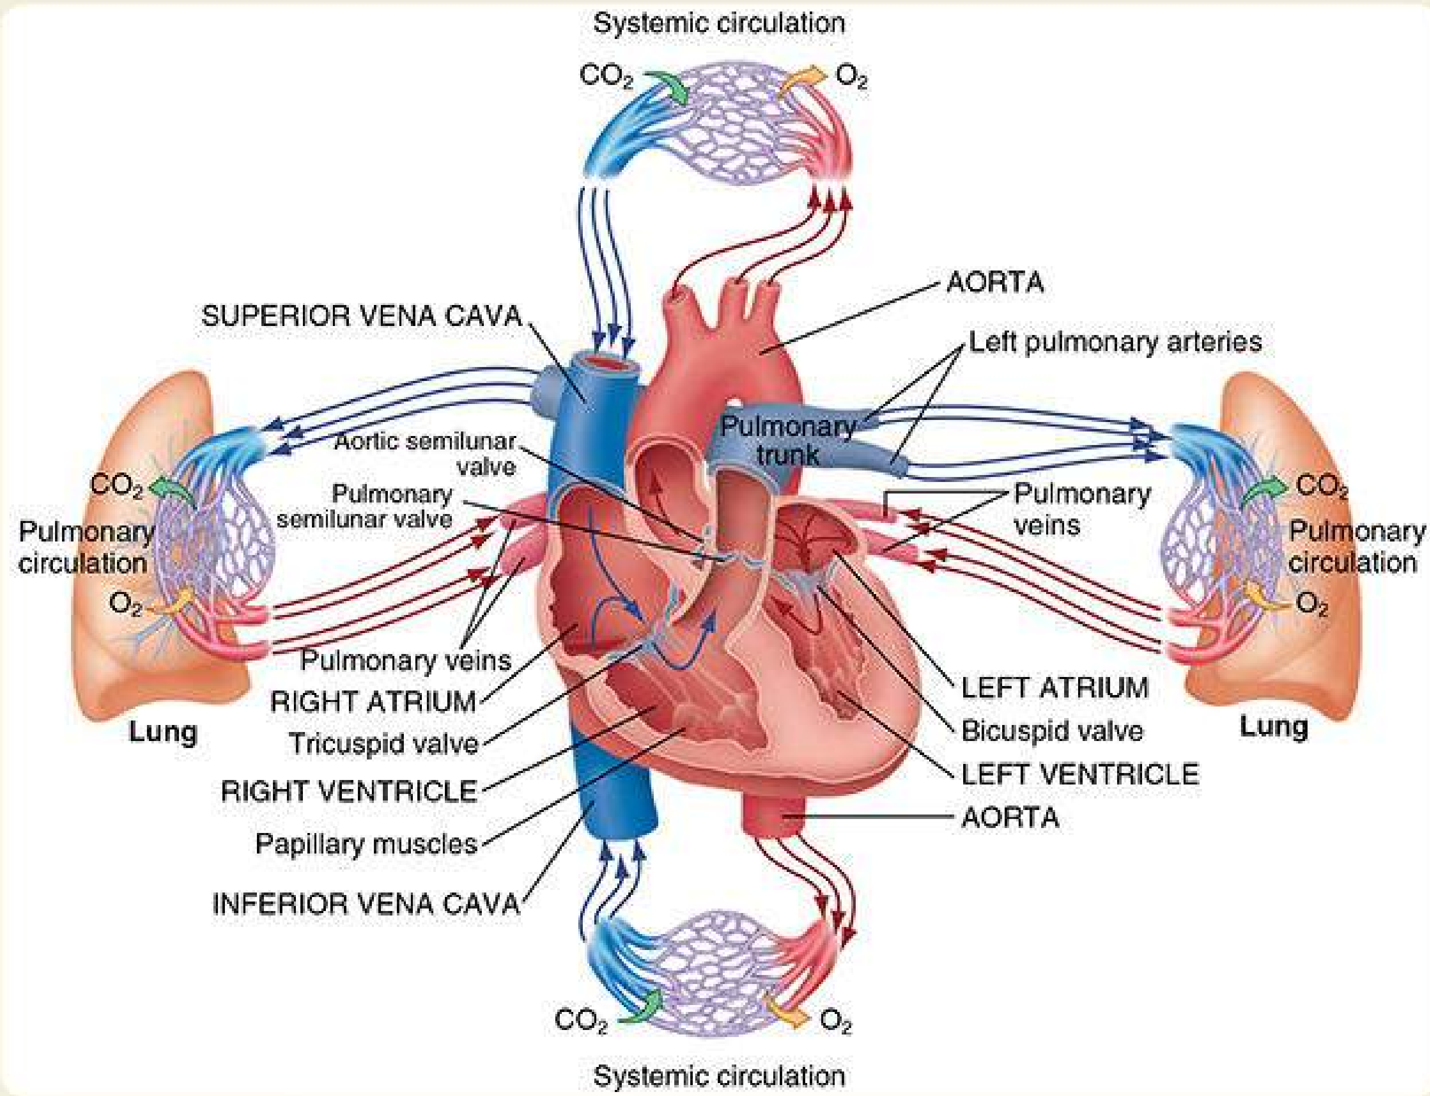

Figure 12-1 The cardiovascular system consists of three parts: the pump (heart), the container (vessels), and the contents (blood). The blood carries oxygen and nutrients through the vessels to the capillary beds, where they are exchanged for waste products.

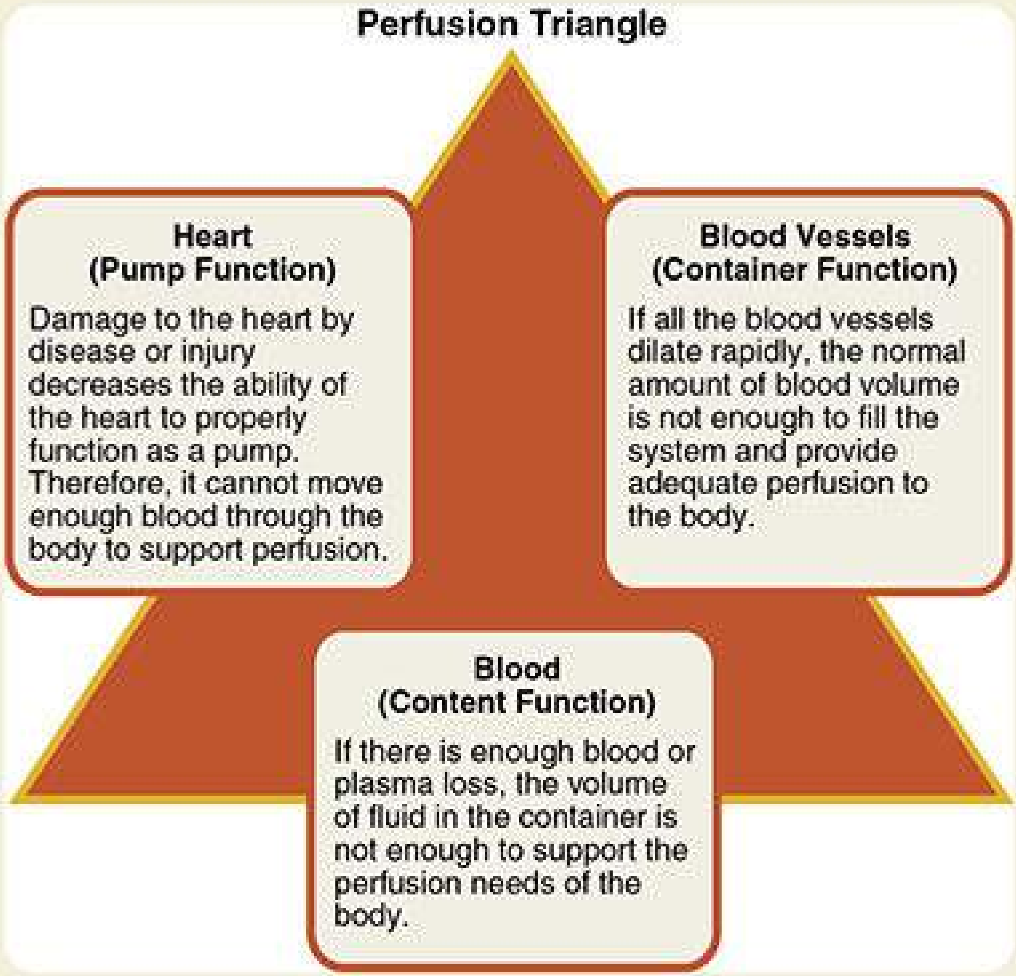

Figure 12-2 The heart, the blood vessels, and the blood represent the three parts of perfusion.

Blood clots are an important response by the body to control blood loss; however, be aware that clots are unstable and prone to rupture because blood keeps moving as a result of pressure generated by the contractions of the heart and the actions of the blood vessels as they dilate and constrict. This pressure, called blood pressure, is usually carefully controlled by the body so that there is always sufficient circulation, or perfusion, in the various tissues and organs. Blood pressure is, in fact, a rough measure of perfusion.

Words of Wisdom

Capillary hydrostatic pressure tends to force fluids through capillary walls, whereas interstitial fluid hydrostatic pressure pushes fluid back into the cells.

Remember that blood pressure is really the pressure of blood within the vessels at any one moment in time. The *systolic* pressure is the peak arterial pressure, or pressure generated every time the heart contracts; the *diastolic* pressure is the pressure maintained within the arteries while the heart rests between heartbeats. **Pulse pressure** is the difference between the systolic and diastolic pressures (systolic – diastolic = pulse pressure). It signifies the amount of force the heart generates with each contraction. A pulse pressure less than 25 mm Hg may be seen in patients with shock.

Blood flow through the capillary beds is regulated by the capillary sphincters, circular muscular walls that constrict and dilate. These **sphincters** are under the control of the **autonomic nervous system**, which regulates involuntary functions such as sweating and digestion. Capillary sphincters also respond to other stimuli such as heat, cold, the need for oxygen, and the need for waste removal. Keep in mind that, under normal circumstances, not all cells have the same needs at the same time. For example, the stomach and intestines have a high need for blood flow during and shortly after eating, when digestion is at a peak. Between meals, blood flow is lessened, and blood is diverted to other areas. The brain, by contrast, needs a constant and consistent supply of blood to function.

Thus, regulation of blood flow is determined by cellular need and is accomplished by vessel constriction or dilation, together with sphincter constriction or dilation. Maintenance of blood flow, or perfusion, is accomplished by the heart, blood vessels, and blood working together.

Perfusion requires more than just having a working cardiovascular system, however. It also requires adequate oxygen exchange in the lungs, adequate nutrients in the form of glucose in the blood, and adequate waste removal, primarily through the lungs. Carbon dioxide is one of the primary waste products of cellular work (metabolism) in the body and is removed from the body by the lungs. This is the reason adequate ventilation and oxygenation is one of your primary concerns. The body has neural and endocrine or hormonal mechanisms in place to help support the respiratory and cardiovascular systems when the need for perfusion of vital organs is increased. These mechanisms, including the autonomic nervous system and certain chemicals called hormones, are triggered when the body senses that the pressure in the system is falling. The sympathetic side of the autonomic nervous system, which is responsible for the fight-or-flight response, will assume more control of the body's functions during a state of shock. This response by the autonomic nervous system causes the release of hormones such as epinephrine and norepinephrine. These hormones cause changes in certain body functions such as an increase in the heart rate and the strength of cardiac contractions. They also cause vasoconstriction in nonessential areas, primarily in the skin and gastrointestinal tract (peripheral vasoconstriction). Together, these actions are designed to maintain pressure in the system and, as a result, sustain perfusion of all vital organs. The parasympathetic nervous system is a division of the autonomic nervous system that controls involuntary functions by sending signals to the cardiac, smooth, and glandular muscles.

Eventually, there is also a shifting of body fluids to help maintain pressure within the system. However, the response of the autonomic nervous system and hormones comes within seconds. It is this response that causes all the signs and symptoms of shock in a patient.

Causes of Shock

Shock can result from many conditions, including bleeding, respiratory failure, acute allergic reactions, and overwhelming infection. In all cases, however, the damage occurs because of insufficient perfusion of organs and tissues. As soon as perfusion stops or becomes impaired, tissues start to die, affecting all local body processes. If the conditions causing shock are not promptly stopped and reversed, death will soon follow.

Words of Wisdom

Shock is a complex physiologic process that gives subtle signs to its presence before it becomes severe. These early signs relate very closely to the events that lead to more severe shock, so it is important for you to know the underlying processes thoroughly. If you understand what causes shock, you will be able to recognize it in many patients before it gets out of control.

Understanding the basic physiologic causes of shock will better prepare you to treat it **Figure 12-3**. There are many types of shock resulting from three basic causes **Table 12-1**.

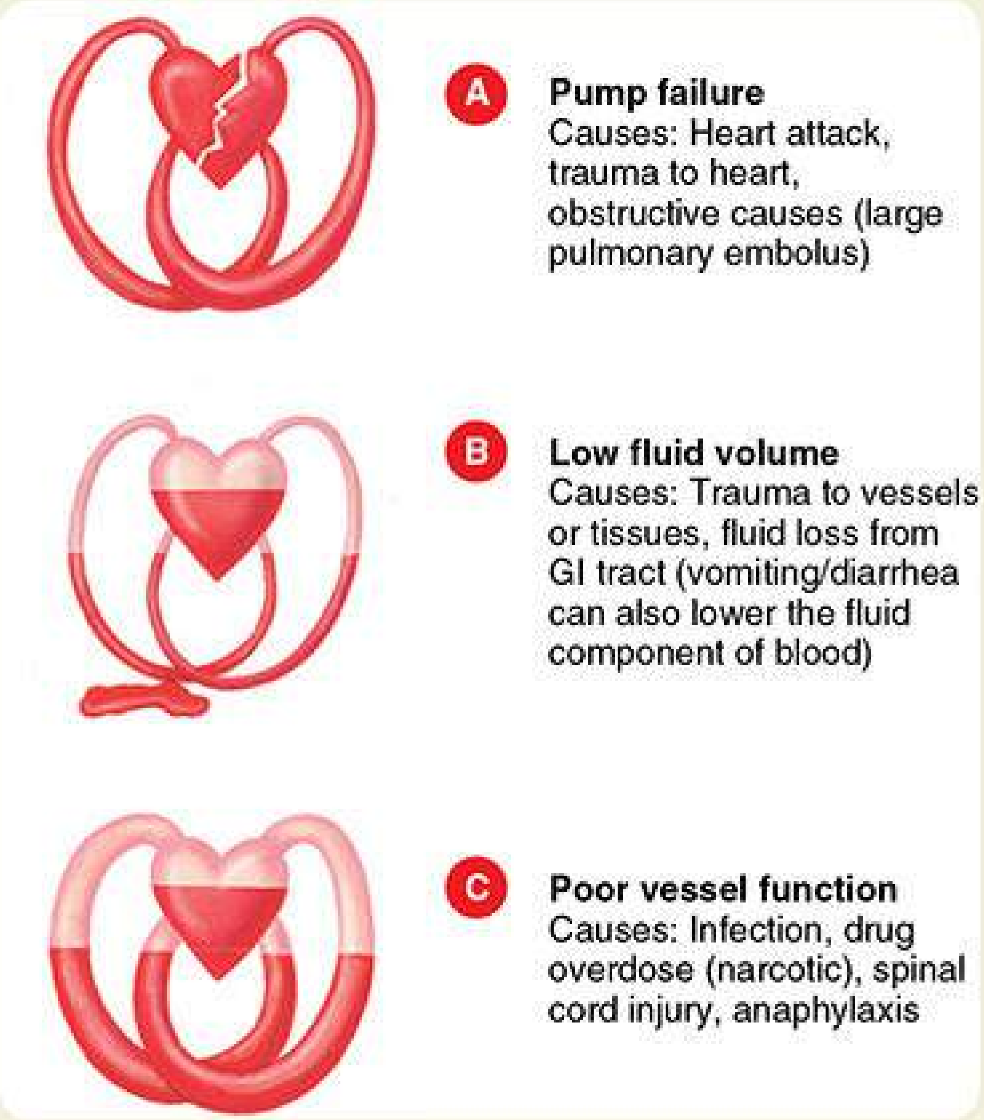

Figure 12-3 There are three basic causes of shock and impaired tissue perfusion. **A.** Pump failure occurs when the heart is damaged by disease, injury, or when an obstruction (typically in a pulmonary artery), prevents it from functioning. The heart may not generate enough energy to move the blood through the system. **B.** Low fluid volume, often a result of bleeding, leads to inadequate perfusion. **C.** The blood vessels can dilate excessively so that the blood within them, even though it is of normal volume, is inadequate to fill the system and provide efficient perfusion.

Table 12-1 Causes of Shock

Cause	Type of Shock
Pump Failure	Cardiogenic shock Obstructive shock ▪ Tension pneumothorax ▪ Cardiac tamponade ▪ Pulmonary embolism
Poor Vessel Function	Distributive shock ▪ Septic shock ▪ Neurogenic shock ▪ Anaphylactic shock ▪ Psychogenic shock
Low Fluid Volume	Hypovolemic shock ▪ Hemorrhagic shock ▪ Non–hemorrhagic shock

Types of Shock

Cardiogenic Shock

Cardiogenic shock is caused by inadequate function of the heart, or pump failure. Circulation of blood throughout the vascular system requires the constant pumping action of a normal and vigorous heart muscle. Many diseases or injuries can cause destruction or inflammation of heart muscle. Within certain limits, the heart can adapt. If too much muscular damage occurs, however, as sometimes happens after a heart attack, the heart no longer functions well. A major effect is the backup of blood into the lungs. The resulting buildup of fluid within the pulmonary tissue is called pulmonary edema. **Edema** is the presence of abnormally large amounts of fluid between cells in body tissues, causing swelling of the affected area **Figure 12-4**. Pulmonary edema leads to impaired respiration, which may be manifested by an increased respiratory rate and abnormal lung sounds.

The muscular contraction of the heart moves blood through the vessels at distinct pressures. For blood to circulate efficiently throughout the entire system, there must be the right amount of pressure and an adequate number of heartbeats. For this reason, the heart has its own electrical system that initiates and regulates its beating. Disease or injury can damage or destroy this system, causing irregular and uncoordinated beats, beats that are too slow (fewer than 60 beats/min), or beats that are too fast (more than 100 beats/min).

Cardiogenic shock develops when the heart cannot maintain sufficient output (cardiac output) to meet the demands of the body. Cardiac output is the volume of blood that the heart can pump per minute and is dependent upon several factors. First, the heart must have adequate strength, which is largely determined by the ability of the heart muscle to contract. This ability to contract is referred to as **myocardial contractility**. Second, the heart must receive adequate blood to pump. As the volume of blood coming to the heart increases, the precontraction pressure in the heart builds up. This precontraction pressure is known as **preload**. As preload increases, the volume of blood within the ventricles increases, which causes the heart muscle to stretch. When the muscle is stretched, myocardial contractility increases, leading to greater force of contraction and increased cardiac output. Lastly, the resistance to flow in the peripheral circulation must be appropriate. The force or resistance against which the heart pumps is known as **afterload**. In general, as afterload increases, cardiac output decreases. Increased afterload may also cause the heart to overwork while trying to maintain adequate cardiac output. High afterload is often the reason that heart failure develops in patients with hypertension. Cardiogenic shock may result from low cardiac output due to high afterload, low preload, poor contractility, or any combination of the three.

YOU are the Provider — PART 2

You arrive at the clinic and are escorted to the patient by a clinic technician. You find the patient lying supine on an examination table. She is conscious, but restless, and her skin is notably pale and diaphoretic. She has a blanket covering her, and she is receiving oxygen via a nasal cannula at 4 L/min. Several attempts at establishing intravenous (IV) access were unsuccessful. Your assessment of the patient reveals the following:

Recording Time: 0 Minutes	
Appearance	Restless, pale, and diaphoretic
Level of consciousness	Conscious and alert, but restless
Airway	Open; clear of secretions or foreign bodies
Breathing	Increased rate; adequate depth
Circulation	Radial pulses, weak and rapid; skin is cool, pale, and diaphoretic

The clinic physician tells you that the patient presented approximately 15 minutes ago reporting abdominal pain and rectal bleeding, which apparently started about 24 hours ago. There is no history of trauma, she has a history of irritable bowel syndrome, she takes lubiprostone (Amitiza) and dicyclomine hydrochloride (Bentyl), and she is allergic to codeine.

3. Based on your assessment, what changes, if any, in the patient’s current treatment are required?

4. How do the patient’s signs and symptoms correlate with the body’s response to inadequate perfusion?

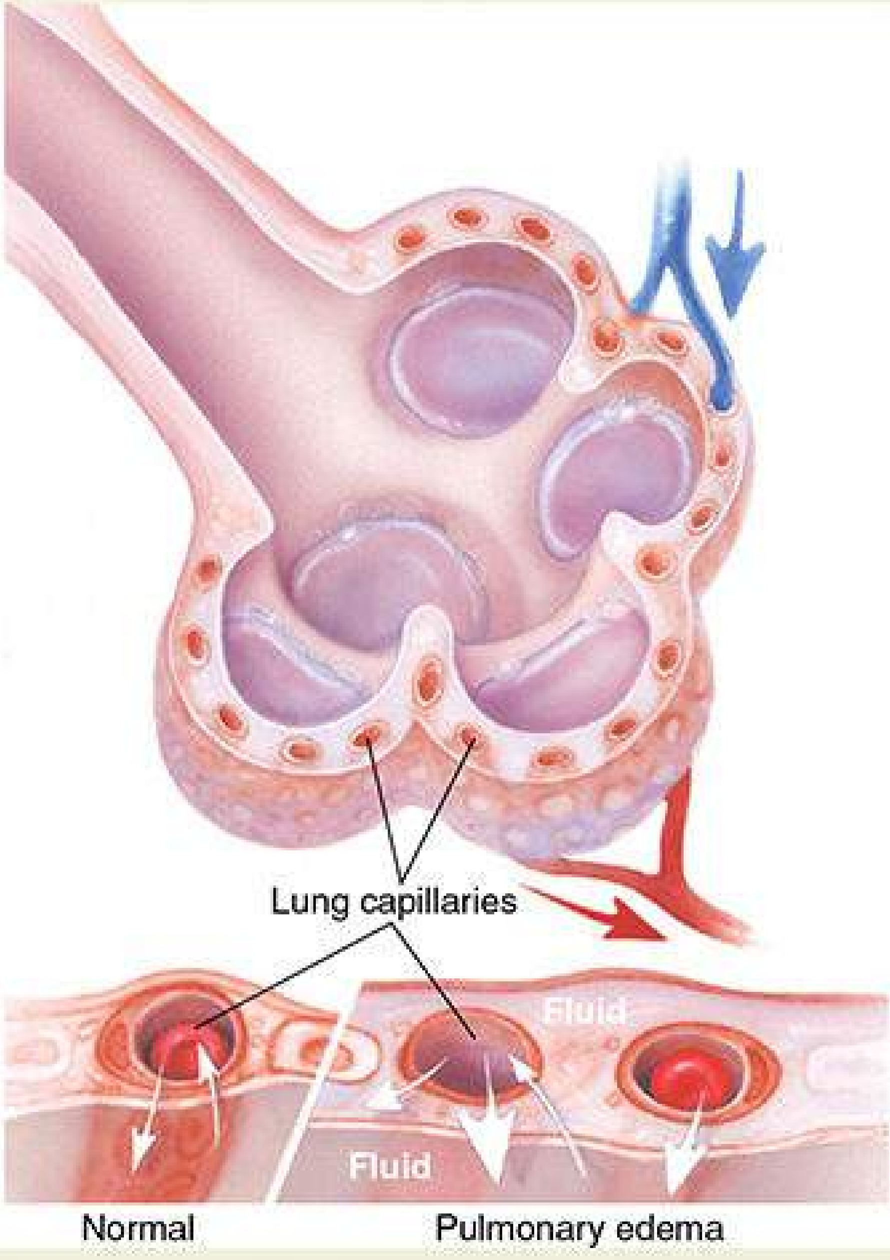

Figure 12-4 Pulmonary edema develops as a result of fluid buildup within the pulmonary tissue. The edema causes swelling and leads to impaired ventilation.

▶ Obstructive Shock

Obstructive shock is cauased by a mechanical obstruction which prevents an adequate volume of blood to fill the heart chambers. Three of the most common examples of obstructive shock are cardiac tamponade, tension pneumothorax, and pulmonary embolism.

A collection of fluid between the pericardial sac and the myocardium is called a **pericardial effusion**. If the effusion becomes large enough, it can prevent the ventricles from filling with blood—a condition called **cardiac tamponade** or pericardial tamponade. This life-threatening condition may be caused by blunt or penetrating trauma that causes hemorrhage around the heart. Large pericardial effusions leading to cardiac tamponade can also be seen in patients with cancer and autoimmune diseases. Cardiac tamponade occurs when blood leaks into the space between the tough fibrous membrane known as the pericardium and the outer walls of the heart, an area called the pericardial sac. As more blood or fluid accumulates in this confined space, the outer walls of the heart become compressed. Because the pericardium has a limited ability to stretch, the accumulated blood or fluid in the pericardial space eventually exerts back pressure on the outer walls of the heart, compressing the walls of the heart, and preventing the heart from completely refilling with blood. Continued pressure within the pericardial sac obstructs the flow of blood into the heart, resulting in decreased outflow from the heart Figure 12-5. Signs and symptoms of cardiac tamponade are referred to as Beck triad, the presence of jugular vein distention, muffled heart sounds, and a narrowing pulse pressure, where the systolic and diastolic blood pressures start to merge (systolic pressure drops and the diastolic pressure rises).

Another obstructive condition occurs with a tension pneumothorax Figure 12-6. A tension pneumothorax is caused by damage to the lung tissue. This damage allows air normally held within the lung to escape into the chest cavity. The lung collapses, and if a pneumothorax is allowed to continue untreated, a sufficient amount of air will accumulate within the chest cavity and begin applying pressure to the structures in the mediastinum. The primary organs in this area are the heart and great vessels (aorta and vena cava). When the trapped air begins to shift the chest organs toward the uninjured side, a pneumothorax becomes known as a tension pneumothorax, which is a very serious and life-threatening condition. As pressure from one side of the chest begins to push the mediastinum toward the other side, the vena cava loses its ability to stay fully expanded. This mechanical compression of the vena cava leads to reduced blood return to the right side of the heart. Blood pressure drops. The patient becomes anxious and short of breath. The heart and respiratory rates increase and become shallower. You may notice difficulty when attempting to ventilate the patient with a bag-valve mask (BVM) as well. The affected side will have decreased or absent lung sounds and the patient will become cyanotic. Tracheal deviation is a late sign of tension pneumothorax.

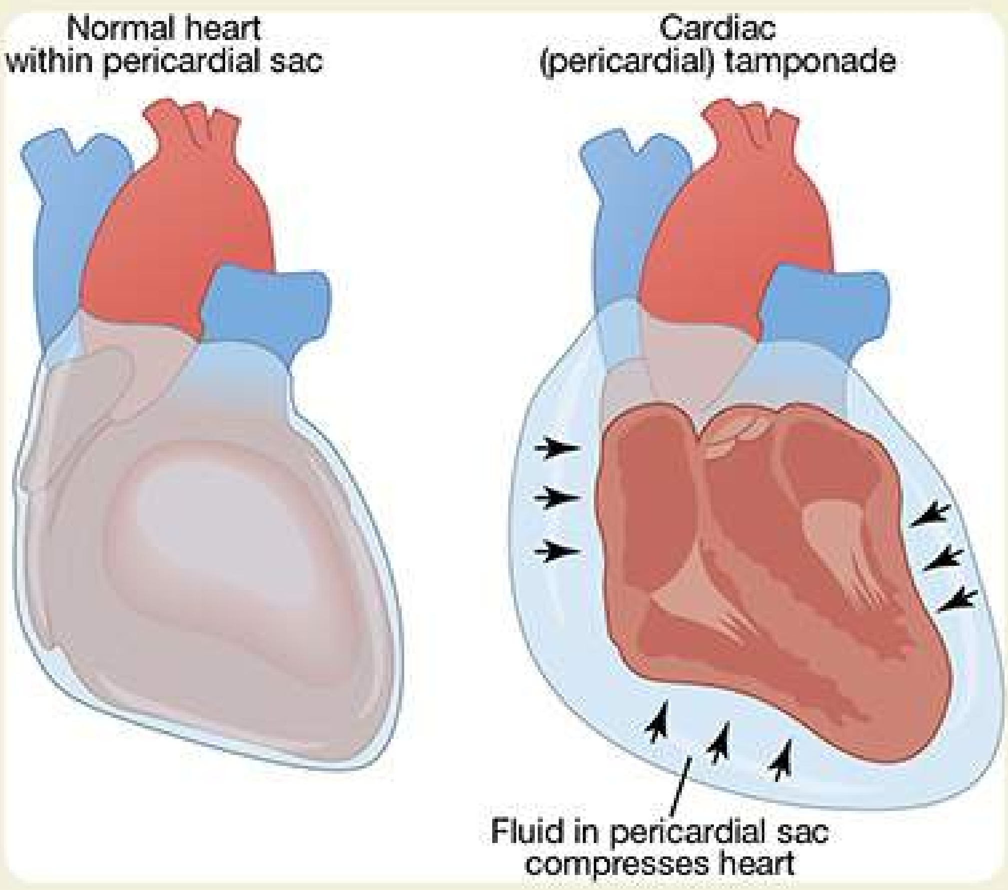

Figure 12-5 Impaired ventricular filling from a pericardial effusion causes cardiac tamponade.

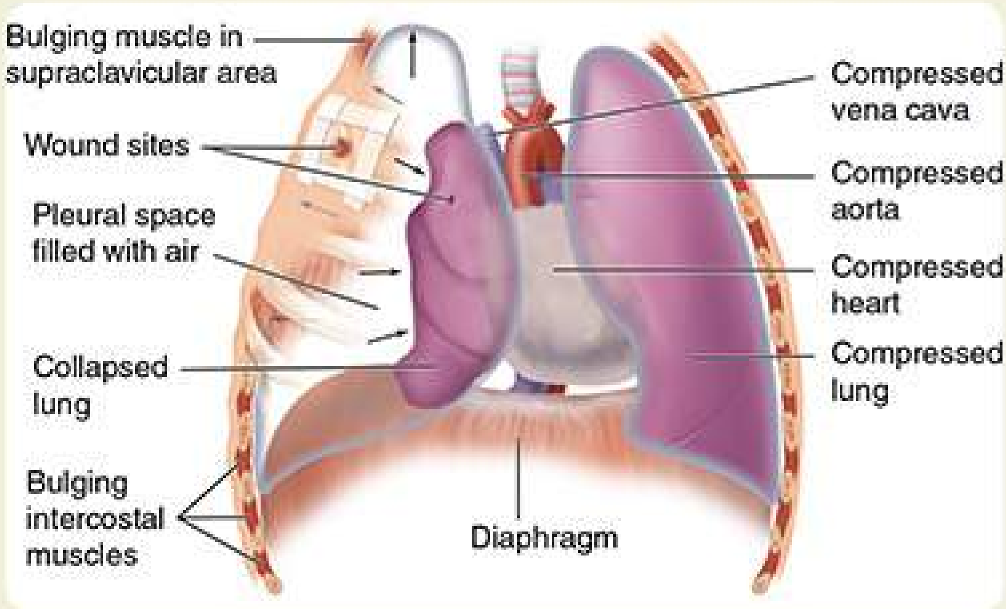

Figure 12-6 A tension pneumothorax is accumulation of air in the pleural space, which eventually compresses the heart and great vessels.

A massive and centrally located pulmonary embolism can also lead to obstructive shock. A **pulmonary embolism** is a blood clot that occurs in the pulmonary circulation and blocks the flow of blood through the pulmonary vessels. When a massive pulmonary embolism occurs, it can prevent blood from being pumped from the right side of the heart to the left, resulting in complete backup of blood in the right ventricle and leading to catastrophic obstructive shock and complete pump failure.

Distributive Shock

Distributive shock results when there is widespread dilation of the small arterioles, small venules, or both. As a result, the circulating blood volume pools in the expanded vascular beds and tissue perfusion decreases. The four most common types of distributive shock are septic shock, neurogenic shock, anaphylactic shock, and psychogenic shock.

Septic Shock

Septic shock occurs as a result of severe infections, usually bacterial, in which toxins (poisons) are generated by the bacteria or by infected body tissues. In this condition, the toxins damage the vessel walls, causing increased cellular permeability. The vessel walls leak and are unable to contract well. Widespread dilation of vessels, in combination with plasma loss through the injured vessel walls, results in shock.

Septic shock is a complex problem. First, there is an insufficient volume of fluid in the container, because much of the plasma has leaked out of the vascular system (hypovolemia). Second, the fluid that has leaked out often collects in the respiratory system, interfering with respiration. Third, the vasodilation leads to a larger-than-normal vascular bed to contain the smaller-than-normal volume of intravascular fluid.

Neurogenic Shock

Damage to the spinal cord, particularly at the upper cervical levels, may cause significant injury to the part of the nervous system that controls the size and muscular tone of the blood vessels. **Neurogenic shock** is usually the result of high spinal cord injury. Although not as common, there are medical causes as well. These include brain conditions, tumors, pressure on the spinal cord, and spina bifida. In neurogenic shock, the muscles in the walls of the blood vessels are cut off from the sympathetic nervous system and nerve impulses that cause them to contract. Therefore, all vessels below the level of the spinal injury dilate widely, increasing the size and capacity of the vascular system **Figure 12-7** and causing blood to pool.

The available 6 L of blood in the body can no longer fill the enlarged vascular system. Even if there is no blood or fluid loss, perfusion of organs and tissues becomes inadequate, and shock occurs. In this condition, a radical change in the size of the vascular system has caused shock. Characteristic signs of this type of shock are the absence of sweating below the level of injury, normal and low heart rate in the presence of hypotension, and normal warm skin.

Words of Wisdom

With neurogenic shock, many other functions that are under the control of the same part of the nervous system are also lost. The most important of them, in an acute injury setting, is the ability to control body temperature. Body temperature in a patient with neurogenic shock can rapidly fall to match that of the environment. In many situations, significant hypothermia occurs, severely complicating the situation. **Hypothermia** is a condition in which the internal body temperature falls below 95°F (35°C), usually after prolonged exposure to cool or freezing temperatures. Maintenance of body temperature is always an important element of treatment for a patient in shock.

Words of Wisdom

Microcirculation is a term used to describe the small vessels in the vasculature that are embedded within organs and responsible for the distribution of blood within tissues. True capillaries are part of microcirculation. They branch off the arterioles and allow for exchange between cells and circulation. The arteriole-venule shunts are short vessels that connect the arteriole and venule at opposite sides. The main functions of microcirculation include the regulation of blood flow and tissue perfusion, blood pressure, tissue fluid, delivery of oxygen, removal of carbon dioxide, and the regulation of body temperature and inflammation.

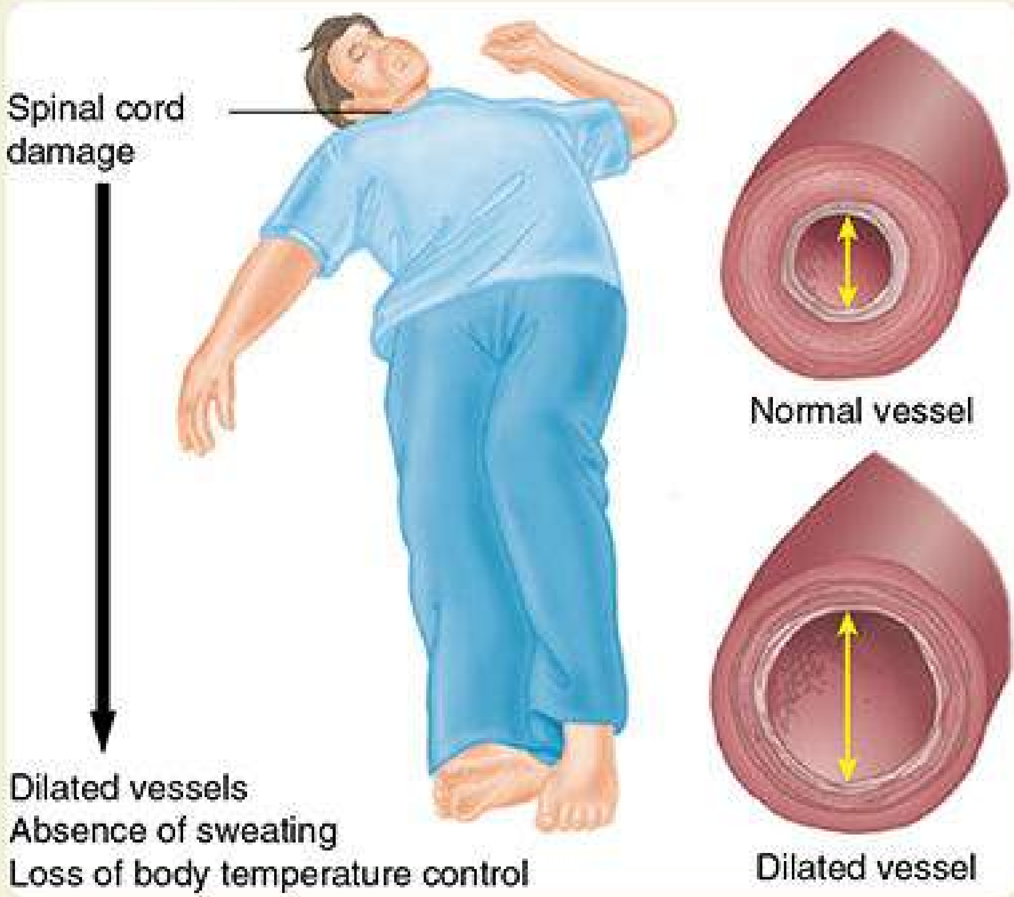

Figure 12-7 Damage to the spinal cord can cause significant injury to the part of the nervous system that controls the size and muscle tone of blood vessels. If the muscles in the blood vessels are cut off from their impulses to contract, the vessels dilate widely, increasing the size and capacity of the vascular system. The blood in the body can no longer fill the enlarged vessels; inadequate perfusion results.

Anaphylactic Shock

Anaphylaxis, or **anaphylactic shock**, occurs when a person reacts violently to a substance to which he or she has been sensitized. **Sensitization** means becoming sensitive to a substance that did not initially cause a reaction. Do not be misled by a patient who reports no history of allergic reaction to a substance on first or second exposure. Each subsequent exposure after sensitization tends to produce a more severe reaction.

Instances that cause severe allergic reactions commonly fall into the following four categories of exposure:

- Injections (tetanus antitoxin, penicillin)
- Stings (wasps, bees, hornets, ants)
- Ingestion (fish, shellfish, nuts, eggs, medication)
- Inhalation (dust, pollen, mold)

Anaphylactic reactions can develop within minutes or even seconds after contact with the substance to which the patient is allergic. There may also be a second phase reaction that occurs 1 to 8 hours after the initial reaction. The signs of such allergic reactions are very distinct and not seen with other forms of shock. Table 12-2 lists the signs of anaphylactic shock in the order in which they typically occur. Note that **cyanosis** (blue discoloration of the skin) is a late sign of anaphylactic shock.

In anaphylactic shock, there is no loss of blood, no mechanical vascular damage, and only a slight possibility of direct cardiac muscular injury. Instead, there is widespread vascular dilation, increased permeability, and bronchoconstriction. The combination of poor oxygenation and poor perfusion in anaphylactic shock may easily prove fatal.

Words of Wisdom

Skin findings such as hives without evidence of any other signs and symptoms of anaphylaxis indicate only allergy, not anaphylaxis. Monitor these patients carefully for development of other findings that suggest anaphylaxis.

Psychogenic Shock

A patient in **psychogenic shock** has had a sudden reaction of the nervous system that produces a temporary, generalized vascular dilation, resulting in fainting, or **syncope**. The fainting episode is temporary, and the patient rouses soon after. Syncope occurs when blood pools in the dilated vessels, reducing the blood supply to the brain; as a result, the brain ceases to function normally, and the patient then faints. While there are many causes of syncope, it is important to realize that some are of a serious nature but others are not. Syncope that is potentially life threatening may be caused by events such as an irregular heartbeat or a brain **aneurysm**. Other non–life-threatening events that cause syncope may be the receipt of bad news or experiencing fear or unpleasant sights (like the sight of blood).

Table 12-2 Signs and Symptoms of Anaphylactic Shock

System	Signs and Symptoms
Skin	▪ Flushed, itchy, or burning, especially over the face and upper part of the chest ▪ Urticaria (hives), which may spread over large areas of the body ▪ Edema, especially of the face, tongue, and lips ▪ Pallor ▪ Cyanosis (a bluish cast to the skin resulting from poor oxygenation of circulating blood) about the lips
Circulatory System	▪ Dilated peripheral blood vessels ▪ Increased vessel permeability ▪ Drop in blood pressure ▪ Weak, barely palpable pulse
Respiratory System	▪ Sneezing or itching in the nasal passages ▪ Stridor ▪ Upper airway obstruction ▪ Tightness in the chest, with a persistent dry cough ▪ Wheezing and dyspnea (difficulty breathing) ▪ Secretions of fluid and mucus into the bronchial passages, alveoli, and lung tissue, causing coughing ▪ Constriction of the bronchi; difficulty drawing air into the lungs ▪ Forced expiration, requiring exertion and accompanied by wheezing ▪ Cessation of breathing
Other	▪ Abdominal cramping ▪ Nausea ▪ Vomiting ▪ Altered mental status ▪ Dizziness ▪ Fainting and coma

Hypovolemic Shock

Hypovolemic shock is the result of an inadequate amount of fluid or volume in the circulatory system. There are hemorrhagic and non-hemorrhagic causes of hypovolemic shock. Injuries involving bleeding may result in hemorrhagic shock, while vomiting and diarrhea may result in non-hemorrhagic hypovolemic shock.

Hypovolemic shock also occurs with severe thermal burns. In this case, loss of intravascular plasma (the colorless part of the blood) is caused by leaking from the circulatory system into the burned tissues that lie adjacent to the injury. Likewise, crushing injuries may result in the loss of blood and plasma from damaged vessels into injured tissues.

Dehydration, the loss of water or fluid from body tissues, can cause or aggravate shock. Fluid loss may be a result of severe vomiting and/or diarrhea. Patients who are very young or old are particularly susceptible to fluid loss and therefore at risk for developing shock through dehydration. People who exercise in hot weather and are not accustomed to it may experience dehydration if they do not drink enough fluids. In these circumstances, the common factor is an insufficient volume of blood within the vascular system to provide adequate circulation to the organs of the body.

Respiratory Insufficiency

A patient with a severe chest injury, such as flail chest, or obstruction of the airway may be unable to breathe in an adequate amount of oxygen. This affects the ventilation process of respiration because not enough oxygen can be inspired to meet the metabolic demand.

An insufficient concentration of oxygen in the blood can produce a life-threatening situation as rapidly as vascular causes of shock, even if the volume of blood, the volume of the vessels, and the action of the heart are all normal. Without oxygen, the organs in the body cannot survive, and their cells promptly start to deteriorate.

Anemia is an abnormally low number of red blood cells. Red blood cells (RBCs) contain hemoglobin, an iron-containing pigment that is responsible for 96% of the transport of oxygen from the lungs to the cells of the body. Each hemoglobin molecule is able to bind to and thus carry four molecules of oxygen. Anemia may be the result of either chronic or acute bleeding, a deficiency in certain vitamins or minerals, or an underlying disease process. If anemia is present, tissues may become hypoxic because the blood is unable to deliver adequate amounts of oxygen to the tissues, even though the available hemoglobin is fully saturated with oxygen and the lungs are delivering enough oxygen to the blood. In this situation, a pulse oximeter may indicate that there is adequate saturation, even though the tissues are actually hypoxic. This type of hypoxia is known as hypoxemic hypoxia.

Certain types of poisoning may also affect the ability of cells to metabolize or carry oxygen. Carbon monoxide has a 250 times greater affinity for hemoglobin than does oxygen. If a patient is in an environment where he or she inhales carbon monoxide, it will bind to the hemoglobin, forming carboxyhemoglobin. Because the carbon monoxide is bound tightly to the hemoglobin, oxygen cannot be transported to the tissues. In another type of poisoning that results in severe functional hypoxia, cyanide impairs the ability of cells to metabolize oxygen effectively, resulting in cellular asphyxia.

The Progression of Shock

Although you cannot see shock, you can see its signs and symptoms Table 12-3. The early stage of shock, while the body can still compensate for blood loss, is called **compensated shock**. The late stage, when blood pressure is falling, is called **decompensated shock**. When shock has progressed too far, it is irreversible; however, there is no way to assess when a patient has reached that point. It is imperative to recognize and treat shock early—well before the patient transitions into the decompensated phase.

Remember that blood pressure may be the last measurable factor to change in shock. As we have seen, the body has several automatic mechanisms to compensate for initial blood loss and to help maintain blood pressure. Thus, by the time you detect a drop in blood pressure, shock is well developed. This is particularly true in infants and children, who can maintain their blood pressure until they have blood loss that is more than half their blood volume. By the time blood pressure drops in infants and children who are in shock, they are close to death.

Table 12-3 Progression of Shock

Progression	Signs and Symptoms
Compensated Shock	▪ Agitation ▪ Anxiety ▪ Restlessness ▪ Feeling of impending doom ▪ Altered mental status ▪ Weak, rapid (thready), or absent pulse ▪ Clammy (pale, cool, moist) skin ▪ Pallor, with cyanosis about the lips ▪ Shallow, rapid breathing ▪ Air hunger (shortness of breath), especially if there is a chest injury ▪ Nausea or vomiting ▪ Capillary refill of longer than 2 seconds in infants and children ▪ Marked thirst ▪ Narrowing pulse pressure
Decompensated Shock	▪ Falling blood pressure (systolic blood pressure of 90 mm Hg or lower in an adult) ▪ Labored or irregular breathing ▪ Ashen, mottled, or cyanotic skin ▪ Thready or absent peripheral pulses ▪ Dull eyes, dilated pupils ▪ Poor urinary output

You should expect shock in many emergency medical situations. For example, you would expect shock to accompany massive external or internal bleeding. You should also expect shock if a patient has any one of the following conditions:

- Multiple severe fractures
- Abdominal or chest injury
- Spinal injury
- A severe infection
- A major heart attack
- Anaphylaxis

Words of Wisdom

Frequently taking and recording vital signs—and observing perfusion indicators such as skin condition and mental status—will give you a window into the progression of shock. Monitoring vital signs every 5 minutes may reveal a pattern that will alert you to the presence of evolving shock. If suspected, expedite transport and begin treatments for shock immediately.

Patient Assessment for Shock

Scene Size-up

As you approach the scene, be alert to potential hazards to your safety. If this is a trauma scene or bleeding is suspected, put on gloves and eye protection, at a minimum. Put several pairs of gloves in your pocket for easy access in case your gloves tear or there are multiple patients with bleeding.

In incidents involving violence, such as assaults or gunshot wounds, make sure that police are on scene. At times you may need to stage several blocks away until law enforcement personnel have secured the area.

When you first see the patient, observe the scene and patient for clues to determine the nature of the illness or the mechanism of injury. This could help you anticipate the potential for development of shock.

Primary Assessment

The primary assessment for a patient with suspected shock should include a rapid exam to determine level of consciousness, identify and manage life-threatening concerns as they are found, and determine priority of the patient and transport. A patient with massive hemorrhage may require a tourniquet (or direct pressure dressings when tourniquets are not feasible or available) *before* the airway is opened. If the patient has obvious life-threatening external bleeding, it should be addressed first (even *before* airway and breathing) by controlling it quickly, then the ABCs can be assessed and treated, and treatments for shock provided.

YOU are the Provider — PART 3

You continue with the treatment initiated by the clinic; however, you remove the nasal cannula and apply high-flow oxygen via a nonrebreathing mask. Your partner takes the patient's vital signs and reports them to you and the clinic physician.

Recording Time: 4 Minutes	
Respirations	24 breaths/min; shallow
Pulse	120 beats/min; weak
Skin	Pale, cool, and diaphoretic
Blood pressure	108/58 mm Hg
Oxygen saturation (Spo_2)	94% (on oxygen)

You bring the stretcher into the room and prepare the patient for immediate transport. The patient remains conscious and alert, but is becoming increasingly restless and tells you that she is extremely thirsty.

5. Is the patient in compensated or decompensated shock? How can you tell?

Provide high-flow oxygen to assist in perfusion of damaged tissues. If the patient has signs of hypoperfusion, treat aggressively and provide rapid transport to the hospital. Request advanced life support (ALS) as necessary to assist with more aggressive shock management. Do not delay transport of the seriously injured trauma patient to complete nonlifesaving treatments in the field, such as splinting extremity fractures; instead, complete these types of treatments en route to the hospital.

When you first visualize your patient, quickly form an initial general impression. This will help you develop an early sense of urgency for care of a patient who appears "sick."

Once you are close to the patient, determine the need for manual spinal stabilization and assess the patient's level of consciousness using the AVPU scale. A patient who has an altered level of consciousness (LOC) may need emergency airway management. If the patient is awake and alert, determine a chief complaint.

Next, quickly assess the airway to ensure it is patent. Be alert to abnormal airway sounds such as gurgling (suction the airway) or stridor, indicating partial airway obstruction. Consider an adjunct such as an oropharyngeal or nasopharyngeal airway for a patient with an altered LOC.

Quickly assess breathing in the patient. Observe the patient for signs of accessory muscle use such as the muscles of the neck, intercostal retractions, or abnormal use of the abdominal muscles. An increased respiratory rate is often an early sign of impending shock. Assess for wheezes or other abnormal breath sounds. Administer high-flow oxygen, or, if needed, assist respirations with a BVM.

Assessing the patient's circulatory status can reveal important clues regarding the presence of shock. Check for the presence of a distal pulse. If you cannot obtain a distal pulse, assess for a central pulse. Make a rapid determination if the pulse is fast, slow, weak, strong, or altogether absent. A rapid pulse suggests compensated shock. In shock or compensated shock, the skin may be cool, clammy, or ashen. If the patient has no pulse and is not breathing, immediately begin cardiopulmonary resuscitation (CPR). Assess for and identify any life-threatening bleeding in trauma patients; if serious bleeding is discovered, treat it at once. You must also quickly assess skin temperature, condition, and color, and check for capillary refill time.

Words of Wisdom

In general, if an adult patient has a radial pulse, the systolic blood pressure will be at least 90 mm Hg; if the patient has a femoral pulse, the systolic pressure will be at least 80 mm Hg; and if the patient has a carotid pulse, the systolic pressure will be at least 70 mm Hg. This is why during CPR we immediately check for a carotid pulse; it is the last to go.

Once you have assessed perfusion, determine whether the patient should be treated as high priority, whether ALS is needed, and which facility to transport to.

Words of Wisdom

Trauma patients with shock, or a suspicious mechanism of injury (MOI), generally should go to a trauma center. Sometimes, local protocols dictate that a patient should be transported to the nearest hospital for stabilization prior to transfer to a definitive treatment center.

History Taking

After the life threats have been managed during the primary assessment, determine the chief complaint. Obtain a medical history and be alert for injury-specific signs and symptoms as well as any pertinent negatives such as loss of sensation. Quickly obtain a SAMPLE history from the patient. Remember, if the patient has a significant change in LOC before arrival at the hospital, you should provide the hospital personnel with this important information.

Secondary Assessment

The secondary assessment is a more detailed, comprehensive examination of the patient that is used to uncover injuries that may have been missed during the primary assessment. The secondary assessment begins by repeating the primary assessment followed by a focused assessment. In some instances, such as a critically injured patient or short transport time, you may not have time to conduct a secondary assessment.

If your patient is a trauma patient with a significant mechanism of injury or multiple injuries, one who gives you a poor initial general impression, or you found problems in the primary assessment, perform a secondary assessment of the entire body. If your patient has a medical problem but is not responsive or problems were noted in the primary assessment, perform a secondary assessment of the entire body. These assessments should be performed quickly but thoroughly to ensure that you do not miss any significant or life-threatening problems or delay needed care.

If your patient has only a simple mechanism of injury, such as a twisted ankle, focus your examination on the specific area affected. Whether your examination is of the entire body or of a specific area, if a life-threatening problem is found, treat it immediately.

When time permits and the patient's condition is stable, perform a thorough examination of the patient. This includes a complete neurologic assessment.

Obtain a complete set of baseline vital signs. If the patient's condition is unstable or could become unstable, reassess vital signs every 5 minutes. If the patient is in stable condition, reassess vital signs every 10 to 15 minutes. Baseline vital signs will help you trend changes in your patient.

In addition to hands-on assessment, use monitoring devices to quantify the patient's oxygenation and circulatory status. Use a noninvasive technique to monitor blood pressure and a pulse oximeter to evaluate the effectiveness of oxygenation. It is recommended to assess the patient's blood pressure with a sphygmomanometer (blood pressure cuff) and stethoscope (manually), before using a noninvasive blood pressure monitor, to establish a baseline blood pressure and to determine the accuracy of the noninvasive blood pressure monitor.

Reassessment

Reassess the patient's vital signs, interventions, chief complaint, ABCs, and mental status. You must determine what interventions are needed for your patient based on the assessment findings. Focus on supporting the cardiovascular system. Treat for shock early and aggressively by providing oxygen and keeping the patient warm.

Emergency Medical Care for Shock

You must begin immediate treatment for shock as soon as you realize that the condition may exist. As with any type of patient care, you should begin by following standard precautions. Control all obvious external bleeding. Place dry, sterile dressings over the bleeding sites, and secure with bandages. If direct pressure is not rapidly successful in the control of bleeding from an extremity, apply a tourniquet proximal to the bleeding site according to local protocol **Figure 12-8**. The use of tourniquets is further described in Chapter 25, *Bleeding*. Make sure the patient has an open airway. Maintain manual in-line stabilization if necessary, and check breathing and pulse.

Comfort, calm, and reassure the patient, while maintaining the patient in the supine position. Never allow patients to eat or drink anything prior to being evaluated by a physician. Patients who have had a severe heart attack or who have lung disease may find it easier to breathe in a sitting or semi-sitting position.

If spinal immobilization is indicated, splint the patient on a backboard. Do not delay transport by applying individual splints in the field when shock is present. If time allows, splint individual extremity fractures during transport. This minimizes pain, bleeding, and discomfort, all of which can aggravate shock. It also prevents the broken bone ends from further damaging adjacent soft tissue.

Remember that inadequate ventilation may be a major factor in the development of shock. Always provide oxygen, assist with ventilations, and use airway control adjuncts as needed, and continue to monitor the patient's breathing. To prevent the loss of body heat, place blankets under and over the patient. Be careful not to overload the patient with covers or attempt to warm the body too much; it is best for the patient to maintain a normal body temperature. Do not use external heat sources, such as hot water bottles or heating pads. They may harm a patient in shock by causing vasodilation and decreasing blood pressure even more.

Figure 12-8 If direct pressure does not quickly control bleeding from an extremity, a tourniquet should be applied proximal to the bleeding site.

Words of Wisdom

Consider whether or not you need to treat each patient you encounter for shock. Many conditions can lead to shock, such as infections, allergic reactions, trauma, and severe dehydration. Learn to recognize shock early and expedite the care and transport for all patients with signs of shock.

Transport the patient and treat additional injuries en route. Consider rendezvousing with ALS if possible, and consider aeromedical transport.

Do not give the patient anything by mouth, no matter how urgently you are asked. To relieve the intense thirst that often accompanies shock, give the patient a moistened piece of gauze to chew or suck.

Accurately record the patient's vital signs approximately every 5 minutes throughout treatment and transport. It is essential to transport trauma patients to the ED as rapidly as possible for definitive treatment. The Golden Hour, also called the Golden Period, refers to the first 60 minutes after injury, which is thought to be a critically important period for the early resuscitation and treatment of severely injured trauma patients. This concept underscores the importance of rapid evaluation, stabilization, and transport. The goal of EMS is to limit on-scene time (time on scene until transport to hospital is started) to 10 minutes or less. Remember to speak calmly and reassuringly to a conscious patient throughout assessment, care, and transport.

Table 12-4 lists the general supportive measures for the major types of shock. Not every measure is used for every type of shock.

Treating Cardiogenic Shock

The patient who is in shock as a result of a heart attack simply cannot generate the necessary power to pump blood throughout the circulatory system.

Keep in mind that chronic lung disease will aggravate cardiogenic shock. If the patient has chronic obstructive pulmonary disease and heart disease, oxygenation of the blood passing through the lungs is impaired. Because fluid is collecting in the lungs, this patient is often able to breathe better in a sitting or semi-sitting position and may tell you so.

Usually, patients with cardiogenic shock do not have any injury, but they may be having chest pain. Such a patient may have taken nitroglycerin before your arrival and may want to take more. Patients in cardiogenic shock should not receive nitroglycerin; by definition they are hypotensive. In addition to low blood pressure, other signs include a weak, irregular pulse; cyanosis about the lips and underneath the fingernails; anxiety; and nausea.

YOU are the Provider — PART 4

The patient is placed onto the stretcher and loaded into the ambulance. You quickly gather the patient records from the clinic physician and begin transport to a hospital that is only 10 minutes away. En route, you continue with your treatment and reassess her condition.

Recording Time: 11 Minutes	
Level of consciousness	Responsive to pain only
Respirations	30 breaths/min; shallower
Pulse	130 beats/min; absent radial pulses (carotid pulse present)
Skin	Pale, cool, and diaphoretic
Blood pressure	84/44 mm Hg
Spo_2	89% (on oxygen)

6. How has your patient's condition changed?

7. Are adjustments in your current interventions required? If so, what?

Table 12-4 Types of Shock

Type of Shock	Examples of Potential Causes	Signs and Symptoms	Treatment
Cardiogenic	Inadequate heart function Disease of muscle tissue Impaired electrical system Disease or injury	Chest pain Irregular pulse Weak pulse Low blood pressure Cyanosis (lips, under nails) Cool, clammy skin Anxiety Crackles (rales) Pulmonary edema	Position comfortably Administer high-flow oxygen Assist ventilations Transport promptly Consider ALS

Obstructive	Mechanical obstruction of the cardiac muscle causing a decrease in cardiac output
	1. Tension pneumothorax
	2. Cardiac tamponade
	3. Pulmonary embolism
		Dependent on cause:
		▪ Dyspnea
		▪ Rapid, weak pulse
		▪ Rapid, shallow breaths
		▪ Decreased lung compliance
		▪ Unilateral, decreased, or absent breath sounds
		▪ Decreased blood pressure
		▪ Jugular vein distention
		▪ Subcutaneous emphysema
		▪ Cyanosis
		▪ Tracheal deviation toward unaffected side
		▪ Beck triad (cardiac tamponade):
		  ▪ Jugular vein distention
		  ▪ Narrowing pulse pressure
		  ▪ Muffled heart tones
			Dependent on cause:
			▪ ALS assist and/or rapid transport
			▪ Administer high-flow oxygen

Septic	Severe bacterial infection	Warm skin or fever Tachycardia Low blood pressure	Transport promptly Administer high-flow oxygen Assist ventilations Keep patient warm Consider ALS
Neurogenic	Damaged cervical spine, which causes widespread blood vessel dilation	Bradycardia (slow pulse) Low blood pressure Signs of neck injury	Secure airway Spinal immobilization Assist ventilations Administer high-flow oxygen Preserve body heat Transport promptly Consider ALS
Anaphylactic	Extreme life-threatening allergic reaction	Can develop within seconds Mild itching or rash Burning skin Vascular dilation Generalized edema Coma Rapid death	Manage the airway Assist ventilations Administer high-flow oxygen Determine cause Assist with administration of epinephrine Transport promptly Consider ALS

Type of Shock	Examples of Potential Causes	Signs and Symptoms	Treatment
Psychogenic (fainting)	Temporary, generalized vascular dilation Anxiety, bad news, sight of injury or blood, prospect of medical treatment, severe pain, illness, tiredness	Rapid pulse Normal or low blood pressure	Determine duration of unconsciousness Position the patient supine Record initial vital signs and mental status Suspect head injury if patient is confused or slow to regain consciousness Transport promptly
Hypovolemic	Loss of blood or fluid	Rapid, weak pulse Low blood pressure Change in mental status Cyanosis (lips, under nails) Cool, clammy skin Increased respiratory rate	Secure airway Assist ventilations Administer high-flow oxygen Control external bleeding Keep warm Transport promptly Consider ALS

Treatment of cardiogenic shock should begin by placing the patient in the position in which breathing is easiest as you give high-flow oxygen. Be ready to assist ventilations as necessary, and have suction nearby in case the patient vomits. Provide prompt transport to the emergency department (ED). If ALS is not already on the scene, consider a rendezvous en route to the hospital if available. Provide calm reassurance to a patient who has had a suspected heart attack. Frequently check for a pulse in an unresponsive patient to identify early whether CPR and an automated external defibrillator are needed.

Treating Obstructive Shock

As discussed previously, two of the most common examples of obstructive shock are cardiac tamponade and tension pneumothorax.

Increasing cardiac output should be the priority in treating cardiac tamponade. The preload must be increased because increasing pressure in the pericardium is squeezing the heart. Apply high-flow oxygen. The only definitive treatment for cardiac tamponade is surgery. Pericardiocentesis involves penetrating the pericardium with a needle to withdraw the accumulated blood from the pericardial sac. This procedure is an advanced skill, and it is rarely performed in the field.

To treat a tension pneumothorax, administer high-flow oxygen via nonrebreathing mask early to prevent hypoxia. Be cautious about providing positive-pressure ventilation to a patient with a tension pneumothorax, as the increase of air will increase the pressure in the chest. Usually the only action that can prevent eventual death from a tension pneumothorax is decompression of the injured side of the chest, relieving the pressure in the chest and allowing the heart to expand fully again. Chest decompression is an ALS skill. Ask for ALS assistance early in the call if available; however, do not delay transport waiting for the arrival of ALS.

Treating Septic Shock

The proper treatment of septic shock requires complex hospital management, including administration of antibiotics. If you suspect that a patient has septic shock, use appropriate standard precautions and transport as promptly as possible, administering high-flow oxygen during transport. Ventilatory support may be necessary to maintain adequate tidal volume. Use blankets to conserve body heat. Sepsis has become an increasingly common illness. Some hospitals have instituted specialized “sepsis teams,” which, when notified, will meet the potential septic patient in the ED. Sepsis teams have protocols that decrease the amount of time spent in identification of the infectious agent and initiation of the appropriate treatment, thereby decreasing the mortality from septic shock.

Treating Neurogenic Shock

Shock that accompanies spinal cord injury is best treated by a combination of all known supportive measures. The patient who has sustained this kind of injury usually will require hospitalization for a long time. Emergency treatment must be directed at obtaining and maintaining a proper airway, providing spinal immobilization, assisting inadequate breathing as needed, conserving body heat, and ensuring the most effective circulation possible.

A patient in neurogenic shock is usually not losing blood; however, the capacity of the blood vessels has become significantly larger than the available volume of the blood inside the vessels. Supplemental oxygen will boost the concentration of oxygen in the blood. If respirations are weak or inadequate, assist ventilations. Because the injury may have disabled the body's normal temperature controls, keep the patient as warm as possible with blankets. Transport the patient promptly to a facility capable of managing spinal injuries.

Treating Anaphylactic Shock

The only really effective treatment of a severe, acute allergic reaction is to administer epinephrine by way of intramuscular injection. For more information on the emergency care for allergic reactions, see Chapter 20, *Immunologic Emergencies*. A patient who is aware of having a specific sensitivity may carry a kit containing epinephrine **Figure 12-9**. If he or she is unable to inject the medication, you may have to do so if you are allowed by local protocol. If the patient's signs and symptoms recur or the patient's condition deteriorates, consult medical control for authorization to administer a repeat injection, if available.

A patient with anaphylaxis requires immediate transport to the ED. Additional emergency care includes high-flow oxygen (10 to 15 L/min via a nonrebreathing mask). Assist ventilations with a BVM if necessary. If possible, attempt to determine what agent caused the reaction (for example, a drug, an insect bite or sting, a food item) and how it was received (for example, by mouth, by inhalation, or by injection). The severity of allergic reactions can vary greatly, with symptoms ranging from mild itching to profound coma and rapid death. Keep in mind that a mild reaction may worsen suddenly or over time. Because of the potential for airway compromise, consider requesting ALS backup, if available.

Figure 12-9 Patients who are known to have anaphylaxis often carry kits with an intramuscular injector or auto-injector containing epinephrine. **A.** An EpiPen. **B.** An Auvi-Q EpiPen.

▶ Treating Psychogenic Shock

In an uncomplicated case of fainting, once the patient collapses and becomes supine, circulation to the brain is usually restored and with it, a normal state of functioning. Remember that psychogenic shock can significantly worsen other types of shock. If it appears the patient fell as a result of psychogenic shock, check for injuries, especially in older patients. If the patient reports not being able to walk after a fall thought to be related to psychogenic shock, you should suspect another problem, such as head injury. Transport the patient promptly. It is not safe to assume based on EMT assessment that any fainting was caused by psychogenic shock alone. All patients with loss of consciousness, even brief, should be transported to the ED for evaluation even if they appear normal once you arrive on scene to evaluate them.

Be sure to record your initial observations of vital signs and level of consciousness. In addition, try to learn from bystanders whether the patient complained of anything before fainting and how long he or she was unconscious.

Treating Hypovolemic Shock

The emergency treatment of hypovolemic or hemorrhagic shock includes the control of all obvious external bleeding. The best initial method to control external bleeding is direct pressure. To prevent continued bleeding, you must apply sufficient pressure to control obvious external bleeding. If bleeding is not controlled with direct pressure, consider use of a tourniquet. Bleeding control, including application of a tourniquet, is discussed in detail in Chapter 25, *Bleeding*. Ensure that you use great care to handle the patient gently and keep him or her warm.

Although you cannot control internal bleeding in the field, it is important to recognize its existence and provide aggressive general support. Secure and maintain an airway, and provide respiratory support, including supplemental oxygen and, if needed, assisted ventilations. Start oxygen as soon as you suspect shock, and continue it during transport; with too little circulating blood, additional oxygen may be lifesaving. Watch to ensure that the patient does not aspirate blood or vomitus, and transport the patient as rapidly as possible to the ED.

Treating Respiratory Insufficiency

In treating the patient who has inadequate respiration, immediately secure and maintain the airway. Clear the mouth and throat of any obstructions including mucus, vomitus, and foreign material. If necessary, provide ventilations with a BVM. Administer supplemental oxygen, and transport the patient promptly.

Treating Shock in Older Patients

Use caution when caring for older patients. As a result of the aging process, older patients generally have more serious complications than younger patients. Although illness is a common complaint among older patients, you must understand that it is not just part of aging. In addition, many older patients take numerous medications that could either mask or mimic signs of shock. Keep in mind the following signs of the normal aging process when managing geriatric patients:

YOU are the Provider — PART 5

You ask your partner to call ahead to the hospital because you are busy caring for the patient and cannot free up your hands. The noninvasive automatic vital sign machine records another set of vital signs. With an estimated time of arrival at the hospital of 5 minutes, you reassess the patient.

Recording Time: 16 Minutes	
Level of consciousness	Responsive to pain only
Respirations	30 breaths/min and shallow (baseline); ventilations are being assisted
Pulse	128 beats/min; absent radial pulses (carotid pulse present)
Skin	Pale, cool, and diaphoretic
Blood pressure	80/40 mm Hg
Spo_2	96% (with assisted ventilation; on oxygen)

You arrive at the hospital and give your report to the charge nurse. Intravenous access is rapidly obtained, the attending physician quickly assesses the patient, and additional treatment is given.

8. What part of the patient's perfusion triangle has failed?
9. How does shock caused by content failure differ from shock caused by container failure?

- The central nervous system often has a delayed response.
- The cardiovascular system has a variety of changes that result in a decrease in the efficiency of the system. On assessment, be alert for higher resting heart rates and irregular pulse rates.
- The respiratory system undergoes significant changes as the elasticity of the lungs and their size and strength decrease. On assessment, be alert for higher respiratory rates, lower tidal volume, and a decreased gag reflex. In addition, remember that cervical arthritis may be present and that dentures may cause an airway obstruction.
- The skin becomes thinner, drier, less elastic, and more fragile, thus providing less protection and thermal regulation (cold and hot).
- The renal system decreases in function and may not respond well to unusual demands such as illness or dehydration.
- The gastrointestinal system sustains changes in gastric motility that may lead to slower gastric emptying.

Treating a pediatric or geriatric patient in shock is no different than treating any other shock patient:

1. Provide in-line spinal stabilization if indicated. If spinal immobilization is not indicated, maintain the patient in a position of comfort.
2. Control life-threatening hemorrhage immediately with direct pressure or tourniquet application when appropriate.
3. Suction as necessary and provide high-flow oxygen via a nonrebreathing mask.
4. Maintain body temperature.
5. Provide rapid transportation.

YOU are the Provider — SUMMARY

1. What additional information should you attempt to gather about the patient while en route to the clinic?

Information of "a woman going into shock" tells you very little. The patient could have a severe injury with internal bleeding, she could be experiencing a severe allergic reaction, or she may have simply fainted. When you are dispatched to any call with minimal information provided, attempt to gather additional information while you are en route. In many cases, the dispatch operator will provide additional patient information—without you asking for it—as it becomes available to him or her. In other cases, you will need to ask the dispatcher to try to make contact with the caller to obtain a patient update. Many EMS systems use an emergency medical dispatcher (EMD); if this is the case, he or she should be able to provide you with more detailed information, as well as give prearrival instructions to the caller.

2. What is shock and how does it relate to perfusion?

Perfusion is the delivery of blood and oxygen and other essential nutrients to the body's cells to keep them alive. While delivering these essential components to the body's cells, waste products such as carbon dioxide are removed from the cell and eliminated from the body. Adequate perfusion is the responsibility of the "perfusion triangle," which consists of three essential components—a functioning pump (the heart), adequate volume (the blood and water), and an intact container (the blood vessels). The respiratory system is also a critical component for adequate perfusion; if oxygen cannot get into the lungs, the heart cannot pump it through the blood vessels and to the cells. Shock is a state of inadequate perfusion (hypoperfusion) of blood through the body's tissues and to the cells and is the result of failure of one or more components of the perfusion triangle or the respiratory system. The type of shock that a patient is experiencing indicates the component of the perfusion triangle that has failed. Regardless of the type of shock, the end result is the same—inadequate perfusion of the body's tissues and cells, which will lead to death if untreated.

3. Based on your assessment, what changes, if any, in the patient's current treatment are required?

The patient clearly has signs of shock—restlessness; tachypnea; tachycardia; weak radial pulses; and cool, pale, diaphoretic skin—and the treatment that has been provided thus far is essentially appropriate. She is being kept warm, and she is receiving oxygen. However, patients with signs of shock need high-flow oxygen. She is presently receiving oxygen via a nasal cannula; this should be changed to a nonrebreathing mask with the flow rate set at 15 L/min. Based on this patient's presentation—abdominal pain and rectal bleeding—you should suspect blood loss (bleeding into the intestines) as the cause of her shock. Blood carries oxygen; if the blood volume decreases, so does the ability of oxygen to get to the cells. Providing a high concentration of oxygen will oxygenate the red blood cells that remain in the circulatory system. In addition to receiving high-flow oxygen, the patient needs IV access and volume replacement to help circulate the oxygenated blood. The physician has been unable to obtain IV access, and since IV therapy is beyond the EMT's level of training, you must prepare the patient for immediate transport. If your transport time to the hospital will be prolonged, you should consider an intercept with ALS, because ALS is trained to establish IV access.

4. How do the patient's signs and symptoms correlate with the body's response to inadequate perfusion?

During shock, the body mounts a physiologic response aimed at maintaining adequate perfusion, most of which is the result of increased activity of the sympathetic nervous system releasing greater quantities of epinephrine (adrenalin) and norepinephrine. Restlessness, perhaps one of the earliest signs of shock, is caused by a decrease in oxygen to the brain. As a result, the number of signals the brain sends to the respiratory muscles increases, which causes an increase in the patient's respiratory rate (tachypnea). Increased levels of epinephrine cause an increase in heart rate and cardiac contractility, and as a result, blood is pumped faster and with greater force throughout the body to compensate for decreased perfusion. Increased levels of norepinephrine cause the blood vessels to constrict (vasoconstriction), thus maintaining the patient's blood pressure. Early in shock, blood is shunted away from areas of lesser need (ie, the skin and muscles) to areas of greater need (ie, heart, lungs, liver, kidneys) by vasoconstriction. This causes the skin to turn pale (pallor) and become cool to the touch. When the sympathetic nervous system activity increases, sweat gland activity increases as well, resulting in diaphoresis (profuse sweating).

5. Is the patient in compensated or decompensated shock? How can you tell?

Signs of compensated shock include restlessness, anxiety, or agitation; tachycardia; rapid, weak (thready) peripheral pulses; tachypnea; and marked thirst. In compensated shock, however, the patient's systolic blood pressure is maintained—usually above 90 mm Hg in adults. Your patient's current blood pressure is 108/58 mm Hg. These signs and symptoms indicate that the patient is in compensated shock. Signs of decompensated shock include systolic blood pressure of 90 mm Hg or lower in an adult; absent peripheral pulses; dilated pupils; ashen, mottled, or cyanotic skin; and a decreasing level of consciousness. It is important to note that the patient's blood pressure is often the last measurable factor to change in shock. By the time a low blood pressure (hypotension) is detected, shock is well developed. In decompensated shock, the body's compensatory mechanisms are no longer able to maintain adequate perfusion. Survival is less likely—even with rapid transport and aggressive treatment at the hospital.

6. How has your patient's condition changed?

Your patient's condition has changed for the worse. Her level of consciousness has decreased (responsive to pain only), her respirations have increased in rate and decreased in depth (reduced tidal volume), her heart rate has increased and her radial pulses are no longer palpable, her blood pressure is below 90 mm Hg (84/44 mm Hg), and her oxygen saturation has fallen—despite the administration of high-flow oxygen. Based on these reassessment findings, your patient is now in decompensated shock with inadequate breathing. As previously discussed, decompensated shock occurs when the body's compensatory mechanisms begin to fail and are no longer able to maintain adequate perfusion. At the clinic, the patient had signs of shock; however, she was still conscious and alert, although restless, and her systolic blood pressure was maintained. Patients can decompensate within a matter of minutes; this fact underscores the criticality of frequent reassessments.

7. Are adjustments in your current interventions required? If so, what?

In terms of shock treatment, you are doing everything that you can. The patient is being kept warm with a blanket and she is receiving high-flow oxygen. An intercept with an ALS unit is not practical, because you are too close to the hospital. However, the patient's breathing is no longer adequate (30 breaths/min and shallow) and requires assistance. Because of her decreased level of consciousness, you should insert a nasopharyngeal airway, as she is responsive to pain and likely has an intact gag reflex. Begin assisting her ventilations with a BVM attached to high-flow oxygen and monitor her closely for signs of improvement or further deterioration. Many EMS systems carry noninvasive blood pressure monitoring devices that automatically take the patient's blood pressure and other vital signs. If you have this capability, set the device to reassess the patient's vital signs at least every 5 minutes or as deemed appropriate by the patient's condition. You are the only EMT in the back with the patient; managing her airway and assisting her ventilations clearly has priority over obtaining a manual blood pressure.

8. What part of the patient's perfusion triangle has failed?

There are three components to the perfusion triangle, each of which must function adequately at all times to maintain adequate perfusion: the heart (pump), the blood vessels (container), and the blood (content). Recalling the patient's chief complaint—abdominal pain and rectal bleeding—she is in shock secondary to blood loss (hemorrhagic shock).

Therefore, the content function of the perfusion triangle has failed. If there is enough blood or plasma loss, internally or externally, the volume of fluid that remains in the container (blood vessels) will not be able to carry sufficient amounts of oxygen to the cells to adequately perfuse them.

9. How does shock caused by content failure differ from shock caused by container failure?

Shock caused by content failure refers to insufficient oxygen delivery to the cells because of inadequate volume and is called hypovolemic shock. Hypovolemia is a generic term that simply means low volume; it could be blood, plasma, water, or a combination. Common causes of hypovolemic shock include blunt or penetrating trauma, burns, and dehydration. Shock that is caused by blood loss specifically is called hemorrhagic shock. The signs of hypovolemic shock include tachycardia; pale, cool, clammy skin; tachypnea; restlessness, agitation, or anxiety; and as a late sign, hypotension. Shock caused by container failure refers to inadequate perfusion because of excessive dilation of the blood vessels, resulting in a decrease in pressure within the circulatory system. Although the volume of blood has not changed, the container that it circulates within has increased; therefore the normal volume of blood is insufficient to fill the system and provide adequate perfusion. Common causes of shock caused by container failure include anaphylaxis, overdose with drugs that suppress the nervous system (ie, narcotics), and spinal cord injury. The classic signs of hypovolemic shock—specifically, tachycardia, pallor, and diaphoresis—will be absent. Instead, the patient’s skin is usually warm and dry, and the heart rate is normal or low.

EMS Patient Care Report (PCR)

Date: 7-21-16	**Incident No.:** 011009	**Nature of Call:** Woman in shock		**Location:** 1111 Cedar Hills Dr.	
Dispatched: 2022	**En Route:** 2023	**At Scene:** 2032	**Transport:** 2043	**At Hospital:** 2053	**In Service:** 2105

Patient Information

Age: 39 **Sex:** F **Weight (in kg [lb]):** 73 kg (160 lb)	**Allergies:** Codeine **Medications:** Amitiza, Bentyl **Past Medical History:** Irritable bowel syndrome **Chief Complaint:** Abdominal pain and rectal bleeding

Vital Signs

Time: 2036	**BP:** 108/58	**Pulse:** 120	**Respirations:** 24	**Spo_2:** 94%
Time: 2043	**BP:** 84/44	**Pulse:** 130	**Respirations:** 30	**Spo_2:** 89%
Time: 2048	**BP:** 80/40	**Pulse:** 128	**Respirations:** 30	**Spo_2:** 96%

EMS Treatment (circle all that apply)

Oxygen @ 15 L/min via (circle one): **NC NRM BVM**		**Assisted Ventilation**	**Airway Adjunct**	**CPR**
Defibrillation	**Bleeding Control**	**Bandaging**	**Splinting**	**Other:** Blanket for warmth

Narrative

9-1-1 dispatch to Cedar Hills Urgent Care Clinic for a "woman going into shock." Arrived on scene and found the patient, a 39-year-old female, lying supine on an exam table. She was conscious and alert, but restless. Her airway was patent and her breathing, although increased in rate, was producing adequate tidal volume. Her skin was cool, pale, and diaphoretic. According to the clinic physician, the patient presented 15 minutes earlier reporting abdominal pain and rectal bleeding, which began approximately 24 hours ago. Prior to EMS arrival, clinic personnel applied oxygen at 4 L/min via nasal cannula and applied a blanket. The physician advised that she attempted to establish IV access several times, but was unsuccessful. Further assessment of the patient revealed that her abdomen was diffusely tender to palpation, and she was actively bleeding from the rectum. Remainder of assessment was unremarkable. The patient denies abdominal trauma and states that she has a history of irritable bowel syndrome. Removed nasal cannula, applied high-flow oxygen via nonrebreathing mask, obtained vital signs, and moved the patient to the ambulance. Departed the scene and continued treatment en route. Reassessment revealed that the patient's mental status had decreased; she was now only responsive to painful stimuli. Her blood pressure had decreased, her radial pulses were absent (carotid pulse was present), her respirations were more rapid and shallow, and her Spo_2 had fallen to 89%. Inserted a nasopharyngeal airway and began assisting her ventilations with a BVM attached to high-flow oxygen. Partner notified the receiving facility and gave radio report. Continued to assist patient's ventilations and monitor her vital signs. She remained hypotensive and tachycardic; however, her Spo_2 increased to 96% with assisted ventilation. Delivered patient to the emergency department staff without incident and gave verbal report to charge nurse. Medic 4 returned to service at 2105.**End of report**

Prep Kit

Ready to Review

- Perfusion requires an intact cardiovascular system and a functioning respiratory system.
- Remember, most types of shock (hypoperfusion) are caused by dysfunction in one or more parts of the perfusion triangle:
  - The pump (the heart)
  - The pipes, or container (blood vessels)
  - The content, or volume (blood)
- Shock (hypoperfusion) is the collapse and failure of the cardiovascular system, when blood circulation slows and eventually stops.
- Blood is the vehicle for carrying oxygen and nutrients through the vessels to the capillary beds and tissue cells, where these supplies are exchanged for waste products.
- Blood contains red blood cells, white blood cells, platelets, and a liquid called plasma.
- The *systolic* pressure is the peak arterial pressure, or pressure generated every time the heart contracts; the *diastolic* pressure is the pressure maintained within the arteries while the heart rests between heartbeats.
- The various types of shock are cardiogenic, obstructive, septic, neurogenic, anaphylactic, psychogenic, and hypovolemic.
- Signs of compensated shock include anxiety or agitation; tachycardia; pale, cool, moist skin; increased respiratory rate; nausea and vomiting; and increased thirst. If there is any question on your part, treat for shock. Early recognition and rapid treatment are important.
- Signs of decompensated shock include labored or irregular respirations, ashen gray or cyanotic skin color, weak or absent distal pulses, dilated pupils, and profound hypotension (systolic blood pressure of 90 mm Hg or lower in an adult).
- Remember, by the time a drop in blood pressure is detected, shock is usually in an advanced stage.
- Anticipate shock in patients who may have the following conditions:
  - Severe infection
  - Significant blunt force trauma or penetrating trauma
  - Massive external bleeding or index of suspicion for major internal bleeding
  - Spinal cord injury
  - Chest or abdominal injury
  - Major heart attack
  - Anaphylaxis
- Treating a pediatric or geriatric patient in shock is no different than treating any other shock patient.
- Treat all patients suspected to be in shock from any cause as follows and in this order:
  - Open and maintain the airway.
  - Control life-threatening hemorrhage immediately with direct pressure or tourniquet application when appropriate.
  - Provide high-flow oxygen, and as needed, provide BVM-assisted ventilations.
  - Maintain normal body temperature with blankets.
  - Provide calm reassurance.
  - Provide prompt transport to the appropriate hospital.

Vital Vocabulary

afterload The force or resistance against which the heart pumps.

anaphylactic shock Severe shock caused by an allergic reaction.

anaphylaxis An extreme, life-threatening, systemic allergic reaction that may include shock and respiratory failure.

aneurysm A swelling or enlargement of a part of an artery, resulting from weakening of the arterial wall.

autonomic nervous system The part of the nervous system that regulates involuntary activities of the body, such as heart rate, blood pressure, and digestion of food.

cardiac tamponade Compression of the heart as the result of buildup of blood or other fluid in the pericardial sac, leading to decreased cardiac output.

cardiogenic shock A state in which not enough oxygen is delivered to the tissues of the body, caused by low output of blood from the heart. It can be a severe complication of a large acute myocardial infarction, as well as other conditions.

compensated shock The early stage of shock, in which the body can still compensate for blood loss.

cyanosis A blue skin discoloration that is caused by a reduced level of oxygen in the blood.

decompensated shock The late stage of shock when blood pressure is falling.

dehydration Loss of water from the tissues of the body.

distributive shock A condition that occurs when there is widespread dilation of the small arterioles, small venules, or both.

edema The presence of abnormally large amounts of fluid between cells in body tissues, causing swelling of the affected area.

homeostasis A balance of all systems of the body.

hypothermia A condition in which the internal body temperature falls below 95°F (35°C).

hypovolemic shock Shock caused by fluid or blood loss.

myocardial contractility The ability of the heart muscle to contract.

neurogenic shock Circulatory failure caused by paralysis of the nerves that control the size of the blood vessels, leading to widespread dilation; seen in patients with spinal cord injuries.

obstructive shock Shock that occurs when there is a block to blood flow in the heart or great vessels, causing an insufficient blood supply to the body's tissues.

perfusion The flow of blood through body tissues and vessels.

pericardial effusion A collection of fluid between the pericardial sac and the myocardium.

preload The precontraction pressure in the heart as the volume of blood builds up.

psychogenic shock Shock caused by a sudden, temporary reduction in blood supply to the brain that causes fainting (syncope).

pulmonary embolism A blood clot that breaks off from a large vein and travels to the blood vessels of the lung, causing obstruction of blood flow.

pulse pressure The difference between the systolic and diastolic pressures.

sensitization Developing a sensitivity to a substance that initially caused no allergic reaction.

septic shock Shock caused by severe infection, usually a bacterial infection.

shock A condition in which the circulatory system fails to provide sufficient circulation to enable every body part to perform its function; also called hypoperfusion.

sphincters Circular muscles that encircle and, by contracting, constrict a duct, tube, or opening.

syncope A fainting spell or transient loss of consciousness.

Assessment *in Action*

You are dispatched to a person who is reporting chest pain and shortness of breath. You arrive to find a conscious 58-year-old woman who is sitting up and reporting severe chest pain and shortness of breath. She is very anxious and tells you she feels like she is going to die. Physical examination shows that her skin is pale, cool, and clammy and her pulse is rapid, weak, and irregular. Her breathing is labored, with a respiratory rate of 28 breaths/ min. Her Spo_2 is 90%. Lung sounds show crackles in all fields. Blood pressure is 92/60 mm Hg.

1. What is your differential diagnosis of this patient?

   A. Hypovolemic shock
   B. Anaphylactic shock
   C. Cardiogenic shock
   D. Neurogenic shock

2. What stage of shock is this patient in? What signs and symptoms lead you to that conclusion?

   A. Compensated
   B. Decompensated
   C. Irreversible
   D. Psychogenic

3. What treatment should be initiated first for this patient?

   A. High-flow oxygen
   B. Administration of nitroglycerin
   C. Rapid transport
   D. Maintain warmth

4. The patient is having trouble breathing. What position should the patient be placed in?

   A. Supine

B. Fowler position
C. Prone
D. Left lateral recumbent

5. What part of the patient's cardiovascular system is failing?

   A. The fluid (blood)
   B. The container (vessels)
   C. The pump (heart)
   D. The control (nervous system)

6. Which of the following terms is used to describe a balance of all body systems?

   A. Hypothermia
   B. Autonomic nervous system
   C. Perfusion
   D. Homeostasis

7. You are watching your patient carefully to see if her condition deteriorates. What signs would alert you to the patient going into the next stage of shock?

8. Define shock.

9. Describe how carbon dioxide is transported from tissues to the lungs.

10. Why is it significant that the patient feels like she is going to die?

CHAPTER

13

BLS Resuscitation

National EMS Education Standard Competencies

Shock and Resuscitation

Applies a fundamental knowledge of the causes, pathophysiology, and management of shock, respiratory failure or arrest, cardiac failure or arrest, and post-resuscitation management.

Knowledge Objectives

1. Explain the elements of basic life support (BLS), how it differs from advanced life support (ALS), and why BLS must be applied rapidly. (pp 514–515)
2. Explain the goals of cardiopulmonary resuscitation (CPR) and when it should be performed on a patient. (p 515)
3. Explain the components of CPR, the five links in the American Heart Association (AHA) chain of survival, and how each one relates to maximizing the survival of a patient. (pp 515–516)
4. Discuss guidelines for circumstances that require the use of an automated external defibrillator (AED) on both adult and pediatric patients experiencing cardiac arrest. (pp 517–518)
5. Explain three special situations related to the use of an AED. (p 518)
6. Describe the proper way to position an adult patient to receive BLS care. (p 519)
7. Describe the purpose of external chest compressions. (p 519)
8. Describe the two techniques EMTs may use to open an adult patient's airway and the circumstances that would determine when each technique would be used. (pp 522–523)
9. Describe the recovery position and circumstances that would warrant its use as well as situations in which it would be contraindicated. (pp 523–524)
10. Describe the process of providing artificial ventilations to an adult patient, ways to avoid gastric distention, and modifications required for a patient with a stoma. (pp 524–526)

11. Explain the steps in providing single-rescuer adult CPR. (pp p 526)
12. Explain the steps in providing two-rescuer adult CPR, including the method for switching positions during the process. (p 526)
13. Describe the different mechanical devices that are available to assist emergency care providers in delivering improved circulatory efforts during CPR. (pp 529, 531–533)
14. Describe the different possible causes of cardiopulmonary arrest in children. (pp 533–534)
15. Explain the four steps of pediatric BLS procedures and how they differ from BLS procedures used in an adult patient. (pp 533–538)
16. Describe the ethical issues related to patient resuscitation, including examples of when not to start CPR on a patient. (pp 539–540)
17. Explain the various factors involved in the decision to stop CPR after it has been started on a patient. (pp 540–541)
18. Explain common causes of foreign body airway obstruction in both children and adults and how to distinguish mild or partial airway obstruction from complete airway obstruction. (pp 541–542)
19. Describe the different methods for removing a foreign body airway obstruction in an infant, child, and adult, including the procedure for a patient with an obstruction who becomes unresponsive. (pp 541–548)
20. Discuss how to provide grief support for a patient's family members and loved ones after resuscitation has ended. (pp 548–550)
21. Discuss the importance of frequent CPR training for EMTs, as well as public education programs that teach compression-only CPR. (p 550)

Skills Objectives

1. Demonstrate how to position an unresponsive adult for CPR. (p 519)
2. Demonstrate how to check for a pulse at the carotid artery in an unresponsive child or adult. (p 519)
3. Demonstrate how to perform external chest compressions on an adult. (pp 520–521, Skill Drill 13-1)
4. Demonstrate how to perform a head tilt–chin lift maneuver on an adult. (pp 522–523)
5. Demonstrate how to perform a jaw-thrust maneuver on an adult. (pp 522–523)
6. Demonstrate how to place a patient in the recovery position. (pp 523–524)
7. Demonstrate how to perform rescue breathing in an adult. (p 524)
8. Demonstrate how to perform one-rescuer adult CPR. (pp 526–527, Skill Drill 13-2)
9. Demonstrate how to perform two-rescuer adult CPR. (pp 526, 528, Skill Drill 13-3)
10. Demonstrate the use of mechanical devices that assist emergency responders in delivering improved circulatory efforts during CPR. (pp 531–533)
11. Demonstrate how to check for a pulse at the brachial artery in an unresponsive infant. (p 534)
12. Demonstrate how to perform external chest compressions on an infant. (p 535, Skill Drill 13-4)
13. Demonstrate how to perform CPR on a child who is between 1 year of age and the onset of puberty. (pp 535–537, Skill Drill 13-5)
14. Demonstrate how to perform a head tilt–chin lift maneuver on a pediatric patient. (p 537)
15. Demonstrate how to perform a jaw-thrust maneuver on a pediatric patient. (p 537)
16. Demonstrate how to perform rescue breathing on a child. (p 538)
17. Demonstrate how to perform rescue breathing on an infant. (p 538)
18. Demonstrate how to remove a foreign body airway obstruction in a responsive adult patient using abdominal thrusts (Heimlich maneuver). (p 543)
19. Demonstrate how to remove a foreign body airway obstruction in a responsive pregnant or obese patient using chest thrusts. (p 543)
20. Demonstrate how to remove a foreign body airway obstruction in a responsive child older than 1 year using abdominal thrusts (Heimlich maneuver). (pp 545–546)
21. Demonstrate how to remove a foreign body airway obstruction in an unresponsive child. (pp 546–547, Skill Drill 13-6)

22. Demonstrate how to remove a foreign body airway obstruction in an infant. (pp 546, 548)

Introduction

The principles of basic life support (BLS) were introduced in 1960. Since then, the specific techniques for the management of cardiac arrest and the delivery of emergency and cardiac care have been reviewed and revised every 5 to 6 years. The goal is to produce the best recommendations possible given the available scientific evidence. The updated guidelines are published in peer-reviewed journals: *Circulation* in the United States and *Resuscitation* in Europe. The most recent review was conducted by the International Liaison Committee on Resuscitation (ILCOR). This revision occurred as a result of a rigorous and systematic review of the newest scientific evidence surrounding the treatment of cardiac arrest and the provision of emergency and cardiac care, using validated, transparent, and scientifically rigorous methodology to produce the best recommendations possible given the available evidence.

This chapter begins with a definition and general discussion of BLS. It then reviews methods for opening and maintaining a patent (open) airway, providing artificial ventilation to a person who is not breathing, providing artificial circulation to a person with no pulse, and removing a foreign body airway obstruction. Each of these topics is followed by a review of the changes in technique that are necessary to treat infants and children. Chapter 2, *Workforce Safety and Wellness,* discusses the methods of preventing the transmission of infectious diseases during cardiopulmonary resuscitation (CPR). Chapter 6, *The Human Body,* discusses the anatomy and physiology of the respiratory and cardiovascular systems. Chapter 41, *The Team Approach to Health Care*, discusses how to work as an effective team in the health care setting. During any emergency, working as a team is critical to give the patient the best chance for a successful outcome.

Words of Wisdom

Although your chances of contracting a disease during CPR training or actual CPR on a patient are very low, both common sense and Occupational Safety and Health Administration guidelines demand that you take reasonable precautions to prevent unnecessary exposure to an infectious disease. Use standard safety precautions to decrease the risk of contracting a disease during CPR, as discussed in Chapter 2, *Workforce Safety and Wellness.*

YOU are the Provider — PART 2

At 1445 hours, you and your partner respond to a local supermarket at 123 Wilshire Avenue where a middle-aged man reportedly collapsed in the parking lot. While you are en route to the scene, dispatch advises you that bystander CPR is in progress. Your response time is less than 5 minutes.

1. What should you immediately do on receiving this update from dispatch?
2. What should be your initial actions on arriving at this scene?

Elements of BLS

Basic life support (BLS) is noninvasive emergency life-saving care that is used to treat medical conditions, including airway obstruction, respiratory arrest, and cardiac arrest. BLS follows a specific sequence for adults and for infants and children. This care focuses on the ABCs: airway (obstruction), breathing (respiratory arrest), and circulation (cardiac arrest or severe bleeding). If the patient is in cardiac arrest, then a CAB sequence (compressions, airway, breathing) is used because chest compressions are essential and must be started as quickly as possible **Figure 13-1**. Ideally, only seconds should pass between the time you recognize that a patient needs BLS and the start of treatment. Remember, brain cells die every second that they are deprived of oxygen. Permanent brain damage is possible after only 4 to 6 minutes without oxygen **Figure 13-2**.

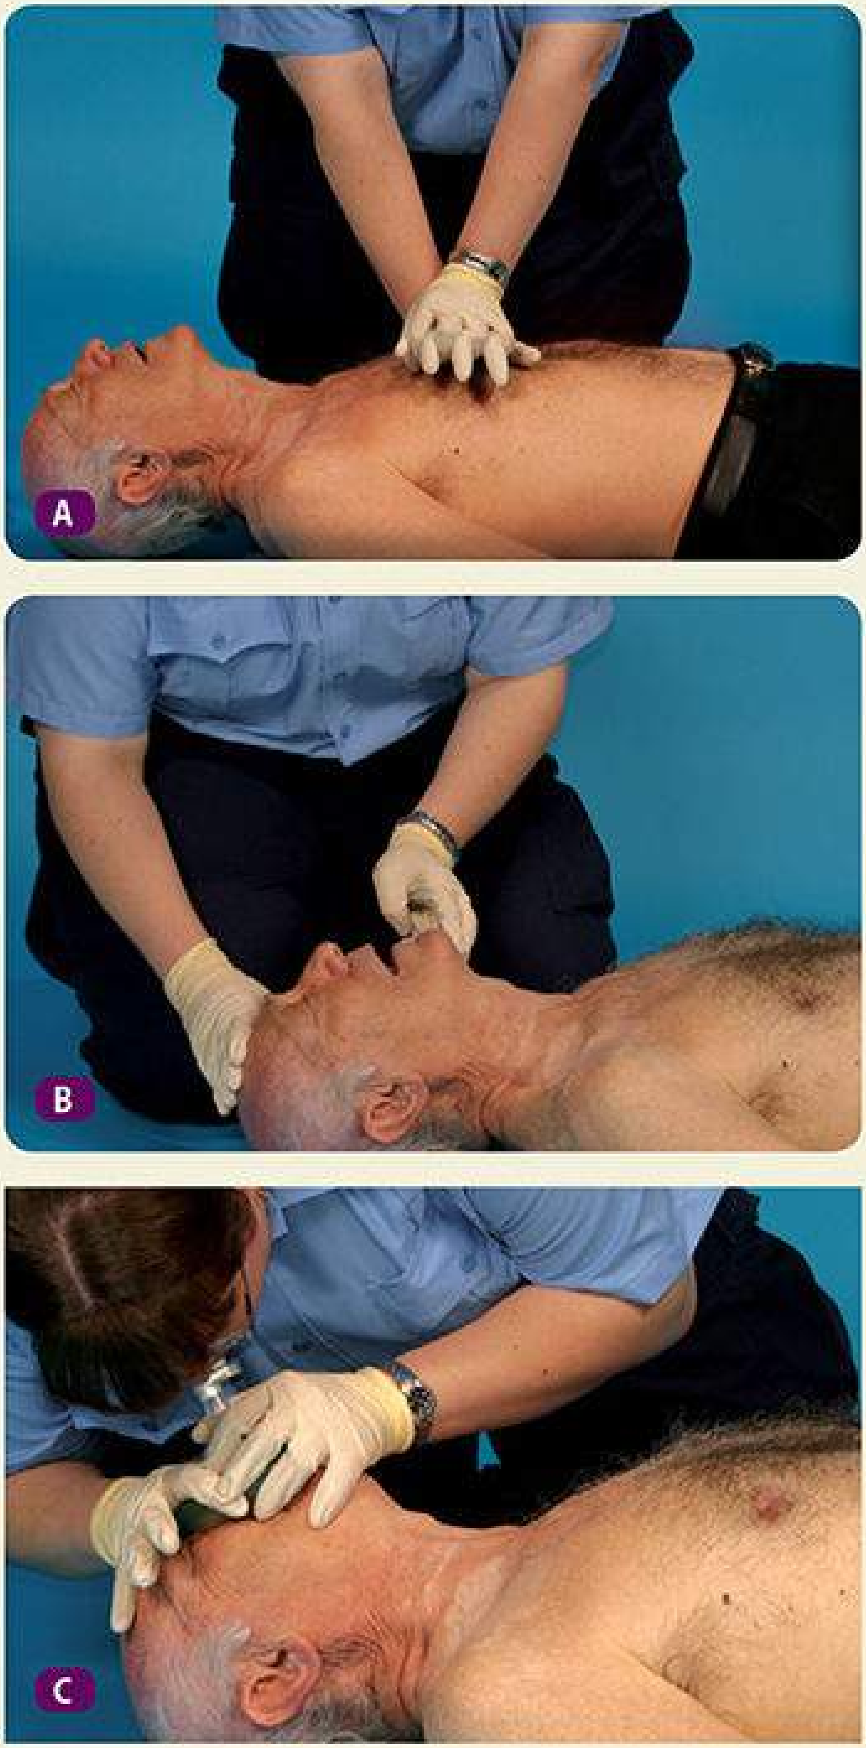

Figure 13-1 CAB: Chest compressions, airway, and breathing.

A, B, & C: © Jones & Bartlett Learning. Courtesy of MIEMSS.

If a patient is not breathing adequately or at all, then you may be able to restore normal breathing simply by opening the airway. However, if the patient has no pulse, then you must combine artificial ventilation with artificial circulation (chest compressions). If breathing stops before the heart stops, then the patient may have enough oxygen in the lungs to stay alive for several minutes. But when cardiac arrest occurs first, the heart and brain stop receiving oxygen immediately.

Cardiopulmonary resuscitation (CPR) is used to establish circulation and artificial ventilation in a patient who is not breathing and has no pulse. The steps for CPR include the following:

1. First, restore circulation by performing chest compressions to circulate blood to the vital organs of the body.
2. Next, perform 30 high-quality compressions to a depth of 2 inches to 2.4 inches (5 cm to 6 cm) in an adult at the rate of 100 to 120 per minute. Next, open the airway with the jaw-thrust or head tilt–chin lift maneuver.
3. Last, restore breathing by providing rescue breaths (via mouth-to-mask ventilation or a bag-valve mask [BVM]). Administer 2 breaths, each over 1 second, while visualizing for chest rise.

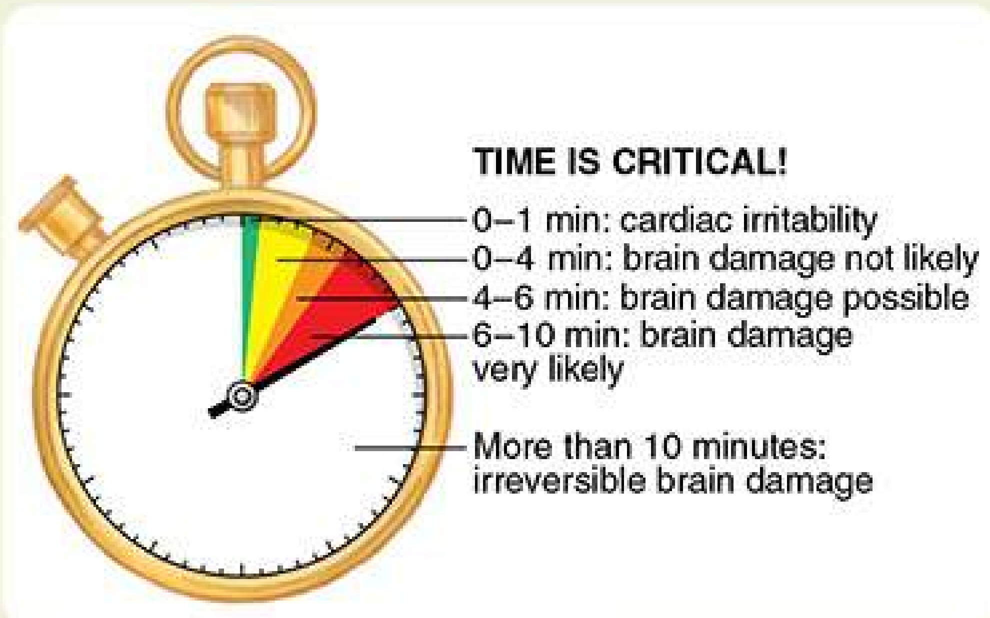

Figure 13-2 Time is critical for patients who are not breathing. If the brain is deprived of oxygen for 4 to 6 minutes, brain damage is possible.

The goal of CPR is to help restore spontaneous breathing and circulation; however, defibrillation and advanced interventions (ie, medication therapy) are often necessary to achieve this outcome. For CPR to be effective, you must be able to quickly identify a patient who is in respiratory and/or cardiac arrest and immediately begin BLS measures **Figure 13-3**.

BLS differs from **advanced life support (ALS)**, which involves advanced lifesaving procedures, such as cardiac monitoring, administration of intravenous (IV) fluids and medications, and the use of advanced airway adjuncts. However, when done correctly, BLS care can maintain life for a short time until ALS measures can be started. In some cases, such as choking, near drowning, or lightning injuries, early BLS measures may be all that is needed to restore a patient's pulse and breathing. Of course, these patients still require transport to the emergency department (ED) for evaluation.

Figure 13-3 You must quickly identify patients in respiratory and/or cardiac arrest so that BLS measures can begin immediately.

The BLS measures are only as effective as the person who is performing them. Your skills may be good immediately after training, but as time goes on, skills will deteriorate unless you practice them regularly.

To survive cardiac arrest, effective CPR at an adequate rate and depth with minimal interruptions is essential until defibrillation can be administered. Therefore, the BLS care you provide as an EMT is an extremely critical factor in the patient's chance for survival.

The Components of CPR

According to the American Heart Association (AHA), 88% of sudden cardiac arrests occur in the home. Few patients who experience cardiac arrest in the prehospital environment survive unless a rapid sequence of events takes place. The AHA has determined an ideal sequence of events, termed the chain of survival, that if taken can improve the chance of successful resuscitation of a patient who experiences sudden cardiac arrest **Figure 13-4**. A successful resuscitation is defined not only by the **return of spontaneous circulation (ROSC)**, but also the survival of the patient to hospital discharge. The five links in the chain of survival are as follows:

1. **Recognition and activation of the emergency response system.** The first step in the chain of survival requires public education and awareness. Laypeople must learn to recognize the early warning signs of a cardiac emergency and immediately activate EMS by calling 9-1-1. This step ensures that emergency responders are dispatched to the scene quickly, thus allowing the other links of the chain to be more effective. In modern EMS systems, the 9-1-1 dispatcher can provide prearrival instructions and direct the caller to provide CPR if needed.

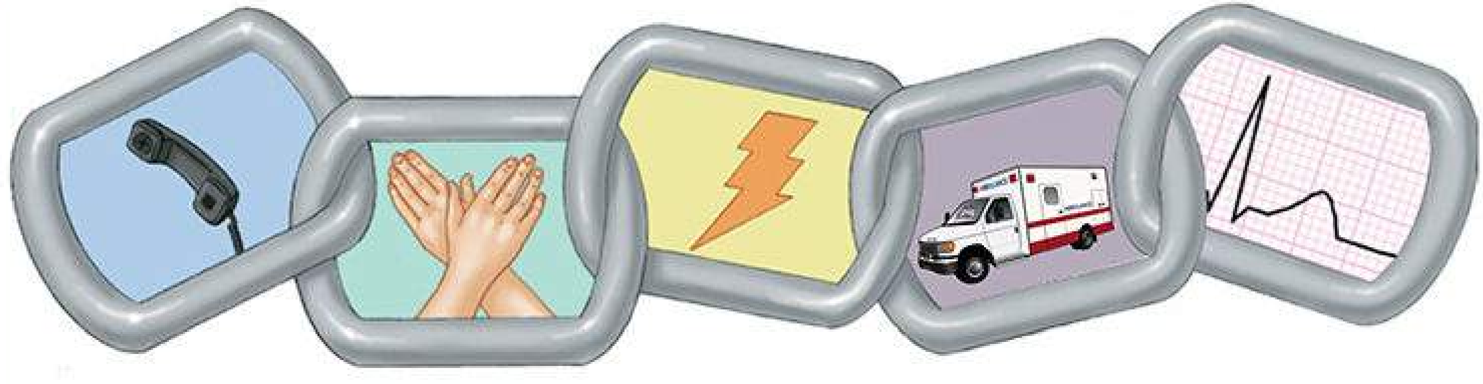

Figure 13-4 The five links of the chain of survival.

2. **Immediate, high-quality CPR.** The initiation of immediate CPR by a bystander is essential for successful resuscitation of a person in cardiac arrest. CPR will keep blood, and therefore oxygen, flowing to the vital organs to keep the patient alive until the other components of the chain are available. The more people trained in CPR in the community, the better the chances of CPR being administered quickly to a person in cardiac arrest. Immediate, high-quality CPR markedly increases the patient's chance of survival, whereas a delay in CPR leads to poor patient outcomes. The lay public as well as emergency responders should all be trained in CPR. Unfortunately, many bystanders are hesitant to perform CPR on a stranger for fear of contracting a disease from mouth-to-mouth breathing, or out of fear of liability. A perception that bystander CPR involves both mouth-to-mouth breathing and chest compressions persists. Laypeople should be educated in performing compression-only (hands-only) CPR.

   For chest compressions to be most effective, they must be given hard and fast. The AHA recommends that compressions be started as quickly as possible after onset of cardiac arrest. Compressions should be between 2 and 2.4 inches in depth (5 to 6 cm) and given at a rate of 100 to 120 per minute. The chest should completely recoil between each compression to maximize blood return to the heart. The rescuer should never lean on the chest between compressions. Interruptions between compressions for any reason should be minimized.
3. **Rapid defibrillation.** Provided that immediate, high-quality CPR with minimal interruption is performed, early defibrillation offers the best opportunity to achieve a successful patient outcome. Automated external defibrillators (AEDs) have become readily available in many schools, fitness clubs, concert venues, sports arenas, government buildings, and other mass gathering places. The simple design of the AED makes it easy for emergency medical providers and laypeople to use with very little training.
4. **Basic and advanced emergency medical services.** This link in the chain describes care provided by EMTs and ALS providers before the patient arrives at the ED. Such care includes continuing high-quality CPR; basic airway management (ie, oral airway insertion, BVM ventilation); advanced airway management (ie, endotracheal [ET] intubation or use of supraglottic airway devices); manual defibrillation; vascular access; transcutaneous pacing; and administration of medications. In addition to the care provided in the prehospital setting, be familiar with the cardiac resuscitation centers in your service area. Your agency should implement a process to ensure early notification and transport to the appropriate receiving facility.
5. **Advanced life support and postarrest care.** After your team delivers the patient to the ED, further cardiopulmonary and neurologic support is provided to improve the patient's recovery when indicated. This support can include additional medication therapy to support blood pressure; targeted temperature management (ie, therapeutic hypothermia); maintenance of blood glucose levels; cardiac catheterization; an electroencephalogram to detect seizure activity; and admission to the intensive care unit for critical care management.

If any one of the links in the chain is not maintained, then the patient is more likely to die. For example, few patients survive cardiac arrest if CPR is not administered within the first few minutes. Likewise, if the time from cardiac arrest to defibrillation is more than 10 minutes, the chance of survival is minimal. The patient's best chance of survival occurs when all links in the chain are continuously maintained.

Assessing the Need for BLS

As always, begin by surveying the scene. Is the scene safe? How many patients are present? What is your initial impression of the patient(s)? Are bystanders present who may have additional information? What is the mechanism of injury or nature of illness? Do you suspect trauma? If you were dispatched to the scene, then does the dispatch information match what you see?

Because of the urgent need to start CPR in a pulseless, nonbreathing patient, you must complete a primary assessment as soon as possible and begin CPR, starting with chest compressions. The first step is to determine unresponsiveness. Gently tap the patient on the shoulder and shout, "Are you okay?" **Figure 13-5**. Clearly, a patient who is responsive does not need CPR. A person who is unresponsive may or may not need CPR. Continue your assessment by simultaneously checking for breathing and a pulse; this step should take no more than 10 seconds. If the patient is in cardiac arrest, then begin CPR immediately.

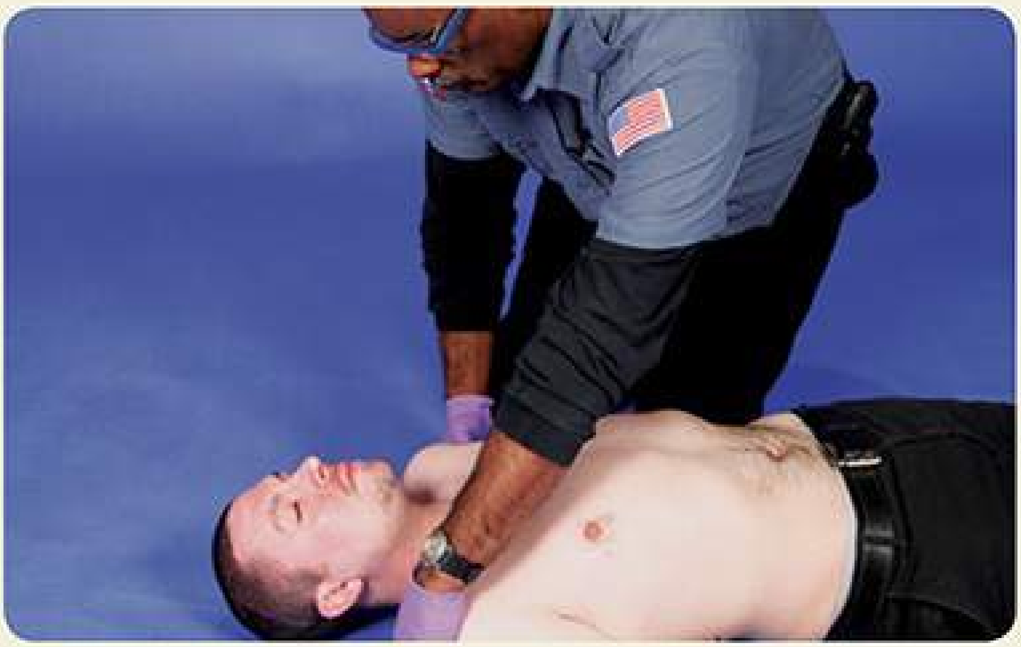

Figure 13-5 Assess an unresponsive patient by first attempting to rouse him or her by tapping on the shoulder.

In some EMS services, EMTs respond in squad units, before the ambulance. If this is the case in your area, then update the responding crew via two-way radio if possible. In other cases, you may encounter a cardiac arrest patient while off duty. If you are alone and off duty, use your mobile phone to call 9-1-1. Recall from Chapter 3, *Medical, Legal, and Ethical Issues,* that you must be familiar with the laws and policies that apply in your service area regarding your duty to act. If you are alone and do not have a mobile phone, then leave the patient to call 9-1-1 and then return to begin CPR. If you choose to intervene while off duty, then you must continue to provide competent care until an equal or higher medical authority assumes care of the patient.

Basic Principles of BLS

The basic principles of BLS are the same for infants, children, and adults. For the purposes of BLS, anyone younger than 1 year is considered an infant. A child is between 1 year of age and the onset of puberty (approximately 12 to 14 years of age), as signified by breast development in girls and underarm, chest, and facial hair in boys. Adulthood is from the onset of puberty and older. Children vary in size. Some small children may best be treated as infants, some larger children as adults. There are two basic differences in providing CPR for infants, children, and adults. The first is that the emergencies in which infants and children require CPR usually have different underlying causes. The second is that there are anatomic differences in adults, children, and infants, such as smaller airways in infants and children than in adults.

Although cardiac arrest in adults usually occurs before respiratory arrest, the reverse is true in infants and children. In most cases, cardiac arrest in children results from respiratory arrest. If untreated, respiratory arrest will quickly lead to cardiac arrest and death. Respiratory arrest in infants and children has a variety of causes, discussed later in this chapter.

Automated External Defibrillation

Most prehospital cardiac arrests occur as the result of a sudden cardiac rhythm disturbance (dysrhythmia), such as ventricular fibrillation (V-fib) or pulseless ventricular tachycardia (V-tach). The normal heart rhythm is known as normal sinus rhythm. V-fib is the disorganized quivering of the ventricles, resulting in no forward blood flow and a state of cardiac arrest. V-tach is a rapid contraction of the ventricles that does not allow for normal filling of the heart. As mentioned previously, according to the AHA, early defibrillation is the link in the chain of survival that is most likely to improve survival rates. The likelihood of survival decreases rapidly over time as long as V-fib or pulseless V-tach persists.

When a patient is in cardiac arrest, begin CPR, starting with high-quality chest compressions, and apply an AED as soon as it is available. If indicated, then defibrillate immediately. Chapter 16, *Cardiovascular Emergencies*, covers AED use in detail.

Words of Wisdom

If you witness a patient's cardiac arrest and an AED is available, then deploy the AED immediately and then begin CPR. However, if you did not witness the patient's cardiac arrest or if an AED is unavailable, then perform CPR and apply the AED as soon as it is available. If two or more rescuers are present, one rescuer should begin CPR while the other prepares to defibrillate using the AED.

AED Usage in Children

AEDs can safely be used in children using the pediatric-sized pads and a dose-attenuating system (energy reducer). However, if these items are unavailable, use adult-sized AED pads. Apply the AED to infants or children after the first five cycles of CPR have been completed. Recall that cardiac arrest in children is usually the result of respiratory failure; therefore, oxygenation and ventilation are vitally important. After the first five cycles of CPR, use the AED to deliver shocks in the same manner as with an adult patient.

If the patient is an infant (between 1 month and 1 year of age), then a manual defibrillator is preferred to an AED; however, this is an ALS skill. As with any cardiac arrest situation, call for ALS backup immediately. If ALS backup with a manual defibrillator is unavailable, then an AED equipped with pediatric-sized pads and a dose attenuator is preferred. If neither is available, then use an AED with adult-sized pads.

If you use adult-sized AED pads on an infant or small child, then do not cut the pads to adjust the size. Instead, use the anterior-posterior placement, following the manufacturer's recommendation.

Words of Wisdom

AEDs are becoming more accessible in the community. Be familiar with your local protocols on pediatric defibrillation. Your service may use a pediatric AED or an AED with a pediatric adapter.

Remember, if the child is past the onset of puberty, follow the adult CPR sequence, including the use of adult-sized AED pads.

Special AED Situations

It is essential to ensure the safety of yourself, others at the scene, and the patient. As such, keep the following factors in mind when using an AED.

Pacemakers and Implanted Defibrillators

You may encounter a patient who has an automated implanted cardioverter-defibrillator (AICD) or pacemaker that delivers shocks directly to the heart if necessary. These devices are used in patients who are at a high risk for certain cardiac dysrhythmias and cardiac arrest. It is easy to recognize AICDs or pacemakers because they create a hard lump beneath the skin, usually on the upper left side of the chest (just below the clavicle). If the AED pads are placed directly over the device, then the effectiveness of the shock delivered by the AED may be reduced, and the shock could potentially damage the implanted device. Therefore, if you identify an AICD or pacemaker, then you should place the AED pads at least 1 inch (2.5 cm) away from the device.

Occasionally, the implanted device will deliver shocks to the patient. If you observe the patient's muscles twitching as if he or she was just shocked, then continue CPR and wait 30 to 60 seconds before delivering a shock from the AED.

Wet Patients

Water conducts electricity. Therefore, the AED should not be used in water. If the patient's chest is wet, then the electrical current may move across the skin rather than between the pads to the patient's heart. If the patient is submerged in water, then pull him or her out of the water and quickly dry the skin before attaching the AED pads. Do not delay CPR to dry the patient thoroughly; instead, quickly wipe off as much moisture as possible from the chest. If the patient is lying in a small puddle of water or in the snow, the AED can be used, but again, the patient's chest should be quickly dried as much as possible.

Transdermal Medication Patches

You may encounter a patient who is receiving medication through a transdermal medication patch, such as nitroglycerin. The medication is absorbed through the skin. The patch could reduce the flow of the electrical current from the AED to the heart and may burn the skin. If the medication patch interferes with AED pad placement, then remove the patch with your gloved hands and wipe the skin to remove any residue prior to attaching the AED pad.

Words of Wisdom

Be familiar with social media platforms and mobile phone dispatch systems used in your service area. For example, free smartphone apps are available that use global positioning system (GPS) technology to alert CPR-trained subscribers that a nearby person is in cardiac arrest. Social media notification systems have not been shown to improve survival from out-of-hospital cardiac arrest. However, the potential benefit of increased bystander-initiated CPR makes it reasonable for you to advocate for the use of such technology.

Positioning the Patient

For CPR to be effective, the patient must be lying supine on a firm, flat surface, with enough clear space around the patient for two rescuers to perform CPR and use the AED. If the patient is crumpled up or lying facedown (prone), then you will need to move him or her to a supine position. Be mindful that you cannot rule out a spinal injury in an unresponsive patient; therefore, protect the patient's neck and move him or her as a unit, without twisting **Figure 13-6**. If the patient is found in a bed, then move him or her to the floor.

If possible, log roll the patient onto a long backboard as you position him or her for CPR; do this as quickly and safely as possible. A backboard will provide support during transport and emergency care. After the patient is properly positioned, you can easily assess the patient to determine whether CPR and defibrillation are necessary.

Check for Breathing and a Pulse

After you have determined that the patient is unresponsive, quickly check for breathing and a pulse. These assessments can occur simultaneously and should take no longer than 10 seconds in total.

Visualize the chest for signs of breathing while palpating for a carotid pulse. Feel for the carotid artery by locating the larynx at the front of the neck and then sliding two fingers toward one side (the side closest to you). The pulse is felt in the groove between the larynx and sternocleidomastoid muscle, with the pads of the index and middle fingers held side by side **Figure 13-7**. Light pressure is sufficient to palpate the pulse.

Figure 13-6 Ensure that the patient is in a supine position. Protect the patient's neck in case a spinal injury is present, and move him or her as a unit, without twisting.

Provide External Chest Compressions

If the patient is not breathing (or is breathing only slowly or occasionally, known as agonal gasps) and does not have a pulse, then begin CPR, starting with chest compressions. It is critical to perform compressions properly. Chest compressions are administered by applying rhythmic pressure and relaxation to the lower half of the sternum. The heart is located slightly to the left of the middle of the chest between the sternum and the spine **Figure 13-8**. Compressions squeeze the heart, thereby acting as a pump to circulate blood. Allow the chest to completely recoil between compressions, which enhances blood return to the heart. Do not lean on the chest between compressions. When artificial ventilation is provided, the blood that is circulated through the lungs during chest compressions is likely to receive adequate oxygen to maintain tissue perfusion. However, even when external chest compressions are performed properly, they circulate only one-third of the blood that is normally pumped by the heart.

Figure 13-7 Feel for the carotid artery by locating the larynx, then slide your index and middle fingers toward one side. You can feel the pulse in the groove between the larynx and sternocleidomastoid muscle.

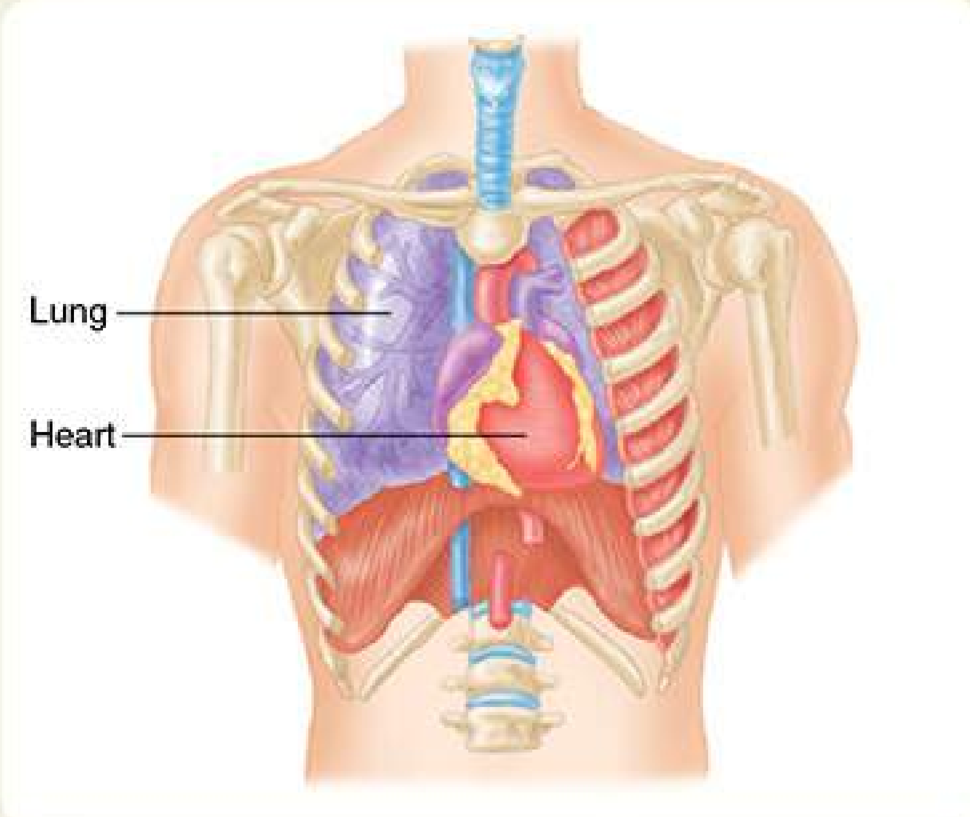

Figure 13-8 The heart lies slightly to the left of the middle of the chest between the sternum and spine.

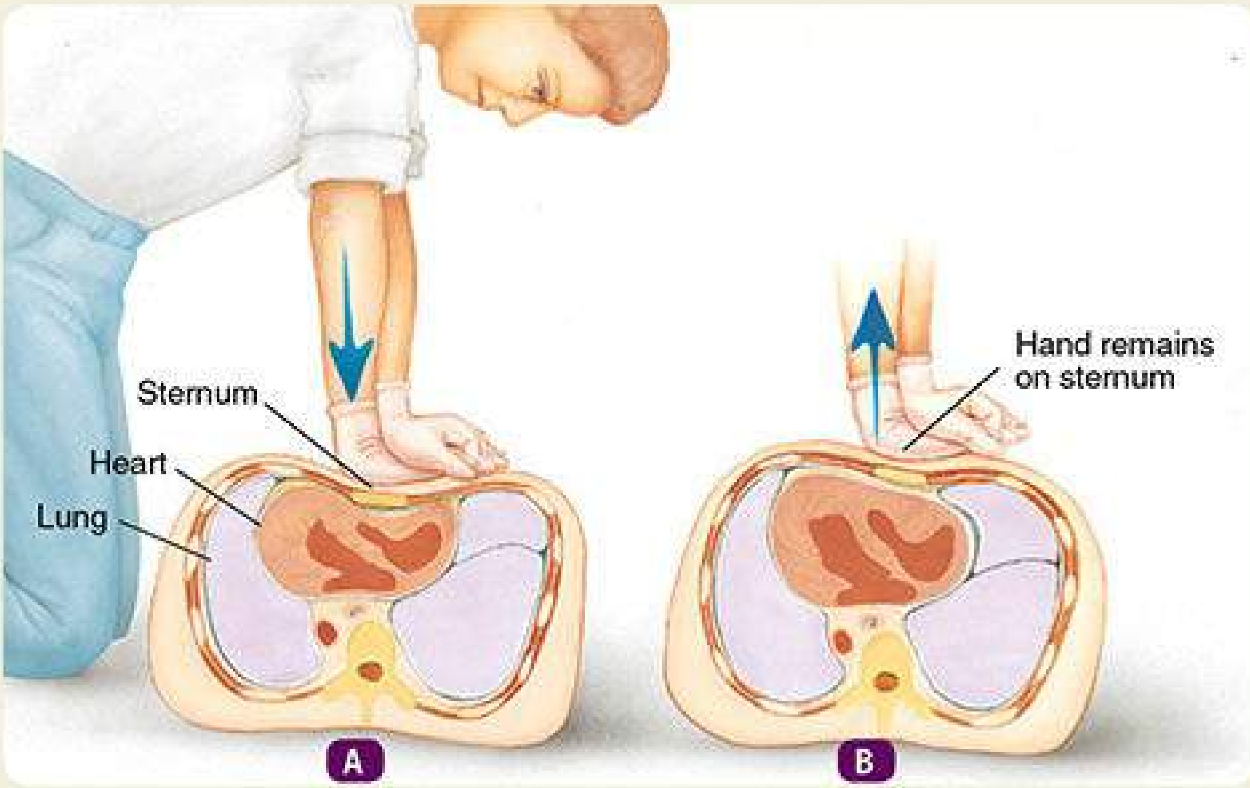

Figure 13-9 **A.** Compression and relaxation should be rhythmic and of equal duration (a 1:1 ratio). **B.** Pressure on the sternum must be released so that the sternum can return to its normal resting position between compressions.

A & B: © Jones & Bartlett Learning.

▶ Proper Hand Position and Compression Technique

With the adult patient, correct hand position is established by placing the heel of one hand on the sternum in the center of the chest (lower half of the sternum). Follow the steps in **Skill Drill 13-1**:

1. Take standard precautions.
2. Place the heel of one hand on the center of the chest over the lower half of the sternum **Step 1**.
3. Place the heel of your other hand over the first hand **Step 2**.
4. With your arms straight, lock your elbows and position your shoulders directly over your hands, so that the thrust of each compression is straight down on the sternum. Your technique may be improved or made more comfortable if you interlock the fingers of your lower hand with the fingers of your upper hand; either way, keep your fingers off the patient's ribs.
5. Depress the sternum to a depth of 2 inches to 2.4 inches (5 cm to 6 cm), using direct downward movement and then rising gently upward **Step 3**. This motion allows pressure to be delivered vertically from your shoulders. Downward pressure produces a compression that must be followed immediately by an equal period of relaxation. The ratio of time devoted to compression versus relaxation should be 1:1. It is important that you allow the chest to return to its normal position; do not lean on the patient's chest between compressions. Compression and relaxation should be of equal duration.

Complications from chest compressions are rare but can include fractured ribs, a lacerated liver, and a fractured sternum. Although these injuries cannot be entirely avoided, you can minimize the chance that they will occur if you use good technique and proper hand placement. Your motions must be smooth, rhythmic, and uninterrupted **Figure 13-9A**. Short, jabbing compressions are not effective in producing artificial blood flow. Do not remove the heel of your hand from the patient's chest during relaxation, but make sure that you completely release pressure on the sternum so that it can return to its normal resting position between compressions Figure 13-9B.

Skill Drill 13-1 Performing Chest Compressions

Step 1

Take standard precautions. Place the heel of one hand on the center of the chest (lower half of the sternum).

Step 2

Place the heel of your other hand over the first hand.

Step 3

With your arms straight, lock your elbows and position your shoulders directly over your hands. Depress the sternum at a rate of 100 to 120 compressions per minute, and to a depth of 2 inches to 2.4 inches (5 cm to 6 cm) using a downward movement. Allow the chest to return to its normal position; do not lean on the chest between compressions. Compression and relaxation should be of equal duration.

Words of Wisdom

When performing chest compressions on an adult, compress the chest to a depth of at least 2 inches (5 cm), but not more than 2.4 inches (6 cm). It is difficult to achieve such a precise depth without the use of a monitoring device that provides immediate feedback Figure 13-10. If such a device is available to you, then use it.

It is more dangerous to compress the chest too lightly than it is to compress too forcefully. Compressing hard can lead to fatigue, and as you become tired, your compressions will become shallower. Therefore, it is critical to push hard and push fast and switch compressors (the person providing chest compressions) every 2 minutes—even if the compressor does not feel tired. CPR feedback devices help ensure a consistent rate and depth of compressions.

Figure 13-10 CPR feedback devices help ensure a consistent rate and depth of compressions.

Words of Wisdom

Chest compressions create blood flow to the heart through filling of the coronary arteries. Every time compressions are stopped, blood flow—and thus, perfusion—to the heart (and brain) drops to zero. It takes 5 to 10 compressions to reestablish effective blood flow to the heart after chest compressions are resumed. Avoid frequent or prolonged interruptions in chest compressions, which lead to poor patient outcomes.

Opening the Airway and Providing Artificial Ventilation

Opening the Airway in Adults

Without an open airway, rescue breathing will not be effective. As discussed in Chapter 10, *Airway Management*, the two techniques for opening the airway in adults are the head tilt–chin lift maneuver and the jaw-thrust maneuver. These manual maneuvers are designed to bring the tongue forward and off the back of the throat. The **head tilt–chin lift maneuver** is effective for opening the airway in most patients when there is no indication of a spinal injury **Figure 13-11**.

In patients who have not sustained trauma, this simple maneuver is sometimes all that is required for the patient to resume breathing. If the patient has any foreign material or vomitus in the mouth, then quickly remove it. Remove any liquid materials from the mouth with a suction device; use your hooked index finger to remove any solid material. **Figure 13-12** reviews how to perform the head tilt-chin lift maneuver in an adult.

If spinal injury is suspected, then use the **jaw-thrust maneuver**. Do not tilt the patient's head back, because you want to minimize movement of the patient's neck. To perform a jaw-thrust maneuver, place your fingers behind the angles of the patient's lower jaw and then move the jaw upward. Keep the head in a neutral position as you move the jaw upward and open the mouth. If the patient's mouth remains closed, then you can use your thumbs to pull down the patient's lower lip to allow breathing. If the jaw thrust fails to open the airway, then the head tilt–chin lift should be used to open the airway. An open airway is the primary goal when caring for trauma patients, and you must ensure an open airway to improve survival. **Figure 13-13** reviews how to perform the jaw-thrust maneuver in an adult.

YOU are the Provider — PART 2

You arrive at the scene and find two bystanders performing CPR on the patient, who appears to be in his late 40s. A second BLS ambulance is en route to the scene and will arrive in about 5 minutes. You perform a primary assessment as your partner opens the AED.

Recording Time: 0 Minutes	
Appearance	Motionless; cyanosis of the face
Level of consciousness	Unresponsive
Airway	Open; clear of secretions or foreign bodies
Breathing	Absent
Circulation	No carotid pulse; skin, cool and pale; no gross bleeding

Your partner takes over performing CPR. One of the bystanders tells you that the patient was about to get into his vehicle when he suddenly grabbed his chest, slumped against the vehicle, and eased himself to the ground. By the time the bystander reached him, he was unresponsive and not breathing. The bystander further tells you that he immediately called 9-1-1 and then began CPR.

3. What links in the chain of survival have been maintained at this point?

4. Why is it so critical to minimize interruptions in CPR?

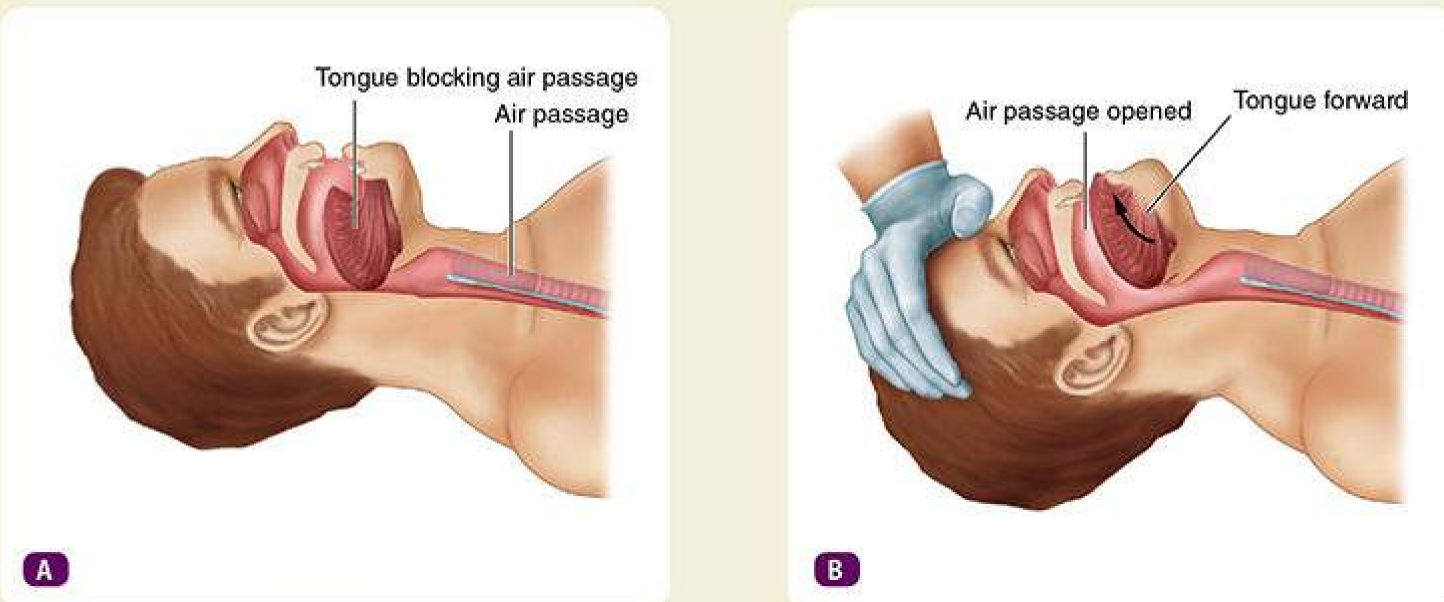

Figure 13-11 **A.** Relaxation of the tongue back into the throat causes airway obstruction. **B.** The head tilt–chin lift maneuver combines two movements of opening the airway; head tilt is shown here.

Figure 13-12 To perform the head tilt–chin lift maneuver, place one hand on the patient's forehead and apply firm backward pressure with your palm to tilt the head back. Next, place the tips of the index and middle fingers of your other hand under the lower jaw near the bony part of the chin. Lift the chin upward, bringing the entire lower jaw with it, helping to tilt the head back.

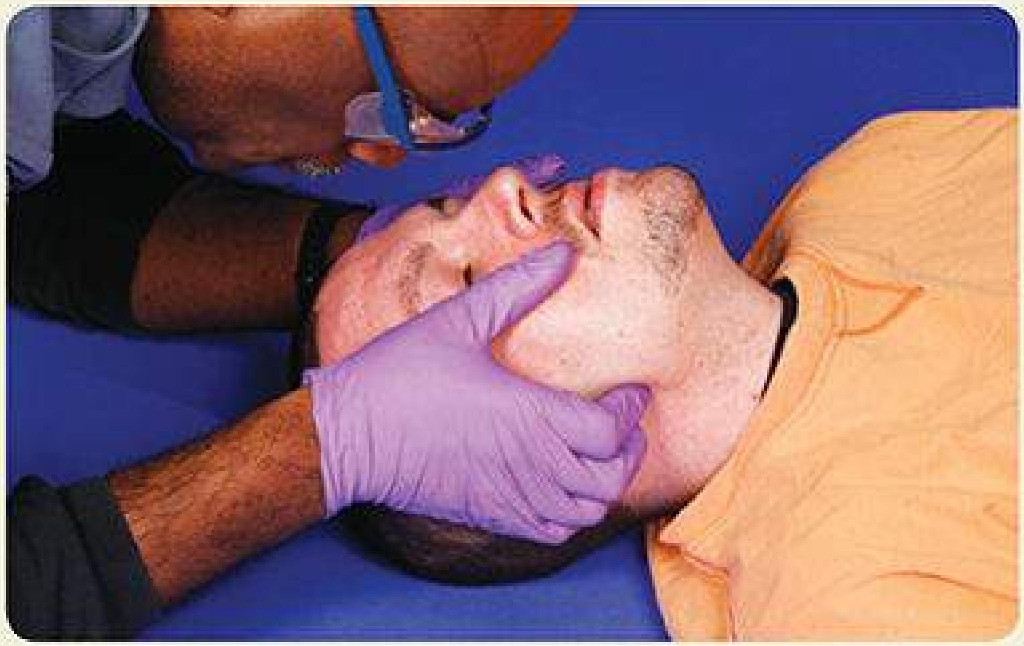

Figure 13-13 To perform the jaw-thrust maneuver, maintain the head in neutral alignment and place your fingers behind the angles of the lower jaw, and move the jaw upward. The completed maneuver should look like this.

Recovery Position

If the patient is breathing adequately on his or her own and has no signs of injury to the spine, hip, or pelvis, then place him or her in the **recovery position**. This position helps to maintain a clear airway in a patient with a decreased level of consciousness who has not sustained traumatic injuries and is breathing adequately on his or her own **Figure 13-14**. It also allows vomitus to drain from the mouth. Roll the patient onto his or her side so that the head, shoulders, and torso move as a unit, without twisting. Then place the top hand under his or her cheek. Never place a patient who has a suspected head or spinal injury in the recovery position because in this position, the spine is not aligned, spinal stabilization is not possible, and further spinal injury could result. Likewise, if the patient has a hip or pelvic injury, then positioning the patient on his or her side could cause fractured bone ends to compress or sever large arteries and veins, resulting in severe internal bleeding. You should suspect an associated spinal injury in any unresponsive patient with a hip or pelvic injury until proven otherwise.

Figure 13-14 The recovery position is used to maintain an open airway in an adequately breathing patient with a decreased level of consciousness who has no spine, hip, or pelvic injuries. It allows vomitus, blood, and any other secretions to drain from the mouth.

Breathing

A lack of oxygen (hypoxia), combined with too much carbon dioxide in the blood (hypercarbia), is lethal. To correct this condition, you must provide slow, deliberate ventilations that last 1 second. This gentle, slow method of ventilating the patient prevents air from being forced into the stomach (discussed later in the chapter).

Provide Artificial Ventilations

Ventilations can be given by one or two EMS providers. Use a barrier device when you administer ventilations in the prehospital environment, such as a pocket mask with a one-way valve or a BVM **Figure 13-15**. Use devices that supply supplemental oxygen when possible. Devices with an oxygen reservoir will provide higher percentages of oxygen to the patient. Regardless of whether you ventilate the patient with or without supplemental oxygen, you should observe the chest for visible rise to assess the effectiveness of your ventilations.

Figure 13-15 When you provide ventilations, use a BVM (shown here) or a pocket mask with one-way valve.

The specific steps of CPR are discussed later in this chapter. Adult BLS procedures are summarized in Table 13-1. Pediatric BLS procedures are summarized in Table 13-2 later in this chapter. Resuscitation of a neonate is discussed in Chapter 33, *Obstetrics and Neonatal Care*.

Recall from Chapter 10, *Airway Management*, that **hyperventilation** (ventilating too fast or with too much force) may cause increased intrathoracic pressure (pressure inside the chest cavity). Increased intrathoracic pressure reduces the amount of blood that returns to the heart, thus decreasing the effectiveness of chest compressions and resulting in the heart and brain receiving decreased amounts of oxygen.

Words of Wisdom

Ventilation is the physical act of moving air in and out of the lungs. Ventilation is required for adequate respiration. Examples of conditions that hinder ventilation include trauma such as flail chest, foreign body airway obstruction, and an injury to the spinal cord that disrupts the phrenic nerve that innervates the diaphragm.

Table 13-1 Review of Adult BLS Procedures

Procedure	
Circulation	
Pulse check	Carotid artery
Compression area	In the center of the chest, in between the nipples
Compression depth	2 in. to 2.4 in. (5 cm to 6 cm)
Compression rate	100 to 120/min
Compression-to-ventilation ratio (until advanced airway is inserted)	30:2
Foreign body obstruction	Responsive: abdominal thrusts (Heimlich maneuver); chest thrusts if patient is pregnant or has obesity Unresponsive: CPR
Airway	
Airway positioning	Head tilt–chin lift; jaw-thrust maneuver if spinal injury is suspected
Breathing	
Ventilations	1 breath every 5 to 6 seconds (10 to 12 breaths/min); about 1 second per breath; visible chest rise
Ventilations with advanced airway placed	1 breath every 6 seconds (a rate of 10 breaths/min)

Stoma Ventilation

Patients who have undergone a laryngectomy (surgical removal of the larynx) often have a permanent tracheal stoma at the midline in the neck. In this case, a stoma is an opening that connects the trachea directly to the skin Figure 13-16. Because it is at the midline, the stoma is the only opening that will move air into the patient's lungs. Patients with a stoma should be ventilated with a BVM or pocket mask device placed directly over the stoma.

Not all stomas are disconnected from the nose and mouth. If air leakage through the nose and mouth interferes with ventilation through the stoma, then cover the nose and mouth with your hand to make a seal. Use a pediatric or infant mask to ventilate through the stoma.

Gastric Distention

Artificial ventilation may result in the stomach becoming filled with air, a condition called gastric distention. Although it occurs more easily in children, this condition also happens frequently in adults. Gastric distention is likely to occur if you hyperventilate the patient. If you ventilate too forcefully, or if the patient's airway is not opened adequately, then the excess gas opens up the collapsible tube (the esophagus) and allows gas to enter the stomach. Therefore, it is important for you to give slow, gentle breaths. Such breaths are also more effective in ventilating the lungs. Excessive inflation of the stomach is dangerous because it can cause the patient to vomit during CPR. It can also reduce lung volume by elevating the diaphragm.

Figure 13-16 **A.** This stoma connects the trachea directly to the skin. **B.** Use a BVM or pocket mask device to ventilate a patient with a stoma.

A & B: © Jones & Bartlett Learning. Courtesy of MIEMSS.

If massive gastric distention interferes with adequate ventilation, then contact medical control. Check the airway again and reposition the patient, watch for rise and fall of the chest, and avoid giving forceful breaths. Have a suction unit available in case the patient vomits. Remember, mortality increases significantly if aspiration occurs. If an ALS provider is available, then he or she can insert an orogastric or nasogastric tube to decompress the stomach.

One-Rescuer Adult CPR

When you provide CPR alone, you must provide a continuous cycle of 30 chest compressions followed by 2 artificial ventilations (a ratio of 30:2). To perform one-rescuer adult CPR, follow the steps in Skill Drill 13-2:

1. Take standard precautions. Establish unresponsiveness and call for additional help; use your mobile phone if needed Step 1.
2. Position the patient properly (supine) on a flat surface.

3. Quickly visualize the chest for signs of breathing while simultaneously palpating for a carotid pulse. Take no more than 10 seconds in total to do this **Step 2**.
4. If pulse and breathing are absent, then perform CPR until an AED is available. Place your hands in the proper position for delivering external chest compressions, as described previously **Step 3**. Give 30 chest compressions at a rate of 100 to 120 per minute for an adult. Each set of 30 compressions should take about 17 seconds.
5. Open the airway according to your suspicion of spinal injury **Step 4**.
6. Give two ventilations of 1 second each and observe for visible chest rise **Step 5**.
7. Continue cycles of 30 chest compressions and two ventilations until additional personnel arrive or the patient starts to move.

Two-Rescuer Adult CPR

You and your team should be able to perform one-rescuer and two-rescuer CPR with ease. Two-rescuer CPR is always preferable because it is less tiring and it facilitates effective chest compressions. In fact, a team approach to CPR and AED use is far superior to the one-rescuer approach. Once one-rescuer CPR is in progress, additional rescuers can be added to the procedure easily. Before assisting with CPR, a second rescuer should apply the AED and then set up airway adjuncts, including a BVM and suction, and insert an oropharyngeal (oral) airway. If CPR is in progress, then the second rescuer should enter the procedure after a cycle of 30 compressions and two ventilations. To perform two-rescuer adult CPR, follow the steps in **Skill Drill 13-3**:

1. Take standard precautions. Establish unresponsiveness while your partner moves to the patient's side to be ready to deliver chest compressions **Step 1**.
2. If the patient is unresponsive, then simultaneously check for breathing and palpate for a carotid pulse; take no more than 10 seconds to do this **Step 2**.
3. If the patient is not breathing and has no pulse, then begin CPR, starting with chest compressions. Give 30 chest compressions at a rate of 100 to 120 per minute. If an AED is available, then apply it and follow its voice prompts. Do *not* interrupt chest compressions to apply the AED pads **Step 3**.
4. Open the airway according to your suspicion of spinal injury **Step 4**.
5. Give two ventilations of 1 second each and observe for visible chest rise **Step 5**.
6. Perform five cycles of 30 compressions and two ventilations (this should take about 2 minutes). After 2 minutes of CPR, the compressor and ventilator should switch positions. The switch time should take no longer than 5 seconds. Reanalyze the patient's cardiac rhythm with the AED every 2 minutes and deliver a shock if indicated.
7. Continue cycles of 30 chest compressions and two ventilations until ALS providers take over or the patient starts to move.

Words of Wisdom

When CPR is in progress on a patient who has an advanced airway device in place (ie, ET tube, King LT supraglottic airway, i-gel supraglottic airway), cycles of CPR are not indicated. Compressions should be continuous at a rate of 100 to 120 per minute and ventilations should occur at a rate of one breath every 6 seconds (10 breaths/min). Do not attempt to synchronize compressions and ventilations; do not pause between compressions to deliver breaths.

Skill Drill 13-2 Performing One-Rescuer Adult CPR

Step 1

Take standard precautions. Establish unresponsiveness and call for help. Use your mobile phone if needed.

Step 2

Check for breathing and a carotid pulse for no more than 10 seconds.

Step 3

If breathing and pulse are absent, then perform CPR until an AED is available. Give 30 chest compressions at a rate of 100 to 120 per minute.

Step 4

Open the airway according to your suspicion of spinal injury.

Step 5

Give two ventilations of 1 second each and observe for visible chest rise. Continue cycles of 30 chest compressions and two ventilations until additional personnel arrive or the patient starts to move.

Skill Drill 13-3 Performing Two-Rescuer Adult CPR

Step 1

Take standard precautions. Establish unresponsiveness and take positions.

Step 2

Check for breathing and a carotid pulse.

Step 3

Begin CPR, starting with chest compressions. Give 30 chest compressions at a rate of 100 to 120 per minute. If the AED is available, then apply it and follow the voice prompts.

Step 4

Open the airway according to your suspicion of spinal injury.

Step 5

Give two ventilations of 1 second each and observe for visible chest rise. Continue cycles of 30 chest compressions and two ventilations (switch roles every five cycles [2 minutes]) until ALS providers take over or the patient starts to move. Reanalyze the patient's cardiac rhythm with the AED every 2 minutes and deliver a shock if indicated.

Switching Positions

It is critical to switch rescuers during CPR to maintain high-quality compressions. After five cycles of CPR (about 2 minutes), the rescuer providing compressions to the patient (the compressor) will begin to tire, and compression quality will decrease. Therefore, compressors should switch positions every 2 minutes. If there are only two rescuers on scene, then the two rescuers will alternate positions. If additional rescuers are available, the compressor should rotate every 2 minutes. During switches, every effort should be made to minimize the time that no compressions are being administered. It should take less than 5 seconds to switch compressors.

The switch between the two rescuers can be easily accomplished. Rescuer one (the first compressor) should finish the cycle of 30 compressions while the second rescuer moves to the opposite side of the chest and moves into position to begin compressions. Rescuer one should deliver two rescue breaths and then rescuer two should take over compressions by administering 30 chest compressions. Rescuer one will then deliver two ventilations and the CPR cycles will continue as needed until the next 2-minute mark (five cycles) is reached, at which time the process will be repeated.

A summary of how to manage cardiac arrest in adults is shown in **Figure 13-17**.

Devices and Techniques to Assist Circulation

The effectiveness of CPR depends on the amount of blood circulated throughout the body as a result of chest compressions. Even under ideal conditions, however, manual chest compressions cannot equate to normal cardiac output. In addition, factors such as rescuer fatigue or inaccurate depth or rate of compressions can further impede the resuscitation process. Before you consider the use of mechanical devices to assist circulation, ensure that your manual chest compressions are of consistently high quality.

Words of Wisdom

Many EMS systems have implemented a pit crew approach to the management of cardiac arrest. The term originated in motor racing, in which teams of technicians rapidly assess and repair vehicles in a matter of seconds. Following this model, each resuscitation team member is assigned a specific role before beginning care of the cardiac arrest patient. For example:

- EMT 1 will be the team leader.
- EMT 2 and EMT 3 will perform CPR.
- EMT 4 will operate the AED.

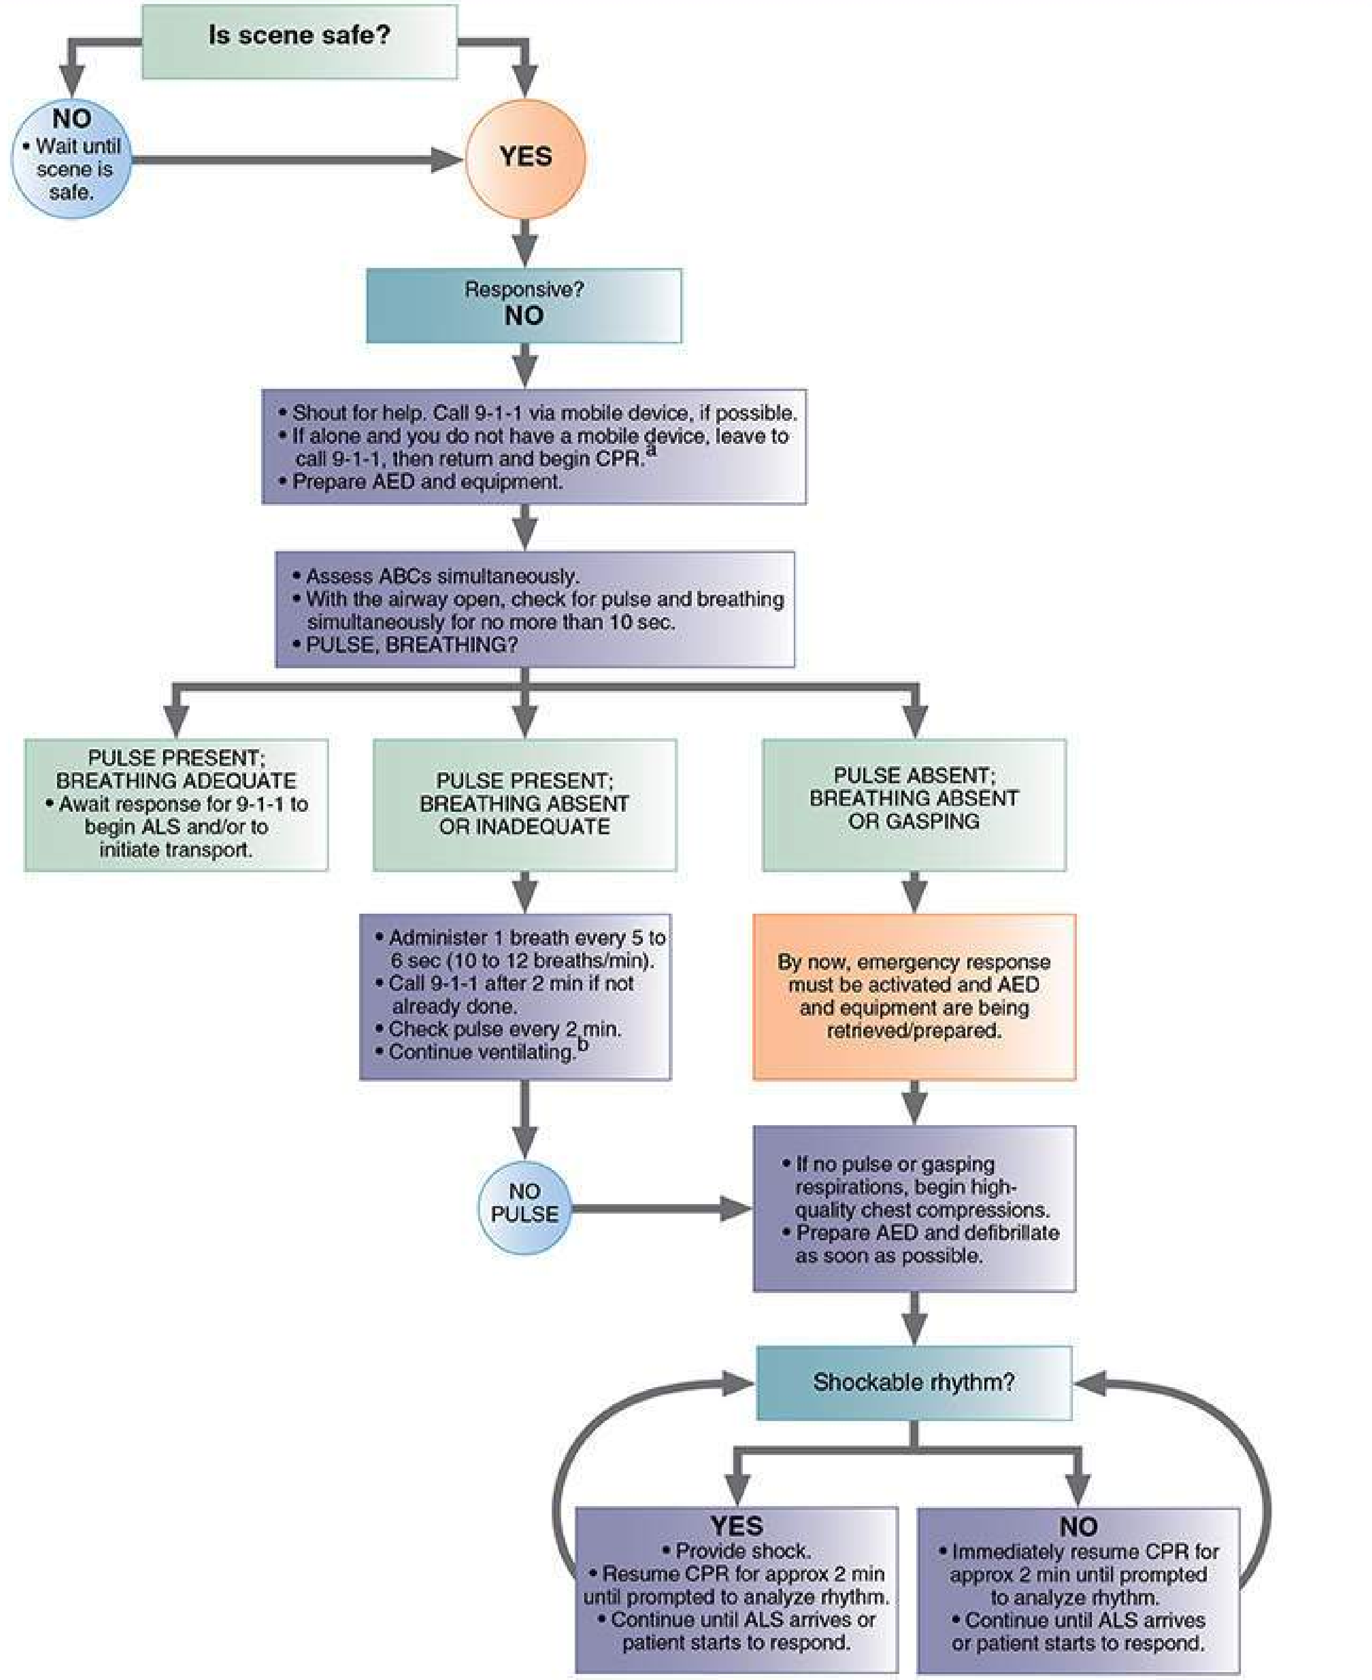
This model clarifies each team member's role and responsibilities, and minimizes confusion on the scene. If there are only two EMTs on scene initially—as is the situation in many cases—then a plan should be developed to integrate additional rescuers into the resuscitation effort as they arrive. This preplanned approach allows rescuers to accomplish multiple steps and assessments simultaneously, rather than the slower, sequential manner used by individual rescuers. Therefore, the pit crew model minimizes the time to first compression. The success of this team approach depends on preplanning, practice, and thorough familiarity with the cardiac arrest algorithm. See Chapter 41, A Team Approach to Health Care, for more information.

Special Populations

On occasion, you may encounter a patient who has a left ventricular assist device (LVAD). The LVAD is a mechanical pump that is implanted in the chest and helps pump blood from the left ventricle to the aorta. A tube from the device passes through the skin and is attached to an external power source that the patient wears on their belt or an over-the-shoulder harness. The LVAD is commonly implanted in patients with severe heart failure or in those who are awaiting a heart transplant. If the LVAD is working, then you will hear a humming sound when listening to the chest with a stethoscope. Blood flows continuously through the LVAD, and the more assistance the LVAD is providing to the heart, the weaker the patient's pulse will be. In some LVAD patients, you may not feel a pulse at all, even though they are responsive and alert. When transporting a patient who has an LVAD, be sure to bring all of the LVAD equipment with you and ensure that the receiving facility is capable of caring for the patient's specific needs.

You should know the location of LVAD patients in your service area. If possible, visit with the patient prior to any emergency to determine his or her specific device and to obtain instructions. Family members are usually knowledgeable about the device; use them as a source of information.

LVAD coordinators are usually available for consult 24 hours a day. These medical professionals typically work at the same facility that placed the device, so they should also be familiar with the patient. Follow your local protocols or contact medical control regarding the treatment of a patient with an LVAD.



[a]If the patient is a child or infant, perform 2 minutes of CPR if needed, then call 9-1-1.

[b]If life-threatening opioid overdose is suspected, administer naloxone, if available, per local protocols and see opioid life-threatening overdose algorithm in Chapter 21, *Toxicology*.

Figure 13-17 Adult cardiac arrest algorithm. Pediatric cardiac arrest follows the same algorithm with the exception of the compression depth and compression-to-ventilation ratio. When performing CPR on pediatric patients, compress to a depth of at least one-third the anterior-posterior diameter of the chest, at a ratio of 30:2 compressions to ventilations (one rescuer) or 15:2 compressions to ventilations (two rescuers).

Several mechanical devices are available to assist emergency responders in maximizing blood flow during CPR. Although improved patient outcomes have not yet been documented, these devices may be considered for use as an adjunct to CPR in select settings when used by properly trained personnel for patients in cardiac arrest in the prehospital or in-hospital setting. These specific settings include instances when limited rescuers are available, when CPR is prolonged, or when CPR is required in a moving ambulance.

Active Compression-Decompression CPR

Active compression-decompression CPR is a technique that involves compressing the chest and then actively pulling it back up to its neutral position or beyond (decompression). This technique may increase the amount of blood that returns to the heart, and thus, the amount of blood ejected from the heart during the compression phase. **Figure 13-18** shows an active compression-decompression CPR device. It features a suction cup that is placed in the center of the chest. After compressing the chest to the proper depth, the rescuer pulls up on the handle of the device to provide active decompression of the chest, thus ensuring that the chest returns to at least its neutral position or even beyond neutral.

Figure 13-18 An active compression-decompression CPR device.

Provided with permission by ZOLL Medical.

▶ Impedance Threshold Device

An **impedance threshold device (ITD)** is a valve device placed between the ET tube and a BVM; it may also be placed between the bag and mask if an ET tube is not in place. The ITD is designed to limit the air entering the lungs during the recoil phase between chest compressions **Figure 13-19**. This results in negative intrathoracic pressure that may draw more blood toward the heart, ultimately resulting in improved cardiac filling and circulation during each chest compression. The ITD may be considered when used together with devices that provide active compression-decompression CPR. It is *not* currently recommended for use with conventional CPR. If ROSC occurs, then the ITD should be removed. You should understand research trends regarding the effectiveness of the ITD.

Figure 13-19 An impedance threshold device.

Courtesy of Advanced Circulatory Systems, Inc.

Mechanical Piston Device

A **mechanical piston device** is a device that depresses the sternum via a compressed gas-powered or electric-powered plunger mounted on a backboard **Figure 13-20**. The patient is positioned supine on the backboard, with the piston positioned on top of the patient with the plunger centered over the patient's thorax in the same manner as with manual chest compressions. The device is then secured to the backboard.

The mechanical piston device allows rescuers to configure the depth and rate of compressions, resulting in consistent delivery. This frees the rescuer to complete other tasks and eliminates rescuer fatigue that results from continuous delivery of manual chest compressions. These devices have been available for many years. The latest versions of these devices offer you the option of providing compressions using a battery instead of an oxygen tank or a compressed air system, thus eliminating the tanks and hoses.

Load-Distributing Band CPR or Vest CPR

The **load-distributing band (LDB)** is a circumferential chest compression device composed of a constricting band and backboard **Figure 13-21**. The device is either electrically or pneumatically driven to compress the heart by putting inward pressure on the thorax.

As with the mechanical piston device, use of the LDB frees the rescuer to complete other tasks. The device weighs less than the early-version mechanical piston devices and can be easier to apply.

Figure 13-20 **A.** A mechanical piston device. **B.** The device in use.

YOU are the Provider — PART 2

With CPR ongoing, you open the AED pads and prepare to apply them to the patient's chest. You note that the patient has a medication patch on the right upper part of his chest. You also see a bulge with a scar over it on the left upper part of his chest. You apply the AED pads, analyze the patient's cardiac rhythm, and receive a "shock advised" message. After delivering the shock, you and your partner resume CPR. The backup ambulance arrives and one of the EMTs assesses the quality of your CPR.

Recording Time: 4 Minutes	
Level of consciousness	Unresponsive
Respirations	Absent (baseline); 2 breaths are being given after every 30 chest compressions; chest rise is visible with each breath
Pulse	Absent (baseline); femoral pulse is palpable with chest compressions
Skin	Pale
Blood pressure	Not measurable
Oxygen saturation (Spo_2)	Not measurable

5. Should you remove the medication patch or leave it in place? Why or why not?
6. What does the bulge and scar over the patient's left chest indicate? How will this affect the way you treat the patient?

Figure 13-21 A load-distributing band.

Provided with permission by ZOLL Medical.

Although a mechanical CPR device may be a reasonable alternative to conventional CPR in specific settings, manual chest compressions remain the standard of care. If your EMS service uses a mechanical CPR device, then it is critical to practice frequently to ensure that you can apply it rapidly. Remember to minimize interruptions to chest compressions while the device is being applied.

Infant and Child CPR

In most cases, cardiac arrest in infants and children follows respiratory arrest, which triggers hypoxia and **ischemia** (decreased oxygen supply) of the heart. Children consume oxygen two to three times as rapidly as adults, so you must first focus on opening the airway and providing artificial ventilation. Often, this will be enough to allow the child to resume spontaneous breathing and, thus, prevent cardiac arrest. Therefore, airway and breathing are the focus of pediatric BLS **Table 13-2**.

Table 13-2 Review of Pediatric BLS Procedures

Procedure	Infants (between age 1 month and 1 year[a])	Children (1 year to onset of puberty[b])
Circulation		
Pulse check	Brachial artery	Carotid or femoral artery
Compression area	Just below the nipple line	In the center of the chest, in between the nipples
Compression width	Two-finger technique or two-thumb-encircling-hands technique	Heel of one or both hands
Compression depth	At least one-third anterior-posterior diameter (about 1.5 in. [4 cm])	At least one-third anterior-posterior diameter (about 2 in. [5 cm])
Compression rate	100 to 120/min	100 to 120/min
Compression-to-ventilation ratio (until advanced airway is inserted)	30:2 (one rescuer); 15:2 (two rescuers)[c]	30:2 (one rescuer); 15:2 (two rescuers)[c]
Foreign body obstruction	Responsive: Back slaps and chest thrusts Unresponsive: CPR	Responsive: Abdominal thrusts (Heimlich maneuver) Unresponsive: CPR
Airway		
	Head tilt–chin lift; jaw-thrust maneuver if spinal injury is suspected	Head tilt–chin lift; jaw-thrust maneuver if spinal injury is suspected
Breathing		
Ventilations	1 breath every 3 to 5 seconds (12 to 20 breaths/min); about 1 second per breath; visible chest rise	1 breath every 3 to 5 seconds (12 to 20 breaths/min); about 1 second per breath; visible chest rise
Ventilations with advanced airway placed	1 breath every 6 seconds (a rate of 10 breaths/min)	1 breath every 6 seconds (a rate of 10 breaths/min)

[a]The AHA defines neonatal patients as birth to age 1 month, and infants as age 1 month to 1 year. Neonatal resuscitation is covered in Chapter 33, *Obstetrics and Neonatal Care.*

[b]Onset of puberty is approximately 12 to 14 years of age, as defined by secondary characteristics (eg, breast development in girls and armpit hair in boys).

[c]Pause compressions to deliver ventilations.

As discussed in Chapter 34, *Pediatric Emergencies,* respiratory issues leading to cardiopulmonary arrest in children can have a number of different causes, including:

- Injury, both blunt and penetrating
- Infections of the respiratory tract or another organ system (croup, epiglottitis)
- A foreign body in the airway
- Submersion (drowning)
- Electrocution
- Poisoning or drug overdose
- Sudden infant death syndrome (SIDS)

Determining Responsiveness

Never shake a child to determine whether he or she is responsive, especially if the possibility of a neck or back injury exists. Instead, gently tap the child on the shoulder, and say loudly, "Are you okay?" **Figure 13-22**. With an infant, gently tap the soles of the feet. If a child is responsive but struggling to breathe, then allow him or her to remain in whatever position is most comfortable.

If you find an unresponsive, apneic, and pulseless child while you are alone and off duty, and you did not witness the child's collapse, perform CPR beginning with chest compressions for approximately five cycles (about 2 minutes), and then stop to call 9-1-1 and retrieve an AED. Do not call 9-1-1 right away, as you would with an adult. Remember that cardiopulmonary arrest in children is most often the result of respiratory failure, not a primary cardiac event. Therefore, children will require immediate restoration of oxygenation, ventilation, and circulation, which can be accomplished by immediately performing five cycles (about 2 minutes) of CPR before activating the EMS system.

Figure 13-22 Never shake a child to determine responsiveness. Rather, gently tap on the shoulder (child) or tap the soles of the feet (infant), and speak loudly.

Words of Wisdom

Although uncommon, you may encounter a child whose cardiac arrest was caused by a primary cardiac event rather than a respiratory problem. If an otherwise healthy child without an apparent respiratory condition suddenly collapses and you witness it, then first confirm that the child is in cardiac arrest. If you are alone without a mobile phone, then leave the child to call 9-1-1 and get an AED before beginning CPR. If you are not alone, then send someone to call 9-1-1 and get an AED while you begin CPR. The sudden collapse of an otherwise healthy child does not indicate a respiratory problem; instead, it suggests a primary cardiac event that may respond to defibrillation. Therefore, it is critical to get the AED to the child's side as soon as possible.

Check for Breathing and a Pulse

After you establish responsiveness, you need to assess breathing and circulation. As with an adult, this assessment can occur simultaneously and should take no longer than 10 seconds. Visualize the chest for signs of breathing and palpate for a pulse in a large central artery. You can usually palpate the carotid or femoral pulse in children older than 1 year, but it is difficult in infants. Therefore, in infants, palpate the brachial artery, which is located on the inner side of the arm, midway between the elbow and shoulder. Place your thumb on the outer surface of the arm between the elbow and shoulder. Then place the tips of your index and middle fingers on the inside of the biceps, and press lightly toward the bone. CPR will be required if the infant or child is not breathing or is not breathing normally (agonal gasps), and a pulse is absent (or less than 60 beats/min).

As with an adult, an infant or child must be lying on a hard, flat surface for effective chest compressions. If you need to carry an infant while providing CPR, then your forearm and hand can serve as the flat surface. Use your palm to support the infant's head. In this way, the infant's shoulders are elevated, and the head is slightly tilted back in a position that will keep the airway open. Ensure that the infant's head is not higher than the rest of the body.

The technique for chest compressions in infants and children differs from adults because of a number of anatomic differences, including the position of the heart, the size of the chest, and the fragile organs of a child. The liver (immediately under the right side of the diaphragm) is relatively large and fragile, especially in infants. The spleen, on the left, is smaller and more fragile in children than in adults. These organs are easily injured if you are not careful in performing chest compressions, so be sure that your hand position is correct before you begin. The chest of an infant is smaller and more pliable than that of an older child or adult; therefore, you should use only two fingers to compress the chest. If two rescuers are performing CPR on an infant, use the two-thumb-encircling-hands technique to deliver chest compressions. In children, especially those older than 8 years, you can use the heel of one or both hands to compress the chest.

Follow these steps to perform infant chest compressions **Skill Drill 13-4** :

1. Take standard precautions. Place the infant on a firm surface, using one hand to keep the head in an open airway position. You can also use a pad or wedge under the shoulders and upper body to keep the head from tilting forward.
2. Imagine a line drawn between the nipples. Place two fingers in the middle of the sternum, just below the nipple line **Step 1**.
3. Using two fingers, compress the sternum at least one-third the anterior-posterior diameter of the chest (approximately 1.5 inches [4 cm] in most infants). Compress the chest at a rate of 100 to 120 per minute.
4. After each compression, allow the sternum to return briefly to its normal position. Allow equal time for compression and relaxation of the chest. Do not remove your fingers from the sternum, and avoid jerky movements **Step 2**.

Coordinate compressions and ventilations in a 30:2 ratio if you are working alone, and 15:2 if you are working with a trained bystander or another health care provider. Ensure the infant's chest fully recoils in between compressions and that the chest visibly rises with each ventilation. You will find this easier to do if you use your free hand to keep the head in the open airway position. If the chest does not rise, or rises only a little, then use a head tilt–chin lift to open the airway. Reassess the infant for signs of spontaneous breathing or a pulse after five cycles (about 2 minutes) of CPR.

Skill Drill 13-5 shows the steps for performing CPR in children between 1 year of age and the onset of puberty:

1. Take standard precautions. Place the child on a firm surface. Place the heel of one or two hands in the center of the chest, in between the nipples. Avoid compression over the lower tip of the sternum, which is called the xiphoid process **Step 1**.

Skill Drill 13-4 Performing Infant Chest Compressions

Step 1

Take standard precautions. Position the infant on a firm surface while maintaining the airway. Place two fingers in the middle of the sternum with one finger just below the nipple line.

Step 2

Use two fingers to compress the chest at least one-third its depth at a rate of 100 to 120 per minute. Allow the sternum to return to its normal position between compressions.

Skill Drill 13-5 Performing CPR on a Child

Step 1

Take standard precautions. Place the child on a firm surface. Identify the location for hand placement, as shown here. Place the heel of one or two hands in the center of the chest, in between the nipples, avoiding the xiphoid process.

Step 2

Compress the chest at least one-third the anterior-posterior diameter of the chest at a rate of 100 to 120 times/min. Coordinate compressions with ventilations in a 30:2 ratio (one rescuer) or 15:2 (two rescuers), pausing for two ventilations. Reassess for a pulse after 2 minutes. If there is no pulse and an AED is available, then resume CPR and apply the AED pads.

Step 3

If the child regains a pulse of greater than 60 beats/min and resumes effective breathing, then place him or her in a position that allows for frequent reassessment of the airway and vital signs during transport.

2. Compress the chest at least one-third the anterior-posterior diameter of the chest (approximately 2 inches [5 cm] in most children) at a rate of 100 to 120 per minute. With pauses for ventilation, the actual number of compressions delivered will be about 80 per minute. In between compressions, allow the chest to fully recoil; do not lean on the chest. Compression and relaxation time should be the same duration. Use smooth movements. Hold your fingers off the child's ribs, and keep the heel of your hand(s) on the sternum.
3. Coordinate compressions and ventilations in a 30:2 ratio for one rescuer and 15:2 for two rescuers, making sure the chest rises with each ventilation. At the end of each cycle, pause for two ventilations **Step 2**.
4. After five cycles (about 2 minutes) reassess for a pulse. If there is no pulse and you have an AED, continue CPR and

apply the AED pads.
5. If the child regains a pulse of greater than 60 beats/min and resumes effective breathing, place him or her in a position that allows for frequent reassessment of the airway and vital signs during transport **Step 3**.

Switching rescuer positions is the same for children as it is for adults, every five cycles (2 minutes) of CPR. Remember, if the child is past the onset of puberty, use the adult CPR sequence, including the use of the AED.

Airway

Infants and toddlers often put toys and other objects, as well as food, in their mouths; therefore, foreign body obstruction of the upper airway is common. You must make sure that the upper airway is open when managing pediatric respiratory emergencies or cardiopulmonary arrest. If the child is unresponsive and lying in a supine position, then the airway may become obstructed when the tongue and throat muscles relax and the tongue falls backward.

If the child is unresponsive but breathing adequately, then place him or her in the recovery position to maintain an open airway and allow drainage of saliva, vomitus, or other secretions from the mouth **Figure 13-23**. Do not use this position if you suspect injury to the spine, hips, or pelvis unless you can secure the child to a backboard that can be tilted to the side. If the child is responsive and breathing, but in a labored fashion, then provide prompt transport to the closest appropriate hospital.

Opening the airway in an infant or child is done by using the same techniques as used for an adult. However, because a child's neck is so flexible, the techniques should be slightly modified. The jaw-thrust maneuver is the best method to use if you suspect a spinal injury in a child. If a second rescuer is present, he or she should immobilize the child's cervical spine. If spinal injury is not suspected, then use the head tilt–chin lift maneuver but modified so that, as you tilt the head back, you are moving it only into the neutral position or a slightly extended position **Figure 13-24**.

Figure 13-23 A child who is unresponsive but breathing adequately should be placed in the recovery position to allow saliva or vomitus to drain from the mouth.

Head Tilt–Chin Lift Maneuver

Perform the head tilt–chin lift maneuver in a child in the following manner:

1. Place one hand on the child's forehead, and tilt the head back gently, with the neck slightly extended.
2. Place two or three fingers (not the thumb) of your other hand under the child's chin, and lift the jaw upward and outward. Do not close the mouth or push under the chin; either move may obstruct rather than open the airway.
3. Remove any visible foreign body or vomitus.

Jaw-Thrust Maneuver

Perform the jaw-thrust maneuver in a child in the following manner:

1. Place two or three fingers under each side of the angle of the lower jaw; lift the jaw upward and outward.
2. If the jaw thrust alone does not open the airway and cervical spine injury is not a consideration, then tilt the head slightly. If cervical spine injury is suspected, then use a second rescuer to immobilize the cervical spine.

Remember that the head of an infant or young child is disproportionately large in comparison with the chest and shoulders. As a result, when a child is lying flat on his or her back, especially on a backboard, the head will bend forward (hyperflexion) onto the upper chest. This position can partially or completely obstruct the upper airway. To avoid this possibility, place a wedge of padding under the child's upper chest and shoulders (torso).

Figure 13-24 Use the head tilt–chin lift maneuver to open the airway in a child who has not sustained a traumatic injury. Do not overextend the neck.

Provide Rescue Breathing

If the child is not breathing but has a pulse, then open the airway and deliver one breath every 3 to 5 seconds (12 to 20 breaths/min) **Figure 13-25**. If the child is not breathing and does not have a pulse, then deliver 2 rescue breaths after every 30 chest compressions (15 chest compressions if two rescuers are present). Each ventilation should last about 1 second and should produce visible chest rise. Use the proper-sized mask and ensure an adequate mask-to-face seal.

If an infant or small child is breathing, then provide prompt transport. Again, a child who is in respiratory distress should be allowed to stay in whatever position is most comfortable. Children who are unresponsive but breathing with difficulty should be kept in a position that allows you to manage the airway and provide ventilatory support, if needed.

In a child with a tracheostomy tube in the neck, remove the mask from the BVM and connect it directly to the tracheostomy tube to ventilate the child. If a BVM is unavailable, a face mask with one-way valve or other barrier device over the tracheostomy site can be used. Place your hand firmly over the child's mouth and nose to prevent the artificial breaths from leaking out of the upper airway.

Figure 13-25 Open the child's airway and provide rescue breathing.

Words of Wisdom

An injured child with a serious airway or breathing problem is likely to need full-time attention from two EMTs. Therefore, it is important for you to arrange for backup from another unit as soon as possible—perhaps even before you arrive at the scene. In such cases, you will need a driver and often additional help with patient care.

Interrupting CPR

CPR is a crucial, lifesaving procedure that provides minimal circulation and ventilation until the patient can receive defibrillation, ALS treatment, and definitive care at the ED. No matter how well CPR is performed, however, it is rarely enough to save a patient's life. If ALS is unavailable at the scene, you must provide transport based on your local protocols and continue CPR on the way. En route to the ED, consider requesting a rendezvous with ALS providers, if available. This will provide ALS care to the patient sooner, improving his or her chance for survival. However, not all EMS systems have ALS support available to them, especially in rural settings.

Special Populations

Children in respiratory distress are often struggling to breathe. As a result, they usually position themselves in a way that keeps the airway open enough for air to move. Let the child stay in that position as long as his or her breathing remains adequate. If you and your partner arrive at the scene and find that the infant or child is not breathing or has cyanosis, then immediate management (including rescue breathing and supplemental oxygen) is essential. Consider requesting additional assistance, if available.

Remember, too, that a child's airway is smaller than that of an adult. Therefore, there is greater resistance to air flow. As a result, you will need to use *slightly* more ventilatory pressure to inflate the lungs. You will know you are giving the correct tidal volume when you see the chest rise. Infants and children should be ventilated once every 3 to 5 seconds, (at a rate of 12 to 20 breaths/min). Do not ventilate too fast or use too much force.

If air enters freely with your initial breaths and the chest rises, then the airway is clear. If air does not enter freely, then check the airway for obstruction. Reposition the patient to open the airway, and attempt to give another breath. If air still does not enter freely, then you must take steps to relieve the obstruction.

Try not to interrupt CPR for more than a few seconds, except when it is absolutely necessary. For example, if you have to move a patient up or down stairs, you should continue CPR until you arrive at the head or foot of the stairs, interrupt CPR at a mutually agreed-on signal, and move quickly to the next level where you can resume CPR. Do not move the patient until all transport arrangements are made so that interruptions to CPR can be kept to a minimum. See Chapter 8, *Lifting and Moving Patients*, to review patient lifting and moving techniques.

Chest compression fraction is the total percentage of time during a resuscitation attempt in which chest compressions are being performed. Make every effort to maintain a chest compression fraction of at least 60% (the higher the better). The more frequent the interruptions in chest compressions, the lower the compression fraction will be. Low compression fractions lead to worse patient outcomes. Most modern cardiac monitors will provide information about chest compression fraction that you can review after a cardiac arrest. If possible, routinely review this information after every arrest so that you can learn ways to improve the chest compression fraction and improve on other key performance indicators.

When Not to Start CPR

As an EMT, it is your responsibility to start CPR on virtually all patients who are in cardiac arrest. There are only three general exceptions to the rule.

First, do not start CPR if the scene is unsafe. The concept of ensuring scene safety applies in cardiac arrest situations, just as it does on any other call.

Second, do not start CPR if the patient has obvious signs of death. Recall from Chapter 3, *Medical, Legal, and Ethical Issues,* that obvious signs of death include an absence of a pulse and breathing, along with any one of the following findings:

- **Rigor mortis**, or stiffening of the body after death
- **Dependent lividity** (livor mortis), a discoloration of the skin caused by pooling of blood **Figure 13-26**
- Putrefaction (decomposition of the body tissues)
- Evidence of nonsurvivable injury, such as decapitation, dismemberment, or being burned beyond recognition.

Rigor mortis and dependent lividity develop after a patient has been dead for a long period.

YOU are the Provider — PART 4

After 2 minutes of CPR, you reanalyze the patient's cardiac rhythm and receive a "no shock advised" message. You and your partner immediately resume CPR. During CPR, your partner ventilates the patient with a BVM and high-flow oxygen. As she attempts to insert an oral airway, the patient starts to gag. You quickly reassess him.

Recording Time: 7 Minutes	
Level of consciousness	Unresponsive
Respirations	Occasional agonal gasps; 4 breaths/min
Pulse	100 beats/min; strong carotid pulse; absent radial pulses
Skin	Skin color is improving
Blood pressure	70/40 mm Hg
Spo_2	82% (on oxygen)

7. How should you continue to treat this patient?

8. Because the patient is no longer in cardiac arrest, should you remove the AED pads? Why or why not?

Figure 13-26 Dependent lividity is an obvious sign of death, caused by blood settling to the areas of the body not in firm contact with the ground. The lividity in this figure is seen as purple discoloration of the back, except in areas that are in firm contact with the ground (scapula and buttock).

Third, do not start CPR if the patient and his or her physician have previously agreed on a do not resuscitate (DNR) order or no-CPR order **Figure 13-27**. DNR orders give you permission not to attempt resuscitation. This may apply only to situations in which the patient is known to be in the terminal stage of an incurable disease. In this situation, CPR would only prolong the patient's death. However, end-of-life issues can be complicated. Advance directives, such as living wills, may express the patient's wishes; however, these documents may not be readily producible by the patient's family or caregiver. In such cases, the safest course is to begin CPR under the rule of implied consent and then contact medical control for further guidance. However, if a valid DNR document or living will is produced, resuscitative efforts may be withheld. Learn your local protocols and the standards in your EMS system for treating terminally ill patients. Some EMS systems have electronic notes on patients who are preregistered with the system. These notes usually specify the amount and extent of treatment that is desired. Other states have specific DNR forms that allow EMS providers to withhold care when the patient, family, and physician have agreed in advance that such a course is most appropriate. It is essential that you understand your local protocols and are aware of the specific restrictions these advance directives imply.

You may also encounter Physician Orders for Life-Sustaining Treatment (POLST) or Medical Orders for Life-Sustaining Treatment (MOLST) forms. These legal documents describe acceptable interventions for the patient in the form of medical orders and must be signed by an authorized medical provider to be valid. Be familiar with POLST or MOLST forms, and learn your local protocols and state laws with regard to withholding end-of-life medical interventions. If you are presented with a POLST or MOLST form, then contact medical control for guidance.

In all other cases, begin CPR on anyone who is in cardiac arrest. It is usually impossible to know how long the patient's brain and vital organs have gone without oxygen. Factors such as air temperature and the basic health of the patient's tissues and organs can affect his or her ability to survive. Therefore, most legal advisers recommend that, when in doubt, always give too much care rather than too little care. Therefore, always start CPR if any doubt exists.

When to Stop CPR

As an EMT, you are generally not responsible for making the decision to stop CPR. After you begin CPR in the field, you must continue until one of the following events occurs (the STOP mnemonic):

S The patient *Starts* breathing and has a pulse.

T The patient's care is *Transferred* to another provider of equal or higher-level training.

O You are *Out* of strength or too tired to continue CPR.

P A *Physician* who is present or providing online medical direction assumes responsibility for the patient and gives direction to discontinue CPR.

Out of strength does not mean merely weary; rather, it means that you are no longer physically able to perform CPR. In short, always continue CPR until the patient's care is transferred to a physician or higher medical authority in the field. In some cases, your medical director or a designated medical control physician may order you to stop CPR on the basis of the patient's condition.

Words of Wisdom

Patients who do not achieve ROSC may be potential kidney or liver donors in select situations (ie, short transport times, rapid access to an organ recovery program). Follow your local protocols regarding the care of potential organ donors.

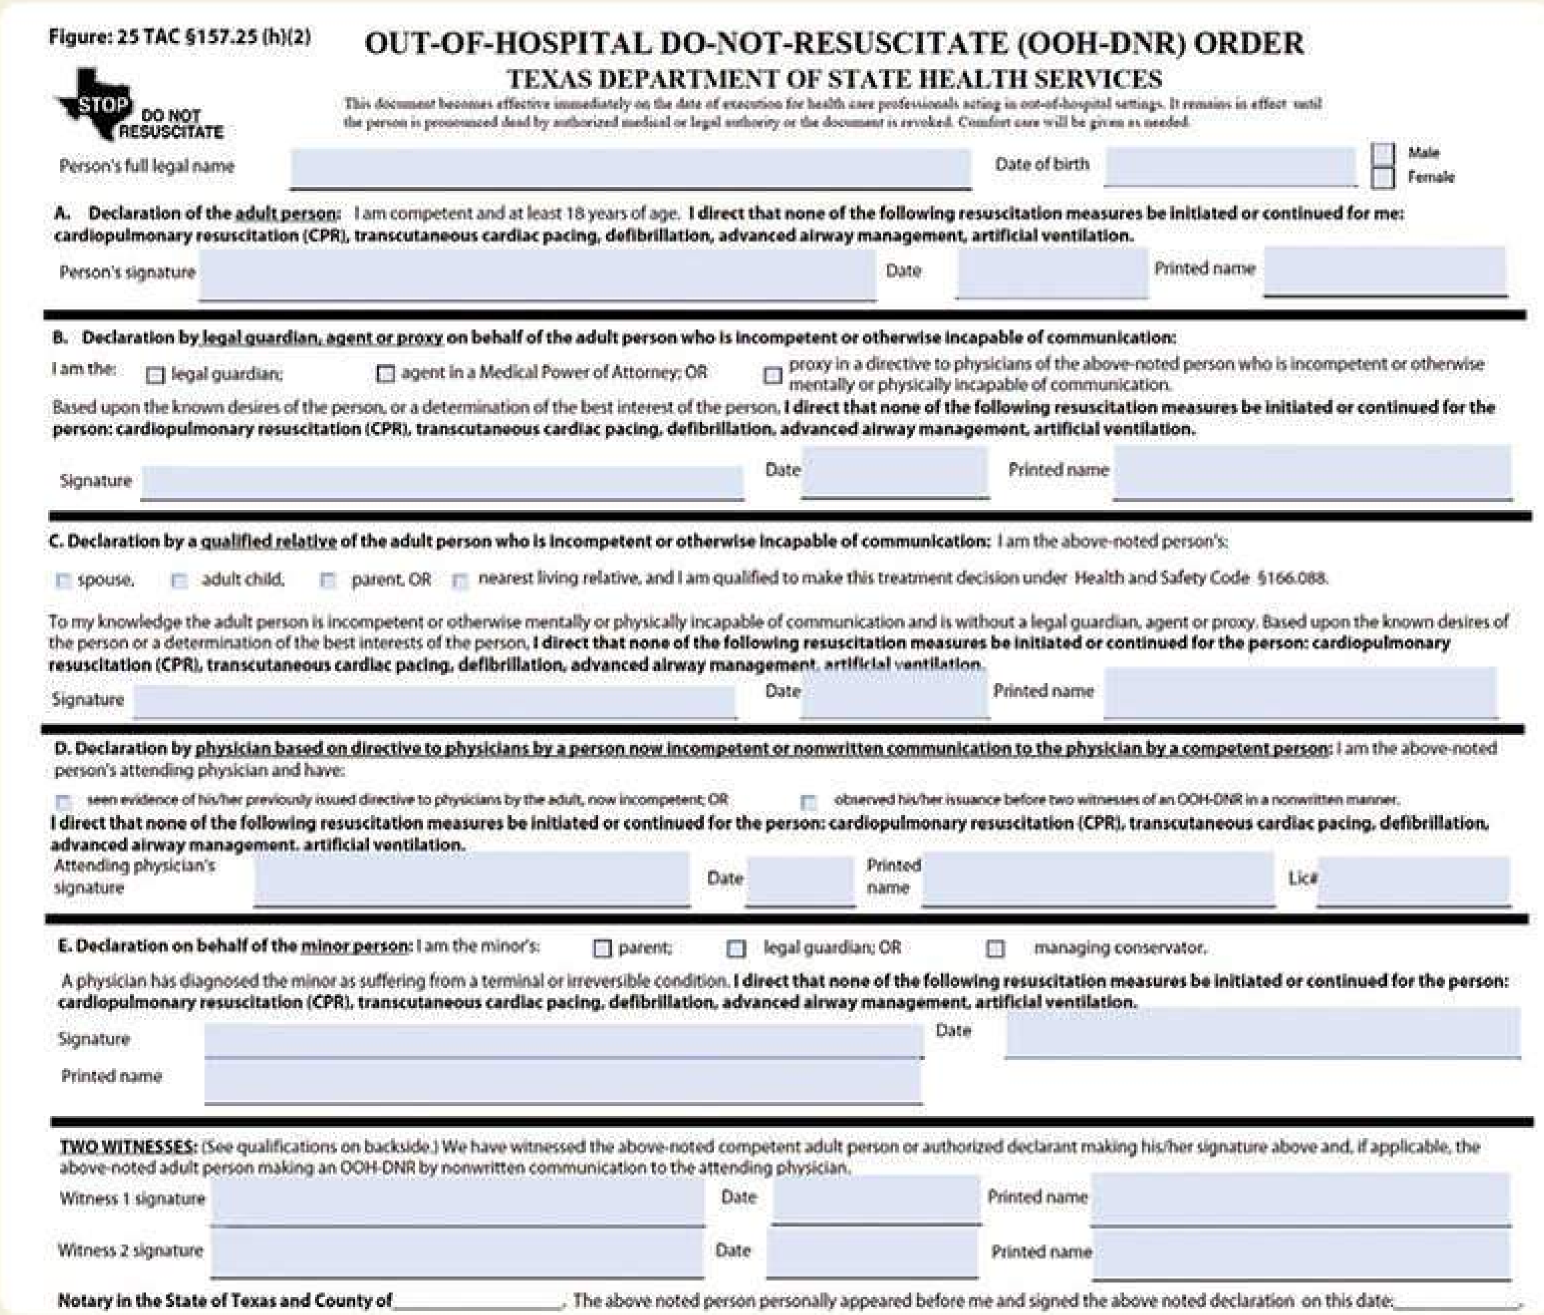

Figure: 25 TAC §157.25 (h)(2)

OUT-OF-HOSPITAL DO-NOT-RESUSCITATE (OOH-DNR) ORDER

TEXAS DEPARTMENT OF STATE HEALTH SERVICES

STOP DO NOT RESUSCITATE

This document becomes effective immediately on the date of execution for health care professionals acting in out-of-hospital settings. It remains in effect until the person is pronounced dead by authorized medical or legal authority or the document is revoked. Comfort care will be given as needed.

Person's full legal name ____ Date of birth ____ ☐ Male ☐ Female

A. Declaration of the adult person: I am competent and at least 18 years of age. **I direct that none of the following resuscitation measures be initiated or continued for me: cardiopulmonary resuscitation (CPR), transcutaneous cardiac pacing, defibrillation, advanced airway management, artificial ventilation.**

Person's signature ____ Date ____ Printed name ____

B. Declaration by legal guardian, agent or proxy on behalf of the adult person who is incompetent or otherwise incapable of communication:

I am the: ☐ legal guardian; ☐ agent in a Medical Power of Attorney; OR ☐ proxy in a directive to physicians of the above-noted person who is incompetent or otherwise mentally or physically incapable of communication.

Based upon the known desires of the person, or a determination of the best interest of the person, **I direct that none of the following resuscitation measures be initiated or continued for the person: cardiopulmonary resuscitation (CPR), transcutaneous cardiac pacing, defibrillation, advanced airway management, artificial ventilation.**

Signature ____ Date ____ Printed name ____

C. Declaration by a qualified relative of the adult person who is incompetent or otherwise incapable of communication: I am the above-noted person's:

☐ spouse, ☐ adult child, ☐ parent, OR ☐ nearest living relative, and I am qualified to make this treatment decision under Health and Safety Code §166.088.

To my knowledge the adult person is incompetent or otherwise mentally or physically incapable of communication and is without a legal guardian, agent or proxy. Based upon the known desires of the person or a determination of the best interests of the person, **I direct that none of the following resuscitation measures be initiated or continued for the person: cardiopulmonary resuscitation (CPR), transcutaneous cardiac pacing, defibrillation, advanced airway management, artificial ventilation.**

Signature ____ Date ____ Printed name ____

D. Declaration by physician based on directive to physicians by a person now incompetent or nonwritten communication to the physician by a competent person: I am the above-noted person's attending physician and have:

☐ seen evidence of his/her previously issued directive to physicians by the adult, now incompetent; OR ☐ observed his/her issuance before two witnesses of an OOH-DNR in a nonwritten manner.

I direct that none of the following resuscitation measures be initiated or continued for the person: cardiopulmonary resuscitation (CPR), transcutaneous cardiac pacing, defibrillation, advanced airway management, artificial ventilation.

Attending physician's signature ____ Date ____ Printed name ____ Lic# ____

E. Declaration on behalf of the minor person: I am the minor's: ☐ parent; ☐ legal guardian; OR ☐ managing conservator.

A physician has diagnosed the minor as suffering from a terminal or irreversible condition. **I direct that none of the following resuscitation measures be initiated or continued for the person: cardiopulmonary resuscitation (CPR), transcutaneous cardiac pacing, defibrillation, advanced airway management, artificial ventilation.**

Signature ____ Date ____

Printed name ____

TWO WITNESSES: (See qualifications on backside.) We have witnessed the above-noted competent adult person or authorized declarant making his/her signature above and, if applicable, the above-noted adult person making an OOH-DNR by nonwritten communication to the attending physician.

Witness 1 signature ____ Date ____ Printed name ____

Witness 2 signature ____ Date ____ Printed name ____

Notary in the State of Texas and County of ____. The above noted person personally appeared before me and signed the above noted declaration on this date: ____.

Figure 13-27 Do not start CPR if the patient and his or her physician have previously agreed on DNR or no-CPR orders. Learn your local protocols for treating terminally ill patients.

Courtesy of Texas Department of State Health Services.

Words of Wisdom

If you choose not to start CPR on a patient in cardiac arrest, then always comply with your local protocols and provide detailed documentation. In particular, record the physical examination signs that led to your decision and reference the protocol that states these signs are a reason not to start CPR. If special circumstances physically prevent you from making resuscitation attempts (for example, if the patient is entrapped in a vehicle), then document the scene conditions thoroughly. These decisions occasionally raise questions that can be put to rest immediately with reference to a well-written report. See Chapter 4, *Communications and Documentation, for more information*.

Every EMS system should have clear standing orders or protocols that provide guidelines for starting and stopping CPR. Your medical director and your system's legal adviser should agree on these protocols, which should be closely administered and reviewed by your medical director.

Foreign Body Airway Obstruction in Adults

Occasionally, a large foreign body will be aspirated and block the upper airway. An airway obstruction may be caused by various factors, including relaxation of the throat muscles in an unresponsive patient, vomited or regurgitated stomach contents, blood, damaged tissue after an injury, dentures, or foreign bodies such as food or small objects.

Large objects that are visible but cannot be removed from the airway with suction, such as loose dentures, large pieces of food, or blood clots, should be swept forward and out with your gloved index finger. Suctioning can then be used as needed to keep the airway clear of thinner secretions such as blood, vomitus, and mucus.

Recognizing Foreign Body Airway Obstruction

An airway obstruction by a foreign body in an adult usually occurs during a meal. In children, it usually occurs during mealtime or at play. If the foreign body is not removed quickly, then the lungs will use up their oxygen supply, and unconsciousness and death will follow. Management is based on the severity of the airway obstruction.

Mild Airway Obstruction

Patients with a mild (partial) airway obstruction are able to exchange adequate amounts of air, but still have signs of respiratory distress. Breathing may be noisy; however, the patient usually has a strong, effective cough. Leave these patients alone! Your main concern is to prevent a mild airway obstruction from becoming a severe (complete) airway obstruction. Abdominal thrusts are *not* indicated for patients with a mild airway obstruction.

For the patient with a mild airway obstruction, first encourage him or her to cough or to continue coughing if they are already doing so. Do not interfere with the patient's own attempts to expel the foreign body. Instead, give supplemental oxygen if needed and provide prompt transport to the ED. Closely monitor the patient and observe for signs of a severe airway obstruction (weak or absent cough, decreasing level of consciousness, cyanosis).

Responsive Patients

A sudden, severe airway obstruction is usually easy to recognize in someone who is eating or has just finished eating. The person is suddenly unable to speak or cough, grasps his or her throat, turns cyanotic, and makes exaggerated efforts to breathe. Either air is not moving into and out of the airway, or the air movement is so slight that it is not detectable. At first, the patient will be responsive and able to clearly indicate the problem. Ask the patient, "Are you choking?" The patient will usually answer by nodding yes. Alternatively, he or she may use the universal sign to indicate airway blockage **Figure 13-28**.

Figure 13-28 Placing the hands at the throat is the universal sign to indicate choking.

If there is a minimal amount of air movement, then you may hear a high-pitched sound called stridor. This occurs when the object is not fully blocking the airway, but the small amount of air entering the lungs is not enough to sustain life and the patient will eventually become unconscious if the obstruction is not relieved.

Unresponsive Patients

When you discover an unresponsive patient, your first step is to determine whether he or she is breathing and has a pulse. The unconsciousness may be caused by airway obstruction, cardiac arrest, or a number of other conditions. If the patient has a pulse, but is not breathing, then you must make sure that the airway is open and unobstructed.

You should suspect an airway obstruction if the standard maneuvers to open the airway and ventilate the lungs are ineffective. If you feel resistance when attempting to ventilate, the patient probably has some type of obstruction.

▶ Removing a Foreign Body Airway Obstruction in an Adult

The manual maneuver recommended for removing severe airway obstructions in responsive adults and children older than 1 year is the abdominal-thrust maneuver (also called the Heimlich maneuver). This technique creates an artificial cough by causing a sudden increase in intrathoracic pressure when thrusts are applied to the subdiaphragmatic region; it is a very effective method for removing a foreign body obstruction from the airway. If the patient with a severe airway obstruction is unresponsive, then perform chest compressions.

Responsive Patients

Abdominal-Thrust Maneuver. The goal of the abdominal-thrust maneuver is to compress the lungs upward and force residual air from the lungs to flow upward and expel the object. In responsive patients with a severe airway obstruction, repeat abdominal thrusts until the foreign body is expelled or the patient becomes unresponsive. Each thrust should be deliberate, with the intent of relieving the obstruction.

To perform abdominal thrusts on a responsive adult Figure 13-29, use the following technique:

1. Stand behind the patient, and wrap your arms around his or her abdomen. Straddle your legs outside the patient's legs. This will allow you to easily slide the patient to the ground if he or she becomes unresponsive.
2. Make a fist with one hand; grasp the fist with the other hand. Place the thumb side of the fist against the patient's abdomen just above the umbilicus and well below the xiphoid process.
3. Press your fist into the patient's abdomen with a quick inward and upward thrust.
4. Continue abdominal thrusts until the object is expelled from the airway or the patient becomes unresponsive.

Figure 13-29 The abdominal-thrust maneuver in a responsive adult. Stand behind the patient and wrap your arms around the patient's abdomen. Place the thumb side of one fist against the patient's abdomen while holding your fist with your other hand. Press your fists into the patient's abdomen, using inward and upward thrusts.

Chest Thrusts. You can perform the abdominal-thrust maneuver safely on all adults and children. However, for women in advanced stages of pregnancy and patients who have obesity, use chest thrusts instead.

To perform chest thrusts on the responsive adult, use the following technique Figure 13-30:

1. Stand behind the patient with your arms directly under the patient's armpits, and wrap your arms around the patient's chest.
2. Make a fist with one hand; grasp the fist with the other hand. Place the thumb side of the fist against the patient's sternum, avoiding the xiphoid process and the edges of the rib cage.
3. Press your fist into the patient's chest with backward thrusts until the object is expelled or the patient becomes unresponsive.
4. If the patient becomes unresponsive, then begin CPR, starting with chest compressions Figure 13-31.

Figure 13-30 Removal of a foreign body obstruction in a responsive adult using chest thrusts. Stand behind the patient and wrap your arms around the patient's chest. Place the thumb side of one fist against the chest while holding your fist with your other hand. Press your fists into the patient's chest with backward thrusts.

Figure 13-31 An unresponsive patient with an airway obstruction requires CPR.

Words of Wisdom

If a responsive choking patient is found lying on the floor, then administer abdominal thrusts by straddling the patient's legs, placing your hands just above the umbilicus, and giving rapid thrusts inward and upward under the rib cage, using the heel of your hand with your other hand on top of it.

Responsive Patients Who Become Unresponsive

A patient with an airway obstruction may become unresponsive while you are attempting to remove the obstruction. In this case, begin CPR, starting with chest compressions. Use the following steps to manage the patient's airway obstruction:

1. Carefully support the patient to the ground and immediately call for help (or send someone to call for help).
2. Perform 30 chest compressions, using the same landmark as you would for CPR (center of the chest, between the nipples). Do not check for a pulse before performing chest compressions.
3. Open the airway and look in the mouth. If you see an object that can easily be removed, then remove it with your fingers and attempt to ventilate. If you do not see an object, then resume chest compressions.
4. Repeat steps 2 and 3 until the obstruction is relieved or ALS providers take over.

If you are able to remove an object from the mouth, then attempt to ventilate. If ventilation produces chest rise, then continue to ventilate and check for a pulse. If a pulse is present but the patient is not breathing, then continue rescue breathing and monitor the pulse. If a pulse is absent, then continue CPR (compressions and ventilations) and apply the AED as soon as it is available.

YOU are the Provider — PART 2

You package the patient, load him into the ambulance, and begin transport to a hospital located 5 miles away. An EMT from the backup ambulance accompanies you in the back and continues rescue breathing. En route, you reassess the patient and then call your radio report to the receiving hospital.

Recording Time: 12 Minutes	
Level of consciousness	Unresponsive
Respirations	8 breaths/min; shallow depth
Pulse	94 beats/min; strong carotid pulse, weak radial pulses
Skin	Pink, cool, and dry
Blood pressure	86/66 mm Hg
Spo_2	95% (on oxygen)

9. Would an ITD benefit your patient at this point?

10. What further treatment, if any, is indicated for this patient?

Unresponsive Patients

When a patient is found unresponsive, it is unlikely you will know what caused the problem. Begin CPR by determining unresponsiveness and checking for breathing and a pulse. If a pulse is present but breathing is absent, then open the airway and attempt to ventilate. If the first ventilation does not produce visible chest rise, then reposition the airway and reattempt to ventilate. If both ventilation attempts do not produce visible chest rise, then perform 30 chest compressions, and then open the airway and look in the mouth. If an object is visible and can easily be removed, then remove it with your fingers and attempt to ventilate. Never perform blind finger sweeps on any patient; doing so may push the obstruction farther into the airway. If an object is not visible or cannot easily be removed, then resume chest compressions. Continue the sequence of chest compressions, opening the airway, and looking inside the mouth until the airway is clear or ALS providers arrive.

Foreign Body Airway Obstruction in Infants and Children

As mentioned previously, airway obstruction is a common problem in infants and children, usually caused by a foreign body (such as food or a toy) or by an infection, resulting in swelling and narrowing of the airway. Try to identify the cause of the obstruction as soon as possible. In patients who have signs and symptoms of an airway infection, do not waste time trying to dislodge a foreign body. Administer supplemental oxygen if needed and immediately transport the child to the ED.

A previously healthy child who is eating or playing with small toys or an infant who is crawling about the house and who suddenly has difficulty breathing has probably aspirated a foreign body. As in adults, foreign bodies may cause a mild or a severe airway obstruction.

With a mild airway obstruction, the child can cough forcefully, although he or she may wheeze between coughs. As long as the patient can breathe, cough, or talk, do not interfere with his or her attempts to expel the foreign body. As with the adult, encourage the child to continue coughing. Administer supplemental oxygen if needed (and tolerated) and provide transport to the ED.

You should intervene only if signs of a severe airway obstruction develop, such as a weak, ineffective cough; cyanosis; stridor; absent air movement; or a decreasing level of consciousness.

Removing a Foreign Body Airway Obstruction in a Child

Responsive Child

If you determine a child older than 1 year has an airway obstruction, then stand or kneel behind the child and provide abdominal thrusts in the same manner as an adult, but use less force, until the object is expelled or the child becomes unresponsive. If the child becomes unresponsive, then follow the same steps as for the unresponsive adult.

To perform the abdominal-thrust maneuver in a responsive child who is in a standing or sitting position, follow these steps **Figure 13-32**:

1. Kneel on one knee behind the child, and circle both of your arms around the child's body. Prepare to give abdominal thrusts by placing your fist just above the patient's umbilicus and well below the xiphoid process. Place your other hand over that fist.

Figure 13-32 To perform the abdominal-thrust maneuver on a child, kneel behind the child on one knee, wrap your arms around his or her body, and place your fist just above the umbilicus and well below the lower tip of the sternum.

2. Give the child abdominal thrusts in an upward direction. Avoid applying force to the lower rib cage or sternum.
3. Repeat this technique until the child expels the foreign body or becomes unresponsive.
4. If the child becomes unresponsive, position the child on a hard surface and immediately call for help (or send someone to call for help).
5. Perform 30 chest compressions (15 compressions if two rescuers are present), using the same landmark as you would for CPR. Do not check for a pulse before performing chest compressions.
6. Open the airway and look inside the mouth. If you see an object that can easily be removed, then remove it with your fingers and attempt to ventilate. If you do not see an object, then resume chest compressions.
7. Repeat steps 5 and 6 until the obstruction is relieved or ALS providers take over.

If you manage to clear the airway obstruction in an unresponsive child but he or she still has no spontaneous breathing or circulation, then perform CPR (compressions and ventilations) and apply the AED as soon as it is available.

Unresponsive Child

If a child older than one year with an airway obstruction becomes unresponsive, he or she is managed in the same manner as an adult. **Skill Drill 13-6** demonstrates the steps for removing a foreign body airway obstruction in an unresponsive child:

1. Take standard precautions. Carefully place the child in a supine position on a firm, flat surface **Step 1**.
2. Perform 30 chest compressions (15 compressions if two rescuers are present), using the same landmark as you would for CPR (lower half of the sternum). Do not check for a pulse before performing chest compressions **Step 2**.
3. Open the airway and look in the mouth **Step 3**.
4. If you see an object that can easily be removed, then remove it with your fingers and attempt to ventilate **Step 4**.
5. If you do not see an object, then resume chest compressions.
6. Repeat the sequence of chest compressions, opening the airway, and looking inside the mouth until the obstruction is relieved or ALS providers take over **Step 5**.

Removing a Foreign Body Airway Obstruction in Infants

Responsive Infants

Do not use abdominal thrusts on a responsive infant with an airway obstruction because of the risk of injury to the immature organs of the abdomen. Instead, perform back slaps and chest thrusts to try to clear a severe airway obstruction in a responsive infant, as follows **Figure 13-33**:

1. Hold the infant facedown, with the body resting on your forearm. Support the infant's jaw and face with your hand, and keep the head lower than the rest of the body.
2. Deliver five back slaps between the shoulder blades, using the heel of your hand.

Figure 13-33 **A.** Hold the infant facedown with the body resting on your forearm. Support the jaw and face with your hand, and keep the head lower than the rest of the body. Give the infant five back slaps between the shoulder blades, using the heel of your hand. **B.** Give the infant five quick chest thrusts, using two fingers placed on the lower half of the sternum.

Skill Drill 13-6

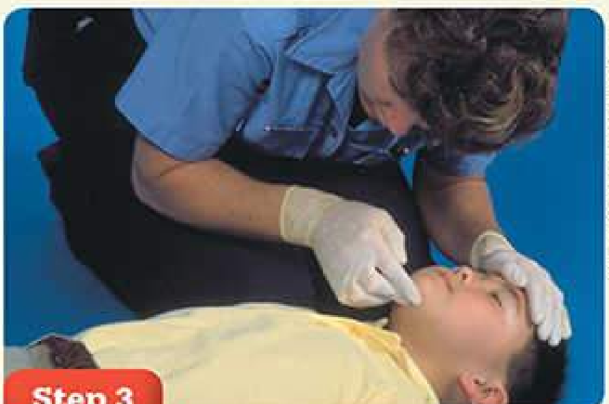
Removing a Foreign Body Airway Obstruction in an Unresponsive Child

Step 1

Take standard precautions. Position the child on a firm, flat surface.

Step 2

Perform chest compressions using the same landmark as you would for CPR.



Step 3

Open the airway and look inside the mouth.

Step 4

If an object is visible and can easily be removed, then remove it with your fingers and attempt rescue breathing.

Step 5

If you do not see an object in the mouth, then resume chest compressions. Continue the sequence of chest compressions, opening the airway, and looking inside the mouth until the obstruction is relieved or ALS providers take over.

3. Place your free hand behind the infant's head and back, and turn the infant faceup on your other forearm and thigh, sandwiching the infant's body between your two hands and arms. The infant's head should remain below the level of the body.
4. Give five quick chest thrusts in the same location and manner as chest compressions, using two fingers placed on the lower half of the sternum. For larger infants, or if you have small hands, you can perform this step by placing the infant in your lap and turning the infant's whole body as a unit between back slaps and chest thrusts.
5. Check the airway. If you can see the foreign body, then remove it. If not, then repeat the cycle as often as necessary.
6. If the infant becomes unresponsive, then begin CPR and follow the same sequence as for a child and adult.

Unresponsive Infants

If the infant becomes unresponsive during your attempts to relieve an airway obstruction, then perform CPR starting with chest compressions. Do not check for a pulse before starting compressions. Open the airway and look in the mouth. If you see an object that can easily be removed, then remove it with your finger and attempt to ventilate; if you do not see an object, then resume chest compressions. Continue the sequence of chest compressions, opening the airway, and looking inside the mouth until the obstruction is relieved or ALS providers take over.

Special Resuscitation Circumstances

Opioid Overdose

An opioid is a narcotic drug that, when taken in excess, depresses the central nervous system and causes respiratory arrest followed by cardiac arrest. Examples of opioids include heroin and oxycodone. In situations where opioid overdose is the suspected cause of a patient's cardiac arrest, bystanders may have administered the antidote naloxone (Narcan) to the patient prior to EMS arrival. Naloxone blocks opiate receptors in the body and reverses the effect of opioid overdose. Naloxone auto-injector devices, intended for use by laypeople (as well as health care providers), are now available in the United States. If you respond to a patient who has possibly overdosed on an opioid, and naloxone was administered by a bystander prior to your arrival, then determine how much of the medication was given and the route by which it was given.

Your EMS medical director may implement a protocol that allows BLS providers to administer naloxone in cases of suspected opioid overdose. The recommended algorithm for implementing naloxone into the cardiac arrest management sequence is discussed in Chapter 21, *Toxicology*.

Standard resuscitative measures (ie, high-quality chest compressions, ventilation, defibrillation) take priority over naloxone administration; do not delay other interventions while awaiting the patient's response to naloxone therapy. Many patients who have overdosed on an opioid have a pulse (although slow) but are not breathing. In these patients, BVM ventilation is the most critical treatment, followed by administration of naloxone if it is available.

Cardiac Arrest in Pregnancy

If you encounter a pregnant patient who is in cardiac arrest, then your priorities are to provide high-quality CPR and relieve pressure off the aorta and vena cava. When the patient lies supine, the pregnant uterus can compress the aorta and vena cava (aortocaval compression). Compression of the vena cava causes a significant decrease in blood return to the heart and, secondarily, in the forward flow of blood to the vital organs.

If the pregnant patient is not in cardiac arrest, then position her on her left side to relieve pressure on the great vessels. However, if she is in cardiac arrest, then this approach is impractical, because she must remain in a supine position to maximize the effectiveness of compressions. Therefore, if the top of the patient's uterus (fundus) can be felt at or above the level of the umbilicus, perform manual displacement of the uterus to the patient's left to relieve aortocaval compression while CPR is being performed. This step will improve the effectiveness of compressions **Figure 13-34**.

Grief Support for Family Members and Loved Ones

Whenever you assist a patient, remember his or her loved ones may also be affected by the emergency. Serious illness, injury, and pediatric patients create an especially high level of anxiety for family members. A health emergency is often hard for family members to understand. In some cases, family members may experience a psychologic crisis that turns into a medical crisis, and may become patients themselves.

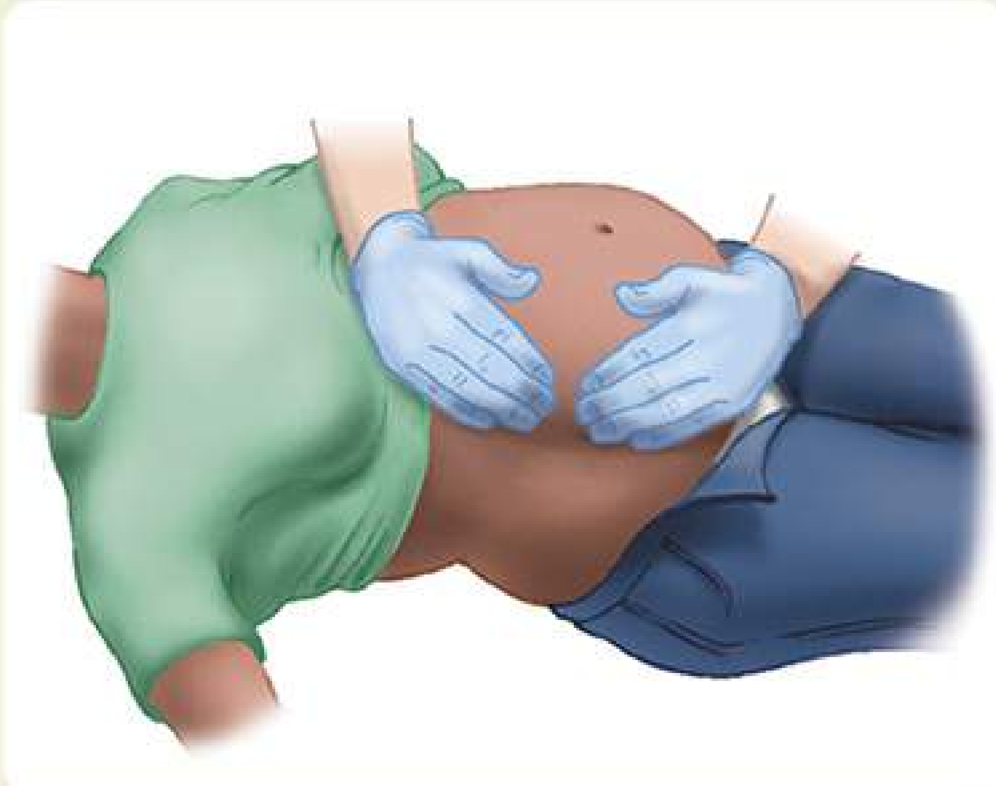


Figure 13-34 Manual left displacement of the uterus. The two-handed technique is shown. Alternatively, one hand can be used.

Consider the scenario of a cardiac arrest in an otherwise healthy 57-year-old man. The family is watching your team perform CPR. They may assume you will bring him back, or, at the very least, will expect you to transport. After 30 minutes or so, you stop resuscitation and start packing your gear, then turn the scene over to the police. The patient is lying dead on the floor.

A trend in cardiac arrest care is to stay on the scene and perform the entire resuscitation in the location where the patient was found, particularly when ALS care is provided at the scene. Many EMS systems advocate this practice because continuous compressions are an important part of an effective resuscitation effort. CPR in the back of an ambulance is generally not as effective. If the patient has not responded to treatment after 20 to 30 minutes (or longer), then many protocols suggest discontinuing resuscitative efforts and not transporting. However, this may create an uncomfortable situation at the scene.

For EMS crews, wanting to help but not knowing what to do can be very stressful. Is it the responsibility of EMS to explain the death to the family? Would you consider the bereaved widow the legal or moral responsibility of EMS? How is good customer care defined here? If you consider a spouse and perhaps other family members to be your patients as well, then it is appropriate to interact with them. Using the above scenario as an example, consider the following things that may make grief support in the field a little easier.

Whereas this cardiac arrest may be one of many similar calls in your career, family members and loved ones will remember this event in detail for the rest of their lives. Your reaction to them will form a lasting impression. Conversely, a mismanaged death notification or poor interaction could leave the family feeling disrespected or ignored. A compassionate and sensitive approach will leave a positive impression of you and your agency. Most important, appropriate and supportive care at the onset of grief may positively affect the family’s grieving process.

Families do not typically expect EMS providers to stop resuscitation and leave their loved one on scene. When death appears imminent and resuscitative efforts are unsuccessful, make the family members aware the patient is not responding to treatment. Discuss with them what is happening so they may be better prepared for the inevitable. Keep the family informed throughout the resuscitation process because it may also help them feel more in control.

Sequential notification starts during resuscitative efforts; family members should be updated as the resuscitation progresses, if possible. Designate one provider to communicate the patient's status to family members, so that information is streamlined from one source rather than from multiple providers. Be concise and clear. For example, say, "Your husband is not breathing and his heart has stopped. We are attempting to restart his heart with the AED." After resuscitation efforts have stopped, it is appropriate to tell them, "As you know, when we arrived, your husband wasn't breathing and did not have a pulse. He has not responded to any of our treatments. I'm sorry, but he has died." Avoid euphemisms such as "passed away" or "passed on," because these expressions may be confusing or misinterpreted. Law enforcement personnel may be involved in the official death declaration and will likely be responsible for what happens next, such as determining whether the medical examiner should be notified.

In a situation where ROSC occurs prior to transport, family members may wish to interact with the patient. This can give them comfort, especially if the patient ultimately does not survive.

After resuscitation has stopped, these other measures can be helpful:

- Take the family to a quiet, private place.
- Introduce yourself and anyone with you.
- Use clear language and speak in a warm, sensitive, and caring manner.
- Try to exhibit calm, reassuring authority.
- Use the patient's name.
- Use eye contact and appropriate touch.
- Expect that family members will show emotion as they begin the grieving process. Be prepared for different reactions, including anger.
- While you are still on scene, be supportive but do not hover.
- Ask if a friend or family member can be called to come and help support them.
- When you need to leave, turn the family over to someone else; for example, a police officer.

Some family members will want to see the deceased. Being able to touch or talk to their loved one may be helpful to them. This may not be advisable in a medical examiner's case. Law enforcement personnel will need to make that determination. It is appropriate to make the body presentable, but follow local protocols regarding movement of the patient or removal of resuscitation equipment.

Another consideration is to ensure that children are not ignored. They may not understand death. Preschool-aged children may be less affected, whereas older children understand death but do not expect it to happen to someone they know. Younger children tend to blame themselves. Teenagers may be highly affected but may mask their feelings.

It is never easy to be the bearer of bad news, but it can help to know you did your best for the family during a difficult situation. Lastly, consider your own feelings in this stressful situation and make sure you seek assistance if needed. See Chapter 2, *Workforce Safety and Wellness*, for a discussion of the emotional aspects of emergency care and stress management.

Education and Training for the EMT

You may go weeks or months without performing CPR on a human, depending on how busy your EMS system is. Like any skill, CPR skills can deteriorate over time. You must practice them often using manikin-based training—ideally more frequently than the standard retraining that occurs every 2 years.

The use of high-fidelity manikins for CPR training is encouraged, if your system's budget allows. If this is not an option, then CPR devices that provide corrective feedback are preferred over devices that only provide voice prompts (ie, a metronome).

CPR self-instruction through video and/or computer-based modules with hands-on practice may be a reasonable alternative to instructor-led courses, because it may facilitate frequent retraining.

Education and Training for the Public

As an EMT, you are a patient advocate. Not only are you responsible for providing the best possible care for your patient, but you must also do your part to facilitate the training of laypeople in the critical skills of CPR and AED operation. Training in CPR and AED usage should not be limited to health care providers. Not enough laypeople are trained to perform these lifesaving skills. Ask yourself, “Who is the *real* first responder?” Obviously, the layperson is likely to be at the scene before you and your team arrive.

As discussed previously, many laypeople assume CPR requires both mouth-to-mouth rescue breathing and chest compressions. As long as this misconception remains, fewer people will be willing to help during an emergency, which means that fewer lives will be saved. If you are asked to train members of your community how to perform compression-only CPR, then you should consider it your professional responsibility and be willing to assist.

It is likely that some citizens in your service area are at increased risk for cardiac arrest. Your agency should make an effort to identify these potential patients and educate their families to recognize cardiac arrest and to train them to perform compression-only CPR.

YOU are the Provider — SUMMARY

1. What should you immediately do on receiving this update from dispatch?

After you are informed that CPR is in progress, you should immediately request additional assistance. Effective treatment of a patient in cardiac arrest requires adequate personnel at the scene and during transport. As an EMT, you must be familiar with the resources that are available to you and know when it is appropriate to request them.

The type of backup you receive (ie, BLS versus ALS) will depend on your EMS system and the resources that are available to you. Combined with high-quality CPR and defibrillation, early advanced care increases the patient’s chance for survival.

If you do not have access to other EMTs or to ALS providers, then request assistance from the fire department. Fire departments are often staffed with at least one or two emergency medical responders who are able to perform CPR and assist with certain BLS interventions.

Regardless of the resources available to you, request them as soon as possible—in this case, as soon as you are advised that CPR is in progress. One EMT cannot effectively treat a cardiac arrest patient during transport; you would have to perform continuous CPR while your partner drives the ambulance (or vice versa), which could result in rescuer fatigue and decreased effectiveness of chest compressions.

2. What should be your initial actions on arriving at this scene?

After ensuring your own safety, approach this patient as you would any other patient, by performing a primary assessment. Although the dispatcher has advised you that bystander CPR is in progress, you must still assess the patient to confirm he is indeed apneic and pulseless and requires CPR.

Your primary assessment should take only a few seconds, just long enough to confirm the patient is in cardiac arrest. If he is in cardiac arrest, then begin CPR immediately, apply the AED as soon as it is available, and analyze the patient’s cardiac rhythm. To avoid interrupting CPR, you should apply the AED pads around your partner’s hands as he or she is performing chest compressions (do not stop compressions to do this).

If the AED advises you to shock, then deliver the shock and immediately resume CPR, starting with chest compressions. If the AED does not advise you to shock, then immediately resume CPR, starting with chest compressions. During CPR, ask the two bystanders if they witnessed the event and determine whether they know anything about the patient (ie, past medical history, events leading up to the arrest).

Regardless of how a call is dispatched and whether or not you are assuming patient care from bystanders or other health care providers, it is important for you to always perform a primary assessment of the patient.

3. What links in the chain of survival have been maintained at this point?

The following links in the chain of survival have been maintained:

- *Recognition and activation of the emergency response system*, because the bystanders quickly recognized the patient was experiencing a cardiac emergency and immediately called 9-1-1.
- *Immediate, high-quality CPR*, because the bystanders began CPR directly after calling 9-1-1.
- *Basic and advanced emergency medical services*, because EMS providers are at the scene providing specialized care to the patient.

The following links in the chain of survival have not been maintained:

- *Rapid defibrillation*, because it has not yet occurred. Of all the links in the chain of survival, early defibrillation has the most profound impact on patient survival. With early access and early CPR, defibrillation may successfully terminate lethal cardiac dysrhythmias in a significant number of patients. For each minute that defibrillation is delayed, the patient's chance for survival decreases by 7% to 10%.
- *Advanced life support and postarrest care*, because ROSC has not been established and the patient has not arrived at the hospital.

4. Why is it so critical to minimize interruptions in CPR?

Even when CPR is performed correctly (that is, at a rate of 100 to 120 compressions per minute and a depth of 2 inches to 2.4 inches [5 cm to 6 cm] in the adult), chest compressions only deliver about one-third of a person's normal cardiac output. When CPR is performed properly and with minimal interruption, it is often enough to keep the patient's vital organs viable until defibrillation and more advanced care can be provided at the ED. Of course, this assumes that defibrillation and advanced care are provided within a short period of time.

Within a few seconds of stopping chest compressions, the pressure generated in the arteries drops to near zero; therefore, frequent or prolonged interruptions in chest compressions will not even provide the minimum perfusion needed to keep the vital organs viable. This has been clearly linked to low survival rates from cardiac arrest. Remember to maintain a chest compression fraction of at least 60%.

As soon as cardiac arrest has been confirmed, it is crucial to begin CPR immediately and apply the AED as soon as it is available. Even when the AED pads are being applied, your partner should continue chest compressions; you should apply the pads around your partner's hands.

5. Should you remove the medication patch or leave it in place? Why or why not?

The patch is located on the patient's right upper chest, which is where you will place one of the AED pads. Because of its location, the patch could interfere with the electrical current to the heart and may cause burns to the patient's skin. To prevent this complication, remove the patch, wipe any residue from the skin, and then apply the AED pads. Remember to take standard precautions!

6. What does the bulge and scar over the patient's left chest indicate? How will this affect the way you treat the patient?

A hard lump or bulge on the patient's chest, usually with a corresponding scar, indicates an AICD or pacemaker. These devices are used in patients who are at high risk for certain cardiac dysrhythmias and cardiac arrest. The AICD will deliver shocks directly to the heart if it detects a lethal cardiac dysrhythmia. Implanted pacemakers are used to increase the patient's heart rate if it falls below a given value.

If the AED pads are placed directly over the device, then shocks delivered by the AED may be less effective. Therefore, if you identify an AICD or pacemaker, place the AED pad at least 1 inch (2.5 cm) away from the device. Because most of these devices are implanted in the upper left chest, this should not be an issue. The pads are placed to the right of the upper sternum and to the lower left chest, just below the nipple, so they should be well beyond 1 inch (2.5 cm) from the device. Follow your local protocols regarding patients with AICDs or implanted pacemakers.

7. How should you continue to treat this patient?

You have restored a pulse in your patient; however, his breathing is not adequate. Agonal gasps are ineffective and do not produce adequate minute volume.

Some patients may have an intact gag reflex, despite being unresponsive; in these cases, an oropharyngeal airway is contraindicated. Insert a nasopharyngeal (nasal) airway and continue to provide rescue breathing. Deliver one breath every 5 to 6 seconds (10 to 12 breaths/min); each breath should be delivered over 1 second (just enough to produce visible chest rise). Closely and carefully monitor the patient's pulse and be prepared to resume CPR if necessary.

Assume the patient has a full stomach and have a suction unit ready in case he regurgitates. Remember that mortality increases significantly if aspiration occurs. It is also important to avoid hyperventilating the patient.

8. Because the patient is no longer in cardiac arrest, should you remove the AED pads? Why or why not?

Although the patient is not in cardiac arrest, he is still at high risk for redeveloping cardiac arrest. Therefore, do not remove the AED pads; simply turn the AED off, continue rescue breathing, and prepare the patient for prompt transport.

9. Would an ITD benefit your patient at this point?

An ITD is a valve device that is placed between the ET tube and resuscitation bag; it can also be placed in between the resuscitation bag and mask if the patient is not intubated. It is only used for patients who are apneic and pulseless. At this point, your patient has a pulse and is breathing (albeit slowly and shallowly); therefore, the ITD is not indicated. Furthermore, the ITD may be of benefit when used during active compression-decompression CPR, but it is not recommended for use during conventional CPR. If ROSC occurs, the ITD must be removed.

10. What further treatment, if any, is indicated for this patient?

Further treatment of your patient should consist of careful monitoring because he remains at high risk for recurrence of cardiac arrest. In patients who are responsive and alert, the presence of a pulse is obvious; however, when a patient is unresponsive, you must frequently reassess for a pulse.

Unresponsive patients are at increased risk for regurgitation, which could lead to aspiration and increased mortality. Vigilantly monitor the patient’s airway status and be prepared to turn his head to the side if he regurgitates. Maintain his airway with manual positioning and a basic airway adjunct; in this case, a nasal airway.

Although the patient is breathing, his breaths are slow and shallow. Slow, shallow (reduced tidal volume) respirations will not produce adequate minute volume; therefore, continue to assist the patient’s ventilations with a BVM, but do not hyperventilate him. Deliver each breath over 1 second while observing for visible chest rise. Monitor his oxygen saturation (SpO_2) level and heart rate to help you determine if your assisted ventilations are adequate.

As mentioned earlier, do not remove the AED pads. Turn the AED off, but be prepared to stop the ambulance if cardiac arrest redevelops.

The patient’s blood pressure (86/66 mm Hg) is still low. Follow your local protocols regarding positioning of the patient to improve his blood pressure.

Narrative

Medic 51 dispatched to grocery store parking lot for "CPR in progress." On arrival at the scene, found two bystanders performing CPR on the patient, a 48-year-old male. Medic 48 was dispatched to the scene to assist. Primary assessment revealed that the patient was apneic and pulseless. Continued one-rescuer CPR for 2 minutes while the AED was being prepared. Per one of the bystanders, the patient was about to get in his vehicle when he suddenly grabbed his chest, slumped against the vehicle, and eased himself to the ground. There was no trauma involved. The bystander further stated that by the time he got to the patient, he was unresponsive and without pulse or breathing. After 2 minutes of CPR, EMS analyzed patient's cardiac rhythm with the AED and received a shock advised message. Delivered single shock and immediately resumed CPR. Medic 48 arrived at scene and assisted with CPR and airway management. The patient's past medical history was unknown, although he had an AICD and was wearing a medication patch, which was removed. Continued CPR for 2 minutes, reanalyzed the patient's cardiac rhythm, and received a no shock advised message. Continued CPR and attempted to insert an oral airway; however, the patient began to gag. Immediate reassessment revealed that he had a strong carotid pulse, but was not breathing adequately. Inserted a nasal airway, continued ventilations at 12 breaths/min, packaged the patient, and loaded him into the ambulance. EMT Smith from Medic 48 assisted with patient care en route to the hospital. En route, reassessed patient and found that he remained unresponsive; his respiratory rate increased, but the depth of his breathing remained shallow. Continued assisted ventilation and called in radio report to the receiving facility. Monitored the patient's pulse, provided additional supportive care, and delivered him to the ED without incident. Gave verbal report to attending physician. Medic 51 cleared the hospital and returned to service at 1528.
End of report

Prep Kit

Ready for Review

- BLS is noninvasive emergency lifesaving care that is used to treat medical conditions, including airway obstruction, respiratory arrest, and cardiac arrest.
- BLS care focuses on the ABCs: airway (obstruction), breathing (respiratory arrest), and circulation (cardiac arrest or severe bleeding). If the patient is in cardiac arrest, a CAB sequence (compressions, airway, breathing) should be used.
- CPR is used to establish artificial ventilation and circulation in a patient who is not breathing and has no pulse.
- The goal of CPR is to help restore spontaneous breathing and circulation; however, advanced procedures such as medications and defibrillation are often necessary for this to occur.
- ALS involves advanced lifesaving procedures, such as cardiac monitoring, administration of IV fluids and medications, and use of advanced airway adjuncts.
- The five links in the chain of survival are (1) recognition and activation of the emergency response system; (2) immediate, high-quality CPR; (3) rapid defibrillation; (4) basic and advanced emergency medical services; and (5) ALS and postarrest care.
- The AED should be applied to any nontrauma cardiac arrest patient as soon as it is available.
- When using an AED on a child between ages 1 and 8 years, use pediatric-sized pads and a dose-attenuating system (energy reducer). If these items are unavailable, then use adult-sized AED pads. In infants (age 1 month to 1 year), manual defibrillation is preferred. If a manual defibrillator is unavailable, then use an AED equipped with pediatric-sized pads and a dose attenuator. If neither option is available, then use adult-sized AED pads.
- As an EMT, it is your responsibility to start CPR in virtually all patients who are in cardiac arrest. The three general exceptions to the rule are as follows: (1) You should not start CPR if the scene is unsafe; (2) You should not start CPR if the patient has obvious signs of death; and (3) You should not start CPR if the patient and his or her physician have a previously agreed-on DNR or no-CPR order.
- As an EMT, you are generally not responsible for making the decision to stop CPR. After you begin CPR in the field, you must continue until one of the following events occurs (the STOP mnemonic):
  - **S**, the patient *Starts* breathing and has a pulse.
  - **T**, the patient's care is *Transferred* to another provider of equal or higher-level training.
  - **O**, you are *Out* of strength or too tired to continue.
  - **P**, a *Physician* who is present or providing online medical direction assumes responsibility for the patient and gives direction to discontinue CPR.
- An airway obstruction may have various causes, including relaxation of the throat muscles in an unresponsive patient; vomited or regurgitated stomach contents; blood; damaged tissue after an injury; dentures; or foreign bodies such as food or small objects.
- The manual maneuver recommended for removing severe airway obstructions in the responsive adult and child is the abdominal-thrust maneuver (the Heimlich maneuver). Use back slaps and chest thrusts to treat a responsive infant with a severe airway obstruction.
- If the adult, child, or infant with a severe airway obstruction is unresponsive, then perform CPR, starting with chest compressions.
- As an EMT, you will encounter situations in which grief support for family and loved ones will be part of your role. After resuscitation has stopped, turn your attention to the family and loved ones, and provide clear communication and emotional support.

Vital Vocabulary

abdominal-thrust maneuver The preferred method to dislodge a severe airway obstruction in adults and children; also called the Heimlich maneuver.

active compression-decompression CPR A technique that involves compressing the chest and then actively pulling it back up to its neutral position or beyond (decompression); may increase the amount of blood that returns to the heart and, thus, the amount of blood ejected from the heart during the compression phase.

advanced life support (ALS) Advanced lifesaving procedures used to treat medical conditions, such as cardiac monitoring, administration of intravenous fluids and medications, and the use of advanced airway adjuncts. EMTs may be trained in some of these areas.

basic life support (BLS) Noninvasive emergency lifesaving care that is used to treat medical conditions, including airway obstruction, respiratory arrest, and cardiac arrest.

cardiopulmonary resuscitation (CPR) The combination of chest compressions and rescue breathing used to establish adequate ventilation and circulation in a patient who is not breathing and has no pulse.

chest compression fraction The total percentage of time during a resuscitation attempt in which active chest compressions are being performed.

dependent lividity Blood settling to the lowest point of the body, causing discoloration of the skin; a definitive sign of death.

gastric distention A condition in which air fills the stomach, often as a result of high volume and pressure during artificial ventilation.

head tilt–chin lift maneuver A combination of two movements to open the airway by tilting the forehead back and lifting the chin; not used for trauma patients.

hyperventilation Rapid or deep breathing that lowers the blood carbon dioxide level below normal; may lead to increased intrathoracic pressure, decreased venous return, and hypotension when associated with BVM use.

impedance threshold device (ITD) A valve device placed between the endotracheal tube and a bag-valve mask that limits the amount of air entering the lungs during the recoil phase between chest compressions.

ischemia A lack of oxygen that deprives tissues of necessary nutrients, resulting from partial or complete blockage of blood flow; potentially reversible because permanent injury has not yet occurred.

jaw-thrust maneuver Technique to open the airway by placing the fingers behind the angle of the jaw and bringing the jaw forward; used for patients who may have a cervical spine injury.

load-distributing band (LDB) A circumferential chest compression device composed of a constricting band and backboard that is either electrically or pneumatically driven to compress the heart by putting inward pressure on the thorax.

mechanical piston device A device that depresses the sternum via a compressed gas-powered or electric-powered plunger mounted on a backboard.

recovery position A side-lying position used to maintain a clear airway in unresponsive patients who are breathing adequately and do not have suspected injuries to the spine, hips, or pelvis.

return of spontaneous circulation (ROSC) The return of a pulse and effective blood flow to the body in a patient who previously was in cardiac arrest.

rigor mortis Stiffening of the body muscles; a definitive sign of death.

stridor A harsh, high-pitched respiratory sound, generally heard during inspiration, that is caused by partial blockage or narrowing of the upper airway; may be audible without a stethoscope.

ventilation Exchange of air between the lungs and the environment, spontaneously by the patient or with assistance from another person, such as an EMT.

Assessment *in Action*

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Your EMS supervisor is conducting a so-called tabletop exercise with your crew in preparation for the next cardiac arrest call and wants to assess your crew's knowledge of cardiac arrest management. She presents your crew with the following scenario questions.

1. Which intervention(s) would have the MOST positive impact on the cardiac arrest patient's outcome?

   A. Advanced airway management
   B. Early CPR and defibrillation
   C. IV fluid administration
   D. Cardiac medications

2. The AED gives a "no shock" message to a patient who is in cardiac arrest. You should:

   A. resume chest compressions.
   B. check for a carotid pulse.
   C. reanalyze the cardiac rhythm.
   D. deliver two rescue breaths.

3. What is the maximum amount of time that should be spent checking for spontaneous breathing in an unresponsive child?

   A. 5 seconds
   B. 10 seconds
   C. 15 seconds
   D. 20 seconds

4. When performing CPR on an adult, you should compress the chest to a depth of ___ at a rate of ___ compressions per minute.

   A. 1 inch to 1.4 inches (2.5 cm to 3.5 cm); 80 to 100
   B. 2 inches to 2.4 inches (5 cm to 6 cm); 80 to 100

C. 1 inch to 1.4 inches (2.5 cm to 3.5 cm); 100 to 120
D. 2 inches to 2.4 inches (5 cm to 6 cm); 100 to 120

5. What is the proper compression-to-ventilation ratio for adult two-rescuer CPR?

A. 15:2
B. 30:2
C. 50:2
D. 75:2

6. When checking for a pulse in an infant, you should palpate which of the following arteries?

A. Carotid
B. Femoral
C. Brachial
D. Dorsalis pedis

7. When you are performing CPR on an adult or child, you should reassess the patient for return of respirations and/or circulation approximately every __________ minutes.

A. 5
B. 3
C. 2
D. 1

8. What is the preferred method of removing a foreign body in an unresponsive child?

A. Back slaps
B. Abdominal thrusts
C. Chest compressions
D. Manual removal

9. After you have started CPR in the field, under what circumstances can you stop?

10. Explain why the presence of gastric distention is dangerous to the patient.

National EMS Education Standard Competencies

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Medical Overview

Assessment and management of a

› Medical complaint (pp 561–568)

Pathophysiology, assessment, and management of medical complaints to include

› Transport mode (pp 567–568)
› Destination decisions (p 568)

Infectious Diseases

Awareness of

› A patient who may have an infectious disease (pp 568–576)

Assessment and management of

› A patient who may have an infectious disease (pp 568–576)

Knowledge Objectives

1. Differentiate between medical emergencies and trauma emergencies, remembering that some patients may have both. (p 561)
2. Name the various categories of common medical emergencies and give examples. (p 561)
3. Describe the evaluation of the nature of illness (NOI). (p 562)
4. Discuss the assessment of a patient with a medical emergency. (pp 562–566)
5. Explain the importance of transport time and destination selection for a medical patient. (p 567)
6. Define infectious disease and communicable disease. (p 569)
7. Discuss diseases of special concern and their routes of transmission, including influenza, herpes simplex, HIV/ AIDS, hepatitis, meningitis, tuberculosis, whooping cough, MRSA, MERS-CoV, and Ebola. (pp 569–575)

Skills Objectives

There are no skills objectives for this chapter.

Introduction

Patients who need EMS assistance generally have experienced either a medical emergency or trauma emergency; in some cases both have occurred. **Trauma emergencies** involve injuries resulting from physical forces applied to the body. **Medical emergencies** involve illnesses or conditions caused by disease. While it is important for you to be able to make the distinction between medical and trauma patients, it is equally important for you to remember that patients may have a combination of medical and trauma conditions affecting their health. For example, a person who has a heart attack while driving may be involved in a crash, or a diabetic patient whose blood glucose level is too low may fall and be injured. This chapter discusses medical emergencies. Chapter 24, *Trauma Overview*, discusses trauma emergencies.

Types of Medical Emergencies

There are many types of medical emergencies Table 14-1. Respiratory emergencies occur when patients have trouble breathing or when the amount of oxygen supplied to the tissues is inadequate. Diseases that can lead to respiratory emergencies include asthma, emphysema, and chronic bronchitis. Cardiovascular emergencies are caused by conditions affecting the circulatory system. The most common examples that require EMS intervention include heart attacks and congestive heart failure. Neurologic emergencies involve the brain and may be caused by a seizure, stroke, or fainting (syncope). Many gastrointestinal conditions can result in a call to EMS for help. The most well-known condition is appendicitis, although there are many others, including diverticulitis and pancreatitis. A urologic emergency can involve kidney stones. The most common endocrine emergencies are caused by complications of diabetes mellitus. Hematologic (blood) emergencies may be the result of sickle cell disease or various types of blood clotting disorders such as hemophilia. Immunologic emergencies involve the body's response to foreign substances. When the body overreacts to a foreign substance, it is commonly referred to as an allergic reaction. Allergic reactions are a type of immunologic medical emergency that can range from fairly minor to life threatening. Toxicologic emergencies, including poisoning and substance abuse, result in other types of medical emergencies. Some medical emergencies are caused by psychological or behavioral problems. Behavioral emergencies may be especially difficult to manage because patients often do not present with typical signs and symptoms. Gynecologic conditions are a special category of medical emergencies that involve the female reproductive organs. These conditions will most likely be very challenging for you because there is little that you can do to treat patients with gynecologic conditions in the prehospital setting. The chapters in this section discuss each of these medical emergencies.

Table 14-1 Common Medical Emergencies

Type of Medical Emergency	Examples of Condition
Respiratory	Asthma, emphysema, chronic bronchitis
Cardiovascular	Heart attack, congestive heart failure
Neurologic	Seizure, stroke, syncope
Gastrointestinal	Appendicitis, diverticulitis, pancreatitis
Urologic	Kidney stones
Endocrine	Diabetes mellitus
Hematologic	Sickle cell disease, hemophilia
Immunologic	Anaphylactic reaction (severe allergy to bee stings, food, or other substances)
Toxicologic	Substance abuse, food, plant, or chemical poisoning
Psychiatric	Alzheimer disease, schizophrenia, depression
Gynecologic	Vaginal bleeding, sexually transmitted disease, pelvic inflammatory disease, ectopic pregnancy

Patient Assessment

Assessment of a medical patient is similar to the assessment of a trauma patient but with a different focus. Whereas trauma assessments focus on the mechanism of injury or physical injuries, most of which are visible through a physical examination, medical patient assessment focuses on the **nature of illness (NOI)**, symptoms, and the patient's chief complaint. When you are assessing a patient, establish an accurate medical history. Information received from dispatch can be helpful in anticipating what you might find when you arrive on scene, but it is conceivable that what appears to be a traumatic emergency may in fact be a medical emergency or vice versa. Use the dispatch information to guide your initial response, but do not get locked into a preconceived idea of the patient's condition strictly from what the dispatcher tells you. During assessment, be aware of several challenges. It is possible that a patient has sustained an injury that distracts you from an underlying condition. For example, a patient may have a medical condition that resulted in a motor vehicle crash, or the patient may have sustained a large laceration and you fail to recognize that the patient has had a hypoglycemic event. Tunnel vision occurs when you become focused on one aspect of the patient's condition and exclude all others, which may cause you to miss an important injury or illness.

Patients may sometimes be uncooperative or even hostile toward those who respond to care for them. Patients may be fearful, angry, and confused and may take out their frustrations on you. It is important that you maintain a professional, calm, nonjudgmental demeanor at all times.

You are obligated as a medical professional to refrain from labeling patients and displaying personal biases. Never assume that you know what the problem is, even when you are treating patients who frequently call for EMS. This attitude could result in missing a serious condition. For example, an intoxicated patient may call 9-1-1 regularly and then call at another time after a fall resulting in a serious head injury. The head injury may be overlooked if you assume the call is a response only to intoxication. Labeling a patient is dangerous, demeaning, and detrimental to you and the patient. Personal biases should never affect your management of a patient. Any biases you may have need to be resolved before you respond to calls. As discussed in Chapter 9, *Patient Assessment*, the major components of patient assessment include the following:

- Scene size-up
- Primary assessment
- History taking
- Secondary assessment
- Reassessment

Scene Size-up

You must complete a scene size-up. The most important aspect of this step is to make sure the scene is safe. Although hazards are not as obvious with medical emergencies as with trauma situations, they still exist and must be considered. Therefore, remain conscious of your safety and the safety of your crew and patient before you enter a scene and throughout the call.

It is also important that you use standard precautions when you respond to an emergency, including wearing gloves and other protective equipment. As soon as possible after your arrival, determine the number of patients who need assistance. In most medical cases, there will be only one patient, but anticipate the possibility of more patients and be prepared. Finally, consider whether you need additional help. If you anticipate needing air transport, an advanced life support (ALS) unit, or police assistance, call for them immediately if you have not already done so, so that they will arrive as soon as possible.

YOU are the Provider — PART 1

Your unit is dispatched to 125 Green Hills Drive for a 36-year-old man with a fever and chills. The time is 1325 hours, there is a fine mist falling, the temperature is 72°F (22.2°C), and the traffic is moderate. You and your partner respond; the scene is located approximately 10 minutes away.

1. What observations should you make when you arrive at the scene before making physical contact with the patient?

Determine the NOI. What signs and symptoms is the patient experiencing? Evaluation of the NOI for a medical patient will provide you with an index of suspicion for different types of serious and/or life-threatening underlying illnesses. The **index of suspicion** is your awareness and concern for potentially serious underlying and unseen injuries or illnesses. Finally, as always, initiate spinal stabilization if indicated.

Primary Assessment

As you approach a medical patient, you should develop a general impression of his or her condition. Perform a rapid examination of the patient to identify life threats. Visual clues include apparent unconsciousness, obvious severe bleeding, or extreme difficulty breathing.

Quickly determine the patient's level of consciousness using the AVPU scale. If the patient is alert on your approach, you can infer several things about his or her condition, but you must always complete the remainder of the primary assessment. If the patient is unconscious as you approach, try to see if you can get a response to verbal stimuli by speaking to the patient while using a gentle touch. If the patient does not respond to your verbal stimulation, pinch the patient's ear or use the trapezius squeeze test (a pinch on the muscle that runs along the side of the neck to the shoulders) to see whether the patient responds. If there is no response to verbal or painful stimuli, consider the patient unresponsive and quickly continue the assessment.

Words of Wisdom

Do not let a relatively normal impression lull you into complacency. The conditions of many medical patients may not appear serious at first.

In conscious patients, ensure the airway is open and they are breathing adequately. Check the respiratory rate, depth, and quality. Consider applying oxygen at this time if there is any indication that breathing has been affected. For unconscious patients, make sure to open the airway using the proper technique for their condition and take several seconds to evaluate their breathing. Apply oxygen to patients in shock, with difficulty breathing, and when low oxygen saturations are measured (Spo_2 less than 94%). Consider having your partner administer oxygen as you continue your assessment. Unconscious patients may need airway adjuncts and ventilatory assistance with a bag-valve mask (BVM).

YOU are the Provider — PART 2

You arrive at the residence and knock on the patient's door. His wife answers and escorts you to the bedroom where you find the patient in a semi-sitting position in his bed. He is conscious and alert, is covered with several blankets, and is shivering. Your primary assessment reveals the following information:

Recording Time: 0 Minutes	
Appearance	Flushed skin, shivering
Level of consciousness	Conscious and alert
Airway	Open; clear of secretions and foreign bodies
Breathing	Increased rate; adequate depth
Circulation	Radial pulses, rapid strong; skin, flushed and hot to the touch

The patient tells you that he began feeling ill the day before but then started running a fever last night. Other than chills and generalized weakness, he denies any other symptoms. He took 400 mg of ibuprofen approximately 30 minutes ago, and his wife took his temperature shortly before your arrival; it read 102.6°F (39.2°C).

2. On the basis of your general impression and primary assessment findings, does this patient require immediate transport?

3. How should you proceed with your care of the patient?

Figure 14-1 Skin color can provide an early and fast indication of several disease processes. Cyanosis presents as blue skin. This photo also shows nail clubbing, associated with chronic hypoxemia seen in various lung and heart diseases.

Quickly assess the circulation in a conscious patient by checking the radial pulse and observing the patient's skin color, temperature, and condition **Figure 14-1**. For unconscious patients, assess the circulation at the carotid artery because generally this is the site of the strongest pulse and it is relatively easy to palpate on a supine person. Also quickly glance around the patient to identify any life threats such as severe bleeding or injury to the chest that affects the breathing. If any life threats are found, address them immediately.

Once you have completed the primary assessment, you should have enough information to make a preliminary transport decision. The following patients should be considered in serious condition and in need of rapid transport: patients who are unconscious or who have an altered mental status, patients with airway or breathing problems, and patients with obvious circulation problems such as severe bleeding or signs of shock. Patients identified as needing rapid transportation still require additional assessment and care.

Words of Wisdom

Once the primary assessment has been completed, a preliminary transport decision should be made.

If the patient does not meet the criteria for rapid transport at this time, continue your assessment on scene and prepare for transport after you have completed the assessment and treatment. If you find that your patient's condition deteriorates during the primary assessment, prepare the patient for immediate transport and complete the assessment en route to the emergency department (ED).

History Taking

With a medical patient, history taking may be the only way to determine what the problem is or what may be causing the problem. It is imperative to gather a thorough history from the patient and/ or any family, friends, or bystanders who may have pertinent information. Family members may be the only people aware that an older patient sustained a head injury the previous week or that a patient has a history of drug abuse. Bystanders may have seen clues prior to the 9-1-1 call that will lead you and the hospital staff to identify the cause of a patient's condition. Investigate the NOI by inquiring about the chief complaint. Identifying signs and symptoms associated with the chief complaint will often help you determine the nature of the condition. Ask about the history of the present illness and ask follow-up questions such as, "Has anything like this ever happened before?" If the patient answers yes, then ask, "What was done at that time?" and "How does this episode compare with previous episodes?"

If a patient is unconscious, survey the scene for evidence of medication containers or medical devices the patient may have been using. Try to obtain as much of the patient's medical history as possible from family members, friends, and bystanders or from the scene itself. Family members or friends may know the patient's allergies, medications, or medical conditions. Ask whether the patient reported any symptoms before he or she lost consciousness. If possible, have a family member accompany you to the hospital to answer questions there as well.

As you continue to gather information, remember to obtain a SAMPLE history and to ask questions about the patient's chief complaint using the OPQRST mnemonic. Ask patients to identify all the symptoms they are experiencing. Make sure you record any allergies, medical conditions, and medications they take **Figure 14-2**. Ask about prescriptions, over-the-counter medications, and herbal medications.

Sometimes older patients will report taking numerous medications. In those situations, it is best to take the medications with you to the hospital, and list them in your report. Ask patients about their medical history to help determine the current problem and identify any other conditions that might cause complications. To obtain a complete history, ask about specific conditions such as heart problems, breathing problems, and blood sugar (glucose) problems. Determine if the patient is taking any medications for these conditions and whether he or she is compliant with the drug regimen. The purpose of these questions is to obtain the most complete medical history possible. In addition, look around the scene for clues, such as prescription pill bottles or home medical equipment, that may help you piece together the patient's medical history and better understand the circumstances surrounding the current medical emergency.

Figure 14-2 History taking is an important part of the patient assessment process.

Words of Wisdom

The mnemonic TACOS can be useful in the assessment process.

T Tobacco
A Alcohol
C Caffeine
O Over-the-counter medications/herbal supplements
S Sexual and street drugs

TACOS can help you understand the underlying conditions a patient may have that could be complicating the chief complaint. It also helps you understand why the medications administered may or may not work for a patient. For example, if you have a male medical patient reporting chest pain and you want to administer nitroglycerin, ask the patient whether he has taken medication to treat erectile dysfunction. The combination of these two medications may cause a dangerous drop in blood pressure. If the answer is yes, follow up by asking how much medication was taken and how often. In another example that involves a young woman who is showing signs of a stroke, you need to ask whether she smokes and takes birth control pills or herbal supplements (substances that increase the risk of clot formation and thus the risk of stroke). TACOS will help you remember to ask these important questions.

Secondary Assessment

In some cases in which the patient is critically ill or injured or the transport time is short, you may not have time to conduct a secondary assessment. In other cases, the secondary assessment may occur on scene or en route to the ED.

Conscious medical patients seldom need a secondary assessment of the entire body or a head-totoe examination, but all conscious patients should undergo a limited or detailed physical examination based on their chief complaint. For example, you should check for pulse, motion, and sensation in all of the patient’s extremities and check the patient’s pupillary reaction if you suspect a neurologic problem. Unconscious patients are unable to tell you what is wrong, so you should always perform a secondary assessment of the entire body or a head-to-toe examination. A full body assessment should help you obtain clues to assess the problem, but this assessment should be performed quickly so it does not delay transport to the hospital.

Words of Wisdom

Medical alert jewelry may provide you with valuable information about why the patient is unconscious.

If the patient's condition does warrant the secondary assessment, begin by carefully examining the head, scalp, and face. Look for evidence of possible trauma, and monitor the patient for any signs of pain with palpation throughout the assessment. Examine the head and face for symmetry, making sure to check the pupils for equality and reactivity to light. Look at the conjunctiva of the eyes for moisture and the ears and nose for any drainage. Look for nasal flaring, and examine the mouth for foreign bodies (including loose teeth or dentures) and pink, moist mucosa.

Examine the neck closely for any evidence of accessory muscle use with respirations. Check for jugular vein distention and tracheal deviation, which can be indicators of respiratory or cardiac problems. While you are examining the neck, make sure to move any clothing so that you can check for a tracheostomy or stoma.

Next, assess the chest and abdomen. At the chest, make sure to check breath sounds and ensure that the patient is breathing adequately with equal chest rise and fall on each side. Carefully inspect and palpate the chest and abdomen to identify any areas of tenderness or swelling. Look for medication patches on the chest or abdomen and any implanted medical devices, which usually can be palpated just under the skin. Check for rigidity and distention in the abdomen, and look for scars on the chest or abdomen that might indicate previous surgeries. Finally, check the pelvis and genital area, asking about pain and looking for signs of incontinence or bleeding.

Palpate the legs and arms for swelling and other abnormalities, making sure to check for distal motion, sensation, and circulation. Note any scars, or track marks, along the veins, which are indicators of intravenous (IV) drug use. Look for medical alert jewelry at the wrists as well. Finally, examine the patient's back to note any irregularities, pain, or scars. At this point, your full assessment of the patient should be complete, and treatment of non–life-threatening conditions should be instituted. Treatment will depend on the condition(s) and your local protocols.

Words of Wisdom

While the use of an automatic blood pressure cuff is convenient, you should always attempt to obtain at least one manual blood pressure reading to be sure it correlates with the automatic reading.

Obtaining a good set of vital signs is critical. Often your partner can begin this process while you are asking about the medical history. Assess the pulse for rate, quality, and regularity at the most appropriate site, either at the radial artery if the patient is conscious, or at the carotid artery if the patient is unconscious. Assess respirations as you assess the pulse to prevent the patient from modifying his or her respirations in response to your observation. Identify the rate, quality, and regularity of the respirations and any difficulties that may be apparent. Finally, obtain an initial blood pressure reading, measuring both systolic and diastolic pressures.

Consider using the automatic blood pressure cuff for future assessments at regular intervals. Depending on your local protocol, other important information to consider obtaining includes a blood glucose level and a pulse oximetry reading. End-tidal CO_2 ($ETCO_2$) monitoring should be considered if the patient complains of respiratory problems.

Reassessment

After completing the assessment and treatment, begin reassessment and continue throughout transport. During the reassessment, repeat the primary assessment and reassess the chief complaint. Look for any changes in the level of consciousness; reassess the airway, breathing, and circulation; and reexamine the transport decision. Consider the need for ALS backup. Obtain another full set of vital signs every 5 minutes for unstable patients or every 15 minutes for stable patients. Reassessment also includes repeating your physical examination to identify and treat changes in the patient's condition.

YOU are the Provider — PART 3

Your partner obtains the patient's vital signs. The patient agrees to transport and asks you to take him to a hospital that he has been to before, which is located 25 miles away. There is another hospital located only 10 miles away.

Recording Time: 5 Minutes	
Respiration	22 breaths/min; regular and adequate
Pulse	110 beats/min; strong and regular
Skin	Flushed; hot to the touch
Blood pressure	124/70 mm Hg
Oxygen saturation (Spo_2)	99%

4. Is it appropriate to transport the patient to the hospital he requested, or should you transport him to the closer facility?

Finally, the reassessment includes reviewing all treatments that have been performed. Reassess oxygen delivery, any bandages or splints applied, and any other treatment that has been performed.

Document any changes that have developed as a result of the treatments, and, if needed, adjust any of the treatments accordingly. Reassessment is an important step in patient assessment to modify care accordingly and so that you have the most current information on the patient's condition when you arrive at the hospital.

Management, Transport, and Destination

Most medical emergencies require a level of treatment beyond that available in the prehospital setting. Also, the treatments depend on an accurate diagnosis of the exact medical condition, which may require advanced testing available in a hospital. The primary prehospital treatments for medical emergencies address the symptoms more than the actual disease process.

Depending on local protocol, it may be beyond the scope of an EMT to administer medications to a patient. In a few limited circumstances, such as the administration of nitroglycerin to a patient with chest pain or to a patient for whom it has been prescribed, an exception may be made. Another exception may be granted to allow an EMT to assist a patient with a prescribed metered-dose inhaler when it is required because of respiratory difficulty.

Administration of medications that are stored in the ambulance is also limited for EMTs and is dependent on state and local protocols. A few of these protocols include administering aspirin for patients having chest pain, administering oral glucose to a patient with diabetes and a low blood glucose level, and possibly administering albuterol to a patient with respiratory difficulty. The administration of activated charcoal to a patient who has ingested a poison is also allowed when it may be beneficial. Each of these situations and any other administration of medication by an EMT require that direct permission be obtained from medical control. The process of obtaining permission includes completing a thorough assessment of the patient before calling medical control. After you give a report to the physician and obtain permission, the medication may be administered. Never administer any medication without first obtaining permission from medical control, and always follow your state and local protocols.

You may also use an automated external defibrillator (AED) on a patient who is pulseless and apneic. In some cases of cardiac arrest, immediate treatment with an AED may provide the best option to resuscitate the patient. The AED is discussed in more detail in Chapter 16, *Cardiovascular Emergencies*. Familiarize yourself with the equipment and medications carried on your ambulance and use them appropriately under a medical director's instruction.

Scene Time

In many cases, the time on scene may be longer for medical patients than for trauma patients. If the patient is not in critical condition, gather as much information as possible from the scene so that you can transmit that information to the physician at the ED. Check the patient's living conditions—heating, air conditioning, cleanliness of environment, adequate food, and so on. Critical patients include those with altered mental status, airway or breathing difficulties, or any sign of circulatory compromise. In addition, a patient who is very old or very young may be considered critical even if they appear to be relatively stable. Critical patients always need rapid transport. The time on scene should be limited to 10 minutes or less for these patients.

Type of Transport

Serious consideration should be given to how best to transport a medical patient. If a life-threatening condition exists, the transportation should include lights and sirens, but if the patient is not critical, consider nonemergency transport. Many patients experiencing a medical emergency do not have immediate life-threatening conditions; therefore, they can be transported without the use of lights and sirens. This is a much safer method of transport and will often result in arrival only a few minutes later than an emergency transport using lights and sirens.

Differentiating a high-priority transport from a low-priority transport is a skill developed with experience, but it is a skill that can be learned. A good rule of thumb for determining the priority of transport is to consider the results of the patient's primary assessment. Patients with an altered mental status, especially if it is still present at the completion of your assessment and treatment, should be considered a high-priority transport. Patients with circulatory compromise, including signs and symptoms of shock, should also be considered a high-priority transport. Most patients with circulatory problems cannot be stabilized in the prehospital setting and need to receive treatment at a hospital quickly but safely. Patients with difficulty breathing generally require high-priority transport. However, if the patient has responded well to your initial treatment, such as oxygen and albuterol administration, lights and sirens may not be necessary.

Modes of transport ultimately come in one of two categories: ground **Figure 14-3** or air **Figure 14-4**. Ground transportation EMS units are generally staffed by EMTs and paramedics. Air transportation EMS units or critical care transport units are generally staffed by critical care transport professionals such as critical care nurses and paramedics. While it is not as common to summon an air ambulance for a medical patient, there are instances where it is advisable. In rural areas with long ground transport times, patients who have possibly experienced a heart attack, a stroke, or a complication of pregnancy could benefit from air transport. Children with serious medical conditions can also benefit from air transport. When you are considering ALS support for a patient, compare the total time for a ground ALS unit to respond and transport to the time required for an ALS helicopter to respond and transport as well as the urgent resources needed by the patient. Follow local protocols and medical direction.

Figure 14-3 Ground transport.

Figure 14-4 Air transport.

LindaCharlton/iStock.

Destination Selection

It is generally appropriate to select the closest ED as your destination. However, there are times when the closest hospital is not necessarily the most appropriate choice. Patients with chest pain as the result of a heart attack may need a facility that is capable of performing heart catheterization, which may not necessarily be available at the closest hospital. If the patient is in cardiac arrest or experiences cardiac arrest during transport, immediately reroute to the closest hospital with emergency facilities. Stroke patients can also benefit from specialized hospital selection. Although most hospitals now have designated stroke teams, taking a possible stroke patient to a hospital without these resources may result in a delay in definitive treatment and may lead to a worse outcome for the patient.

Some medical patients may benefit from on-scene treatment provided by advanced EMS personnel such as paramedics. It is important to recognize early when paramedics can provide added value on a scene so that, if they are readily available, they can be called to respond in a timely manner.

Infectious Diseases

As discussed in Chapter 2, *Workforce Safety and Wellness*, you will be called on to treat and transport patients with a variety of infectious or communicable diseases. Chapter 2 discusses the routes of transmission and standard precautions that responders need to take to reduce risk and increase prevention. This chapter discusses the awareness, assessment, and management of a patient who may have a communicable or infectious disease. Chapter 37, *Transport Operations*, discusses decontamination techniques after transport.

General Assessment Principles

The assessment of a patient suspected to have an infectious disease should be approached much like any other medical patient. With most patients who have a potentially infectious disease in the prehospital setting, the next step after scene size-up and primary assessment is to gather patient history, using OPQRST to elaborate on the patient's chief complaint. Typical chief complaints include fever, nausea, rash, pleuritic chest pain, difficulty breathing, vomiting, and diarrhea. Obtain a SAMPLE history and a set of baseline vital signs, paying particular attention to medications the patient is currently taking and the events leading up to today's problem. Also ask whether the patient has recently traveled or has come in contact with someone who has traveled. Always show respect for the feelings of the patient, family members, and others at the scene.

General Management Principles

The general management of the patient with a suspected infectious disease first focuses on any life-threatening conditions that were identified in the primary assessment (airway management, oxygen and ventilatory assistance, bleeding control, and circulatory support). Remember to be empathetic. Because most of these patients will have a fever of unexplained origin or mild breathing problems, place the patient in the position of comfort on the stretcher and keep him or her warm. Remember to use standard precautions for your own safety. Always follow your agency's exposure control plan regarding cleaning equipment, properly discarding any disposable supplies, and washing linens.

Epidemic and Pandemic Considerations

An **epidemic** occurs when new cases of a disease in a human population substantially exceed the number expected based on recent experience. A **pandemic** is an outbreak that occurs on a global scale. A flu pandemic occurs when a new influenza virus for which people have little or no immunity emerges. The disease can spread easily from person to person, cause serious illness, and be found in multiple countries in a short time. Obviously, there would be no specific vaccine immediately available.

Words of Wisdom

An **infectious disease** is a medical condition caused by the growth and spread of small harmful organisms within the body. A **communicable disease** is a disease that can be spread from one person or species to another. Most of these diseases are much harder to be infected with than is commonly believed. In addition, there are many immunizations, protective techniques, and devices that can be used to minimize your risk of infection. When these protective measures are used, the risk of your contracting a serious infectious disease is negligible.

Common or Serious Communicable Diseases

Influenza

Influenza, commonly known as flu, is primarily an animal respiratory disease that has mutated to infect humans. It can affect all people, but those with chronic medical conditions, compromised immune systems, the very young, and the very old are particularly susceptible to complications of the disease. All strains of influenza are transmitted by direct contact with nasal secretions and aerosolized droplets from coughing and sneezing by infected people.

The H1N1 virus, which was initially identified as the swine flu in 2009, is a specific form of influenza. This virus has been present for years in animals. Many deaths have been caused by the H1N1 virus, although deaths caused by other influenza viruses have also occurred. The most positive effect of the outbreak of the H1N1 virus has been the general public's greater awareness of the routes of transmission of contagious diseases. This increased awareness could result in a reduction of all communicable diseases, not only H1N1.

Many potentially serious diseases can be passed by the respiratory route; therefore, you need to wear personal protective equipment (PPE), such as gloves, eye protection, and a high-efficiency particle absorbing (HEPA) respirator, at a minimum. Viruses can live for several days on surfaces, so frequent handwashing is also important. Maintain your vaccinations and stay up-to-date on the latest Centers for Disease Control and Prevention (CDC) recommendations. Place a surgical mask on patients with suspected or confirmed respiratory disease. Wear a HEPA respirator during any aerosol-generating procedures such as suctioning of airway secretions, performing cardiopulmonary resuscitation, or assisting with endotracheal intubation.

An annual influenza immunization is important, especially for EMS personnel, to protect providers and patients. The influenza virus is constantly changing. Experts adjust vaccines from year to year to provide protection against the strains most likely to affect the population. Vaccination effectively decreases transmission rates and limits (though does not eliminate) the disease incidence. Complications of the vaccine are far less common and severe than complications of the flu, which kills people every year. The theory that immunizations cause autism has been proven through research to be untrue.

Herpes Simplex

Herpes simplex is a common virus strain carried by humans. Eighty percent of people carrying the virus are asymptomatic, but symptomatic infections cause eruptions of tiny fluid-filled blisters called *vesicles* that often appear on the lips or genitals. Herpes simplex can cause more serious illnesses like pneumonia and meningitis in the very young, very old, and immuno-compromised patients. The primary mode of infection is through close personal contact, so standard precautions are generally sufficient to prevent spread to or from health care workers.

HIV Infection

Exposure to the virus that causes acquired immunodeficiency syndrome (AIDS) is a risk that EMTs face on a regular basis. It is this prospect that led to the development of standard precautions. There is no vaccine to protect against human immunodeficiency virus (HIV) infection, and despite great progress in drug treatments, AIDS can still be fatal. However, with treatment, patients can expect a near-normal lifespan. HIV attacks the body's immune system, making it difficult for the natural defenses to fight disease. If the HIV infection develops into AIDS, minor illnesses can become fatal to the patient. Fortunately, HIV is not easily transmitted in your work setting. For example, it is far less contagious than hepatitis B. HIV infection is a potential hazard only when deposited on mucous membranes or directly into the bloodstream.

This can occur via sexual contact or exposure to blood or body fluids, meaning your risk of infection is limited to exposure to an infected patient's blood and body fluids. Exposure can take place in the following ways:

- The patient's blood is splashed or sprayed into your eyes, nose, or mouth or into an open sore or cut, however tiny; even a microscopic opening in the skin is an invitation for infection with a virus.

Words of Wisdom

Causes of Infectious Disease

Organism	Description	Example
Bacteria	Grow and reproduce outside the human cell in the appropriate temperature and with the appropriate nutrients	*Salmonella*
Viruses	Smaller than bacteria; multiply only inside a host and die when exposed to the environment	Human immunodeficiency virus
Fungi	Similar to bacteria in that they require the appropriate nutrients and organic material to grow	Mold
Protozoa (parasites)	One-celled microscopic organisms, some of which cause disease	Amoebas
Helminths (parasites)	Invertebrates with long, flexible, rounded, or flattened bodies	Worms

- You have blood from the infected patient on your hands and then touch your own eyes, nose, mouth, or an open sore or cut.
- A needle used to inject the patient breaks your skin. The risk to you from a single injection, even with a hollow-bore needle, is small, probably less than 1 in 1,000. However, this is by far the most dangerous form of exposure.
- Broken glass at a motor vehicle crash or other incident penetrates your glove (and skin), which may have already been covered with blood from an infected patient.

Many patients who are infected with HIV do not show any symptoms. This is why health care workers should wear gloves any time they are likely to come into contact with secretions or blood from any patient. Always put on gloves before leaving the ambulance to care for a patient. Also, take great care in handling and properly disposing of needles and other sharp objects in a sharps container so that you and others are not inadvertently exposed to them. Finally, cover any open wounds that you have whenever you are on the job.

If you have any reason to think that a patient's blood or secretions may have entered your system, especially through contact with a patient's blood, seek medical advice as soon as possible and notify your infectious disease officer. If you know that the patient is infected with HIV, your physician may suggest immediate treatment to try to prevent you from becoming infected. However, if the patient is an unlikely candidate for HIV infection, your physician may recommend that you and the patient be tested before you undergo therapy. As scientists learn more about HIV infection, testing and treatment recommendations change. It is important that you immediately see your physician (or your program's designated physician) any time you have a significant exposure to a communicable or infectious disease. Know the policy for your system, and take time now to consider what you would do in the event of exposure.

Hepatitis

The term hepatitis refers to an inflammation (and often infection) of the liver. Hepatitis can be caused by a number of different viruses and toxins. Early signs of viral hepatitis include loss of appetite, vomiting, fever, fatigue, sore throat, cough, and muscle and joint pain. Several weeks later, jaundice (yellow eyes and skin) and right upper quadrant abdominal pain develop **Figure 14-5**. The severity of toxin-induced hepatitis depends on the amount of agent absorbed and the duration of exposure. Toxin-induced hepatitis is not contagious. There is no sure way to tell which patients with hepatitis have a contagious form of the disease and which do not. **Table 14-2** shows the characteristics of different types of hepatitis, from which you can assess your risk of exposure. Hepatitis A can be transmitted only from a patient who has an acute infection, whereas hepatitis B and hepatitis C can be transmitted from long-term carriers who have no signs of illness. A carrier is a person (or animal) in whom an infectious organism has taken up permanent residence and may or may not cause any active disease. Carriers may never know that they harbor the organism; however, they can infect other people.

Figure 14-5 Jaundice is a sign of a hepatitis infection.

YOU are the Provider PART 4

You place the patient onto the stretcher, load him into the ambulance, and begin transport to the hospital.

Recording Time: 12 Minutes	
Level of consciousness	Conscious and alert
Respiration	22 breaths/min; regular and adequate
Pulse	104 beats/min; strong and regular
Skin	Flushed, warm, and moist
Blood pressure	122/68 mm Hg
Spo_2	98%

You set the automatic vital sign device to reassess his vital signs every 15 minutes. The patient tells you that he thinks his fever is breaking because he is sweating. En route, his vital signs and overall condition are reassessed and remain unchanged.

5. Should you set the vital sign device to reassess his vital signs at shorter intervals? Why or why not?

6. On the basis of the patient's chief complaint, what additional information can you obtain by using the OPQRST mnemonic?

Table 14-2 Characteristics of Hepatitis

Type	Route of Infection	Incubation Period	Chronic Infection	Vaccine and Treatment	Comments
		Viral Hepatitis			
Hepatitis A (infectious)	Fecal–oral, infected food or drink	2–6 wk	Chronic condition does not exist	Vaccine is available; no specific treatment is available; body will clear the infection on its own	Mild illness; approximately 2% of patients die; after acute infection, the patient has life-long immunity
Hepatitis B	Blood, sexual contact, saliva, urine, breast milk	4–12 wk	Chronic infection affects up to 10% of patients and up to 90% of newborns who have the disease	Vaccine is available; treatment is minimally effective	Up to 30% of patients may become chronic carriers; patients are asymptomatic and without signs of liver disease, but they may infect others; approximately 1% to 2% of patients die
Hepatitis C	Blood, sexual contact	2–10 wk	Chronic infection affects 90% of patients	No vaccine is available; treatment is costly but effective for many strains of hepatitis C.	Cirrhosis of the liver develops in 50% of patients with chronic hepatitis C; chronic infection increases the risk of cancer of the liver
Hepatitis D	Blood, sexual contact	4–12 wk	Chronic infection is common	No vaccine is available; no treatment is available	Occurs only in patients with active hepatitis B infection; fulminant disease may develop in 20% of patients
		Toxin-Induced Hepatitis			
Medications, drugs, and alcohol	Inhalation, skin or mucous membrane exposure, oral ingestion, or intravenous administration	Within hours to days following exposure	Some chemicals may initiate an inflammatory response that continues to cause liver damage long after the chemical is out of the body	No vaccine is available; treatment is to stop exposure; in patients with an overdose of acetaminophen, certain drugs may minimize liver injury if given early enough	This type of hepatitis is not contagious; patients with toxin-induced hepatitis may have liver damage and jaundice; not every exposure to a toxin will cause liver damage.

Hepatitis A is transmitted orally through oral or fecal contamination. This means that, generally, you must eat or drink something that is contaminated with the virus. Contamination is the presence of an infectious organism on or in an object. The organisms that cause hepatitis B and C are transmitted through vehicles other than food or water. For example, these organisms may enter the body through a transfusion or needlestick with infected blood, which puts health care workers at high risk for contracting hepatitis B, the more contagious and virulent form. **Virulence** is the strength or ability of a pathogen to produce disease. Hepatitis B is far more contagious than HIV. For this reason, vaccination with hepatitis B vaccine is highly recommended for EMTs. Unfortunately, not everyone who is vaccinated develops immediate immunity to the virus. Sometimes, but not always, an additional dose will provide immunity. You should be tested after vaccination to determine your immune status.

If you are stuck with a needle or injured in some other way while caring for a patient who might have hepatitis, see your physician immediately.

Words of Wisdom

Patients with track marks are at high risk for hepatitis B, hepatitis C, and HIV.

Meningitis

Meningitis is an inflammation of the meningeal coverings of the brain and spinal cord. Patients with meningitis will have signs and symptoms such as fever, headache, stiff neck, and altered mental status. It is an uncommon but very frightening infectious disease. Meningitis can be caused by viruses or bacteria, most of which are not contagious. However, one form, **meningococcal meningitis**, is highly contagious. The meningococcus bacterium colonizes the human nose and throat and only rarely causes an acute infection. When it does, it can be lethal. Patients with this kind of infection often have red blotches on their skin; however, many patients with forms of meningitis that are not contagious also have red blotches.

Only laboratory tests can sort out the different forms of meningitis; therefore, you should take standard precautions with any patient who is suspected of having meningitis. Wearing gloves and a mask will go a long way to prevent the patient's secretions from getting into your nose and mouth. Again, the risk of infection is small, even if the organism is transmitted. For this reason, vaccines, which are available for most types of meningococcus, are rarely used. Meningitis can be treated at the ED with antibiotics.

Words of Wisdom

Meningococcal meningitis is an inflammation of the meningeal coverings of the brain and spinal cord that can be highly contagious. The bacteria that cause meningococcal meningitis can be spread by the exchange of respiratory secretions through coughing and sneezing. The effects are lethal in some cases. Victims who survive can be left with brain damage, hearing loss, or learning disabilities. Patients may present with flulike symptoms, but high fever, severe headache, photophobia (light sensitivity), and a stiff neck in adults are symptoms unique to meningitis. Patients sometimes have an altered level of consciousness and can have red blotches on the skin. Use respiratory protection, provide rapid transportation, and provide early notification to the ED so they can make specific preparations for accepting a highly contagious patient.

After treating a patient with meningitis, contact your employer health representative. Many states consider meningitis reportable and will notify you that one of your patients was diagnosed with meningitis. Prophylactic treatment may be recommended for you.

Tuberculosis

Most patients who are infected with *Mycobacterium tuberculosis* (the tubercle bacillus) are well most of the time. If the disease involves the brain or kidneys, the patient is only slightly contagious. In the United States, however, **tuberculosis** is a chronic mycobacterial disease that usually strikes the lungs. Disease that occurs shortly after infection is called primary tuberculosis. Except in infants, this infection is not usually serious. After the primary infection, the tubercle bacillus is rendered dormant by the patient's immune system. However, even after decades of lying dormant, this germ can reactivate. Reactive tuberculosis is common and can be much more difficult to treat, especially because an increasing number of tuberculosis strains have grown resistant to most antibiotics.

Although tuberculosis is often hard to distinguish from other diseases, patients who pose the highest risk almost invariably have a cough. Therefore, for your safety, you should consider respiratory tuberculosis to be the only contagious form because it is the only one that is spread by airborne transmission. The droplets produced by coughing are not the real problem. The real problem is the droplet nuclei, which are the remnants of the droplets after the excess water has evaporated. These particles are tiny enough to be invisible and can remain suspended in the air for a long time. In fact, as long as these particles are shielded from ultraviolet light, they can remain alive for decades. Particles that are the size of droplet nuclei are not stopped by routine surgical masks. Inhaled, they are carried directly to the alveoli of the lungs, where the bacteria may begin to grow. N95 or HEPA masks are required to stop droplet nuclei **Figure 14-6**.

Why is tuberculosis not more common than it is? After all, absolute protection from infection with the tubercle bacillus does not exist. Everyone who breathes is at risk. According to the CDC, one-third of the world's population is infected with tuberculosis. The vaccine for tuberculosis, called BCG, is only rarely used in the United States. Under normal circumstances, however, the mechanism of transmission used by *Mycobacterium tuberculosis* is not very efficient. Infected air is easily diluted with uninfected air. *M tuberculosis* is one of those germs that typically cause no illness in a new host. In fact, many patients with tuberculosis do not even transmit the infection to family members. However, in crowded environments with poor ventilation, the disease spreads more easily.

Figure 14-6 Wear an N95 mask when treating a patient whom you suspect has tuberculosis.

Special Populations

The aging process can pose a threat to the body's natural defense mechanisms against invading microorganisms. As a person ages, his or her physical defenses weaken or are eliminated. The skin's thinning and loss of supportive collagen, along with a reduction in the number of blood vessels, allow bacteria or viruses to enter the body with less resistance. The respiratory system cannot trap and eliminate bacteria and viruses in the airways as efficiently as it once did. Additionally, the gastrointestinal system allows easier entry for bacteria or viruses through the intestines. As the body ages, physical barriers to entry weaken, the immune system deteriorates, and invading organisms are not as easily identified as abnormal. Infectious agents can take hold in older people much more easily because of reduced defenses.

When transporting an older patient, protect the patient from the environment because extremes in heat or cold can further reduce the body's defenses. If the patient has a cold or the flu, protect yourself. However, remember that your defense system is probably much stronger than that of the patient.

People who are immunosuppressed from chronic illnesses, cancer treatment, or organ transplants may also lack the ability to fight certain infections. Ensure that these patients are not exposed to any additional conditions that could lead to an infection.

If you are exposed to a patient who is found to have pulmonary tuberculosis, you will be given a tuberculin skin test. This simple skin test determines whether a person has been infected with *M tuberculosis*. A positive result means that exposure has occurred; it does not mean that the person has active tuberculosis. It takes at least 6 weeks for the bacteria to show up in the laboratory test. So if you are tested for the disease within a few weeks of the exposure and your results are positive, this means that you were exposed to tuberculosis at an earlier time from somebody else. You will probably never identify the source. Most transmissions occur silently, so it is necessary that you have tuberculin skin tests regularly. If the infection is found before you become ill, preventive therapy is almost 100% effective. Usually, a daily dose of the medication isoniazid will prevent the development of active infection.

Whooping Cough

Whooping cough, also called pertussis, is an airborne disease caused by bacteria that mostly affects children younger than 6 years. Signs and symptoms include fever and a "whoop" sound that occurs when the patient tries to inhale after a coughing attack.

The best way to prevent infection from whooping cough is to be vaccinated with a diphtheria, tetanus, and pertussis vaccine (DTaP). Providers who have previously had this vaccine should make sure they are up-to-date with a booster. For added protection, place a mask on the patient and on yourself.

Methicillin-Resistant Staphylococcus Aureus

Methicillin-resistant *Staphylococcus aureus* (MRSA) is a bacterium that causes infections and is resistant to many antibiotics. In health care settings, MRSA is believed to be transmitted from patient to patient via unwashed hands of health care providers. Studies have shown that 5% to 15% of health care providers carry MRSA in their nares. The pathogen can subsequently be transferred to skin and other areas of the body through a break in the skin. Surfaces contaminated with MRSA do not seem to be important in transmission. Factors that increase the risk for developing MRSA include antibiotic therapy, prolonged hospital stays, a stay in an intensive care or burn unit, and exposure to an infected patient.

The incubation period for MRSA appears to be between 5 and 45 days. The communicable period varies, as patients who have active infection may carry MRSA for months. MRSA results in soft-tissue infections. Its signs and symptoms may involve localized skin abscesses, and sepsis may be found in older patients with the infection.

Global Health Issues

MERS-CoV

Middle East respiratory syndrome coronavirus (MERS-CoV) is a virus most commonly found in bats and camels living in the Middle East. The first human case of MERS-CoV was discovered in 2012 in Saudi Arabia. While most clusters of human infections are found in the Middle East, reported cases of MERS-CoV have been found in Europe and the United States. Common patient symptoms include high fever, cough, muscle aches, vomiting, and diarrhea. In some cases, renal failure, respiratory failure, and death have been reported. There is presently no cure or vaccine for this virus. If you suspect your patient might have MERS-CoV, place a surgical mask on him or her and notify the receiving facility.

Ebola

In 2014, an outbreak of the Ebola virus in West Africa caused international concern. Several infected people with the virus traveled to other countries, including the United States, motivating EMS and health care facilities to prepare for further outbreaks. The incubation period is approximately 6 to 12 days after exposure; however, symptoms may not begin to appear for as long as 21 days after infection. Symptoms include watery diarrhea, vomiting, fever, body aches, and bleeding. The fatality rate can be as high as 70% if effective supportive treatment in an intensive care unit is not initiated promptly. If you suspect your patient may have this condition, place a surgical mask on him or her and follow PPE precautions as outlined by local protocols and the CDC. Immediately notify the receiving facility that your patient may have or may have been exposed to the Ebola virus.

Travel Medicine

Every day, thousands of people travel to various countries. While humans share many common germs, some are confined to certain areas of the world. As an EMS provider, you must be aware of this when assessing a patient who recently traveled outside the United States.

Patients who acquire an illness from another country can present with a variety of symptoms depending on the illness. They may have a fever, cough, vomiting, bloody diarrhea, body aches, and rashes. In many cases, the patient experiences mild symptoms and does not require EMS. However, some patients become extremely ill, requiring urgent evaluation and treatment. When you encounter an ill patient with a recent travel history, place a mask on the patient and gather as much information as possible. Important questions to ask the patient include:

- Where did you recently travel?
- Did you receive any vaccinations before your trip?
- Were you exposed to any infectious diseases?
- Is there anyone else in your travel party who is sick?
- What types of food did you eat?
- What was your source of drinking water?

Words of Wisdom

The ability of your EMS system to support you in the event of exposure to a communicable disease depends on your understanding of how an exposure to potentially infectious materials can occur and your immediate reporting of the exposure. Make notes right away to ensure that you remember all pertinent information, and report the possible exposure immediately after the response, following your service's guidelines.

If you suspect the patient has a communicable illness, follow appropriate PPE precautions and notify the receiving facility. While treatment for many travel-related illnesses is primarily supportive in the prehospital environment, always be prepared to manage life-threatening conditions should the patient become unstable.

Conclusion

Although trauma patients often present with dramatic signs and symptoms, the assessment and treatment you provide for them are fairly straightforward. The assessment and treatment of medical patients on the other hand can be very challenging and interesting because of the nature of medical conditions. The condition of a medical patient may not be as apparent as in a trauma patient and, therefore, treatment may not be as straightforward. You must remember that delays of any kind in an attempt to diagnose a condition can be harmful to the patient and thus are not recommended. Your best approach is to keep calm, use your patient assessment skills, treat the patient's symptoms, report to medical control, and transport the patient safely to the emergency department. Finally, keep in mind that patients sometimes have more than one problem, so you must be prepared to handle any combination of conditions, including conditions of medical patients who have been involved in traumatic situations.

YOU are the Provider — PART 5

With an estimated time of arrival at the hospital of 5 minutes, you reassess the patient and call in your radio report. The hospital acknowledges your report and is awaiting your arrival. The patient tells you that he feels better, but is very thirsty.

Recording Time: 21 Minutes	
Level of consciousness	Conscious and alert
Respiration	18 breaths/min; regular and adequate
Pulse	90 beats/min; strong and regular
Skin	Warm and moist; less flushed
Blood pressure	128/72 mm Hg
Spo_2	98%

The patient is delivered to the hospital without incident, and you give your verbal report to a staff nurse, who assumes care of the patient. The receiving nurse reassesses the patient's temperature and notes a reading of 99.8°F (37.7°C). After cleaning the ambulance, you return to service.

7. How and why do the patient's vital signs differ from your initial readings?

YOU are the Provider — SUMMARY

1. What observations should you make when you arrive at the scene before making physical contact with the patient?

When arriving at any scene, your first priority is to assess for any actual or potential hazards that could pose a risk to your safety and your partner's. Remember to use standard precautions before making contact with the patient! Next, assess the environment in which the patient is found. As you approach the patient, form a general impression that will help you rapidly recognize life-threatening conditions before making physical contact with the patient. Apparent unconsciousness, obvious external bleeding, and severe difficulty breathing are but a few of the visual clues that you may recognize during the initial general impression. After visually assessing the scene, the patient's environment, and the patient, proceed with the primary assessment.

2. On the basis of your general impression and primary assessment findings, does this patient require immediate transport?

Your patient is clearly sick; he has a high fever and reports weakness. However, he is conscious and alert and does not have any airway, breathing, or circulation problems. His heart rate and respiratory rate are both increased; however, his heart rate is strong and palpable at the radial artery, and his breathing is producing adequate tidal volume. Tachypnea and tachycardia are common physiologic responses to fever. At the present time, there are no signs indicating the need for immediate transport.

3. How should you proceed with your care of the patient?

You have already determined the patient's chief complaint and have begun initial treatment. Because his condition is stable, immediate transport is not indicated; therefore, proceed by inquiring about the history of his present illness, taking his vital signs, obtaining a SAMPLE history, and performing a secondary assessment. The secondary assessment of a medical patient should primarily focus on his or her chief complaint and presenting signs and symptoms. A baseline set of vital signs—including pulse oximetry, and if indicated, a blood glucose level—are often obtained by your partner while you are assessing the patient. The baseline vital signs can then be compared with future readings (trending) to determine if the patient's condition is unchanged, has improved, or has worsened.

4. Is it appropriate to transport the patient to the hospital he requested, or should you transport him to the closer facility?

Generally speaking, patients should be transported to the hospital of their choice when at all possible. Ultimately, however, the destination facility should be dictated by the patient's condition as well as local protocols and medical direction. Your patient is in stable condition—that is, he has no airway, breathing, or circulation problems. Therefore, it is not unreasonable to comply with his request and transport him to the hospital of his choice. However, you should inform him that if his condition worsens, it may be necessary to divert to a closer facility. If his wife will be following you in her personal vehicle, ask for her mobile phone number, if she has one, so you can contact her should diversion to a closer facility become necessary.

5. Should you set the vital sign device to reassess his vital signs at shorter intervals? Why or why not?

On the basis of your patient's stable condition, reassessing his vital signs every 15 minutes is appropriate at this time. If his condition worsens, you can always set the machine to record his vital signs at shorter intervals. Vital signs are only one component of reassessment. You should also monitor the patient's level of consciousness and other parameters (eg, skin condition and temperature, breathing status, pulse regularity and strength) en route. In many cases, these parameters change when a patient's condition is deteriorating before the vital signs change.

6. On the basis of the patient's chief complaint, what additional information can you obtain by using the OPQRST mnemonic?

Not every component of the OPQRST mnemonic will apply to every patient; however, there are some components that will. Your patient's chief complaint was fever, chills, and weakness. An acute onset of fever versus fever that developed slowly is important to note and can aid the ED physician in his or her diagnosis. The presence of provoking or palliating factors can also be established. In a patient with a fever, ask him or her if any antipyretics (fever-reducing medications), such as ibuprofen or acetaminophen, were taken and if they seemed to help, and if there is a particular position that improves or worsens his symptoms. Because the patient is not reporting pain or discomfort, there is no "quality" to determine; however, if the patient begins to report pain or discomfort, ask him to describe it. Radiating or referred pain cannot be established in this patient because he is not experiencing pain, but if pain is involved, ask the patient to assign it a number initially and then ask again at regular intervals. When establishing the time of onset, you are asking for a specific time that the symptoms began (eg, yesterday around 1500 hours.

7. How and why do the patient's vital signs differ from your initial readings?

The patient's blood pressure has remained consistent throughout your encounter with him. However, his heart rate, respiratory rate, and skin condition are different from previous readings.

His chief complaint was fever, chills, and weakness. Fever usually causes chills, which cause the patient to expend a lot of energy and can make him or her feel weak. Fever also increases a person's metabolic rate, resulting in the production of more heat energy. Physiologically, the body responds to an increased metabolic rate by increasing its vital functions—namely, respirations and heart rate. Thus, when the patient's temperature was 102.6°F (39.2°C), his body was responding with tachypnea and tachycardia. However, as his temperature reduced to 99.8°F (37.7°C), so did his metabolic rate and, thus, his respiratory rate and heart rate.

When a person is actively "running a fever," the skin is typically flushed (red), abnormally warm or hot, and dry. However, as the fever begins to subside, sweating occurs, which is the body's way of removing heat through evaporation.

EMS Patient Care Report (PCR)

Date: 7-29-16	**Incident No.:** 011109	**Nature of Call:** Sick person		**Location:** 125 Green Hills Dr	
Dispatched: 1325	**En Route:** 1325	**At Scene:** 1335	**Transport:** 1348	**At Hospital:** 1402	**In Service:** 1413

Patient Information

Age: 36 **Sex:** M **Weight (in kg [lb]):** 79 kg (175 lb)	**Allergies:** No known allergies **Medications:** Ibuprofen **Past Medical History:** None **Chief Complaint:** Fever, chills, and weakness

Narrative

9-1-1 dispatch for a 36-year-old man with fever and chills. On arrival at the scene, found the patient in a semi-sitting position in his bed. He was conscious and alert, his airway was patent, and his breathing was adequate. Patient stated that he began feeling bad the day before and began running a fever last night. He also reported chills and weakness, but denied any other symptoms. Approximately 30 minutes prior to EMS arrival, patient took 400 mg of ibuprofen. His wife took his temperature just prior to EMS arrival and noted a reading of 102.6°F (39.2°C). Obtained vital signs and performed additional assessment. Patient's skin was noted to be flushed, hot, and dry. His breath sounds were clear to auscultation bilaterally and he denied a cough. He further denied any significant past medical history and stated no allergies to medications. Completed assessment and treatment at the scene and began transport to the hospital with the patient in position of comfort. En route, continued to monitor patient's condition and vital signs as indicated. He remained conscious and alert, and his vital signs improved; he was less tachypneic and tachycardic. Patient stated that he felt better but was very thirsty. At this point, it was also noticed that patient began to sweat and his skin was less flushed. Remainder of transport was uneventful. Reassessed vital signs shortly before arrival at the hospital. Delivered patient to emergency department without incident and gave verbal report to staff nurse. Upon arrival, receiving nurse reassessed his temperature; a reading of 99.8°F (37.7°C) was noted. Medic 14 returned to service at 1413.**End of report**

Prep Kit

Ready for Review

- Trauma emergencies are injuries that are the result of physical forces applied to the body. Medical emergencies require EMS attention because of illnesses or conditions not caused by an outside force.
- The assessment of a medical patient is similar to the assessment of a trauma patient but with a different focus. Whereas a trauma assessment focuses on physical injuries, most of which are visible through a physical examination, medical patient assessment is usually more focused on symptoms and depends more on establishing an accurate medical history.
- Many medical patients may not appear to be seriously ill at first glance.
- For conscious medical patients, obtaining a thorough patient history can be one of the most beneficial aspects of the patient assessment. Try to determine the nature of the illness by asking questions about the patient's chief complaint.
- Conscious medical patients seldom need a secondary assessment of the entire body, but all should get a detailed physical examination based on their chief complaint. On the other hand, you should always perform a secondary assessment of the entire body on unconscious patients; this head-to-toe assessment may give you clues to help identify the problem. Your secondary assessment of an unconscious or unstable patient should never delay transport.
- Most medical emergencies require a level of treatment beyond what is available in the prehospital setting. Also, the treatments depend on an accurate diagnosis of the exact medical condition; therefore, advanced testing in the hospital may be required.
- If the patient is not in critical condition, you should gather as much important information as possible from the scene so that you can transmit that information to the physician at the ED.
- Many medical emergency patients do not have immediate life-threatening conditions. If a life-threatening condition exists, transportation should include the use of lights and sirens, but if that is not the case, careful consideration should be given to nonemergency transport.
- Modes of transport ultimately come in one of two categories: ground or air.
- Many medical patients will benefit from being transported to a specific hospital capable of handling their particular condition.
- Because it is often impossible to tell which patients have infectious diseases, you should avoid direct contact with the blood and body fluids of all patients.
- If you think you may have been exposed to an infectious disease, see your physician (or your employer's designated physician) immediately.
- Seven infectious diseases of special concern are:
  - Influenza
  - HIV infection
  - Hepatitis
  - Meningitis
  - Tuberculosis
  - MERS-CoV
  - Ebola
- Infection control should be an important part of your daily routine. Be sure to follow the proper steps when dealing with potential exposure situations.
- Patients who recently traveled outside of the United States should be screened for possible infectious illnesses. If you suspect the patient has a travel-related illness, place a mask on him or her, follow appropriate PPE, and gather as much information as possible.

Vital Vocabulary

communicable disease A disease that can be spread from one person or species to another.

epidemic Occurs when new cases of a disease in a human population substantially exceed the number expected based on recent experience.

herpes simplex A common virus that is asymptomatic in 80% of people carrying it, but characterized by small blisters on the lips or genitals in symptomatic infections.

index of suspicion Awareness that unseen life-threatening injuries or illness may exist.

infectious disease A medical condition caused by the growth and spread of small, harmful organisms within the body.

influenza A virus that has crossed the animal/ human barrier and infected humans and that kills thousands of people every year.

medical emergencies Emergencies that are not caused by an outside force; illnesses or conditions.

meningitis An inflammation of the meningeal coverings of the brain and spinal cord; it is usually caused by a virus or a bacterium.

meningococcal meningitis An inflammation of the meningeal coverings of the brain and spinal cord; can be highly contagious.

methicillin-resistant *Staphylococcus aureus* (MRSA) A bacterium that can cause infections in different parts of the body and is often resistant to commonly used antibiotics; it is transmitted by different routes, including the respiratory route, and can be found on the skin, in surgical wounds, in the bloodstream, lungs, and urinary tract.

nature of illness (NOI) The general type of illness a patient is experiencing.

pandemic An outbreak that occurs on a global scale.

trauma emergencies Emergencies that are the result of physical forces applied to the body; injuries.

tuberculosis A chronic bacterial disease, caused by Mycobacterium tuberculosis, that usually affects the lungs but can also affect other organs such as the brain and kidneys; it is spread by cough and can lie dormant in a person's lungs for decades and then reactivate.

virulence The strength or ability of a pathogen to produce disease.

Assessment *in Action*

You are dispatched to a local residence for a 70-year-old man reporting difficulty breathing. On arrival, you find the patient sitting in the living room on home oxygen. As you approach the patient, you notice he appears to be in respiratory distress and is using accessory muscles to help with breathing. He is unable to speak due to his difficulty breathing. His wife informs you that the patient has been ill for the past 2 days with a cough and increasing shortness of breath. He has a past medical history of chronic obstructive pulmonary disease (COPD), hypertension, and diabetes.

1. What is the first step in the assessment process for this patient?

   A. Manage the airway
   B. Obtain vital signs
   C. Determine scene safety
   D. Perform a secondary assessment

2. What is the general impression of this patient?

   A. The patient is experiencing mild dyspnea.
   B. The patient appears stable.
   C. The patient appears well.
   D. The patient needs immediate intervention.

3. Your transport decision should be based on the:

   A. secondary assessment.
   B. past medical history.
   C. physical examination.
   D. primary assessment.

4. What mnemonic is used to gather a patient's health information?

   A. AVPU
   B. SAMPLE
   C. OPQRST
   D. DUMBELS

5. After you assess the ABCs, what should be done for this patient?

   A. Transport
   B. Secondary assessment
   C. Vital signs
   D. Reassessment

6. What standard precautions should be taken with this patient?

   A. Gloves only
   B. Gloves and mask
   C. Gloves, mask, and eye protection
   D. Mask only

7. Which of the following best describes a communicable disease?

   A. The growth and spread of small harmful organisms within the body
   B. A disease that can be spread from one person or species to another
   C. A disease that cannot be transmitted from one person to another
   D. Presence of infectious organisms on or in objects

8. If this patient recently traveled outside of the country, what questions would you ask him?

9. List the seven infectious diseases of concern for EMS personnel.

10. The acronym TACOS can be helpful in determining factors that may be contributing to the chief complaint. What does each letter of this acronym represent?

CHAPTER 15

Respiratory Emergencies

EMS Education Standard Competencies

Medicine

Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

Respiratory

Anatomy, signs, symptoms, and management of respiratory emergencies including those that affect the

› Upper airway (pp 585–593, 609–615)
› Lower airway (pp 585–593, 609–615)

Anatomy, physiology, pathophysiology, assessment, and management of

› Epiglottitis (pp 591, 602–609, 615)
› Spontaneous pneumothorax (pp 599, 602–609, 616–617)
› Pulmonary edema (pp 593–594, 602–609, 615–616)
› Asthma (pp 595, 597, 602–609, 616)
› Chronic obstructive pulmonary disease (pp 594–596, 602–609, 616)
› Environmental/industrial exposure (pp 601–609, 617)
› Toxic gas (pp 601–609, 617)
› Pertussis (pp 592–593, 602–609, 615)
› Cystic fibrosis (pp 602–609, 618–619)
› Pulmonary embolism (pp 600–609, 617)
› Pneumonia (pp 592, 602–609, 615)
› Viral respiratory infections (pp 590–593, 602–609, 615)

Knowledge Objectives

1. List the structures and functions of the upper and lower airways, lungs, and accessory structures of the respiratory

system. (p 585)
2. Explain the physiology of respiration; include the signs of normal breathing. (pp 586–587)
3. Discuss the pathophysiology of respiration, including examples of the common signs and symptoms a patient with inadequate breathing may present with in an emergency situation. (pp 587–588)
4. Explain the special patient assessment and care considerations that are required for geriatric patients who are experiencing respiratory distress. (pp 589, 592–593, 618–619)
5. Describe different respiratory conditions that cause dyspnea, including their causes, assessment findings and symptoms, complications, and specific prehospital management and transport decisions. (pp 589–590, 609–619)
6. List the characteristics of infectious diseases that are frequently associated with dyspnea. (pp 590–593)
7. Discuss some pandemic considerations related to the spread of influenza type A and strategies EMTs should employ to protect themselves from infection during a possible crisis situation. (pp 590, 593)
8. Explain the special patient assessment and care considerations that are required for pediatric patients who are experiencing respiratory distress. (pp 590–593, 597, 615–619)
9. Describe the assessment of a patient who is in respiratory distress and the relationship of the assessment findings to patient management and transport decisions. (pp 602–609)
10. Describe the primary emergency medical care of a person who is in respiratory distress. (pp 602–605, 609–615)
11. List five different types of adventitious breath sounds, their signs and symptoms, and the disease process associated with each one. (p 605)
12. State the generic name, medication forms, dose, administration, indications, actions, and contraindications for medications that are administered via metered-dose inhalers (MDI) and small-volume nebulizers. (pp 610–615)

Skills Objectives

1. Demonstrate the process of history taking to obtain more information related to a patient's chief complaint based on a case scenario. (pp 605–607)
2. Demonstrate how to use the OPQRST assessment to obtain more specific information about a patient's breathing problem. (p 606)
3. Demonstrate how to use the PASTE assessment to obtain more specific information about a patient's breathing problem. (p 607)
4. Demonstrate how to assist a patient with the administration of a metered-dose inhaler. (pp 612–613, Skill Drill 15-1)
5. Demonstrate how to assist a patient with the administration of a small-volume nebulizer. (pp 613–615, Skill Drill 15-2)

Introduction

As an EMT, you will often encounter the patient complaint of **dyspnea**, when a patient reports shortness of breath or has difficulty breathing. It is a symptom of many different conditions, from the common cold or asthma to heart failure and pulmonary embolism. You may not be able to determine what is causing dyspnea in a particular patient; this can be difficult even for physicians. Also, several different problems may be contributing to a patient's dyspnea at the same time, including some that are life threatening. Even without making a definitive diagnosis, you will often be able to improve the patient's symptoms or save the patient's life.

This chapter begins with a basic review of respiratory anatomy and physiology as defined more thoroughly in Chapter 10, *Airway Management*. It then looks at common medical problems that can impair normal respiratory functioning and cause dyspnea. This chapter then goes on to explain specific strategies you can use to assess a patient who has difficulty breathing, using the patient assessment template and organized approach established in Chapter 9, *Patient Assessment*. You will learn the signs and symptoms of each condition, and topics such as foreign body and anatomic airway obstruction, lung infections, and chronic airway disease. You should keep all these medical possibilities in mind as you obtain the patient's history and perform a physical assessment; these processes will be described in detail in this chapter. The information you collect will help you to decide on the proper treatment, which can differ according to the probable cause of the dyspnea.

Remember, the sensation of not getting enough air can be terrifying, regardless of its cause. As an EMT, you should be prepared to fully treat your patient, addressing not just the symptom and the underlying problem, but also the anxiety it produces.

Anatomy of the Respiratory System

The respiratory system consists of the structures of the body that contribute to the breathing process **Figure 15-1**. These structures include the diaphragm, the muscles of the chest wall, the accessory muscles of breathing, and the nerves from the brain and spinal cord to those muscles.

The upper airway consists of all anatomic airway structures above the level of the vocal cords. These include the nose, mouth, jaw, oral cavity, pharynx, and larynx. Air enters the upper airway through the nose and mouth, and it is here that the air is filtered, warmed, and humidified. The upper airway ends at the larynx, which is protected by the epiglottis. This leaf-shaped valve folds over the larynx during swallowing and diverts food and fluid into the esophagus. During normal breathing, the epiglottis returns to an upright position, allowing air to flow freely between the vocal cords into and out of the trachea. Air moves through the trachea into and out of the lungs.

The principal function of the lungs is **respiration**, which is the exchange of oxygen and carbon dioxide. To reach the lower airways, air travels through the trachea into each lung, first passing through the left and right mainstem bronchus (larger airways), then on to the bronchioles (smaller airways), and finally into the alveoli. The alveoli are microscopic, thin-walled air sacs where the actual exchange of oxygen and carbon dioxide occurs.

YOU are the Provider — PART 1

It is 0430 hours when the alert tones sound, “Medic 81, respond to 109 East Lawler for a 72-year-old woman with shortness of breath.” You recognize the address as one to which you have responded on numerous occasions. The woman lives alone; has emphysema, hypertension, and gout; and routinely refuses EMS transport. You and your partner proceed to the scene. The weather is clear, and the temperature is 65°F (18.3°C).

1. What is emphysema? What is the typical cause?
2. Why is it especially significant that *this* patient called 9-1-1?

Physiology of Respiration

As discussed in Chapter 10, *Airway Management*, the two processes that occur during respiration are inspiration, the act of breathing in (inhaling), and expiration, the act of breathing out (exhaling). During respiration, oxygen is provided to the blood, and carbon dioxide is removed from it. In healthy lungs, this exchange of gases takes place rapidly at the level of the alveoli **Figure 15-2**. The alveoli lie against the pulmonary capillary vessels, and as oxygen enters the alveoli from inhalation, it passes freely through tiny passages in the alveolar wall into these capillaries through the process of diffusion. The oxygen is then carried to the heart, which then pumps the oxygen around the body. Carbon dioxide produced by the body’s cells returns to the lungs in the blood that circulates through and around the alveolar air spaces. The carbon dioxide diffuses back into the alveoli and travels back up the bronchial tree and out through the upper airways during exhalation **Figure 15-3**. Again, carbon dioxide is “exchanged” for oxygen, which travels in exactly the opposite direction (during inhalation).

Through this whole process of respiration, the brain stem constantly senses the level of carbon dioxide in the arterial blood. The level of carbon dioxide bathing the brain stem stimulates a healthy person to breathe. If the level of carbon dioxide drops too low, the person automatically breathes at a slower rate and less deeply. As a result, less carbon dioxide is expired, allowing carbon dioxide levels in the blood to return to normal. Although considered a waste gas, some level of carbon dioxide in the blood is actually necessary and, in addition to stimulating breathing, helps balance pH. If the level of carbon dioxide in the arterial blood rises above normal, the person breathes more rapidly and more deeply. When more fresh air is brought into the alveoli, more carbon dioxide diffuses out of the bloodstream, thereby lowering the level of carbon dioxide in the blood.

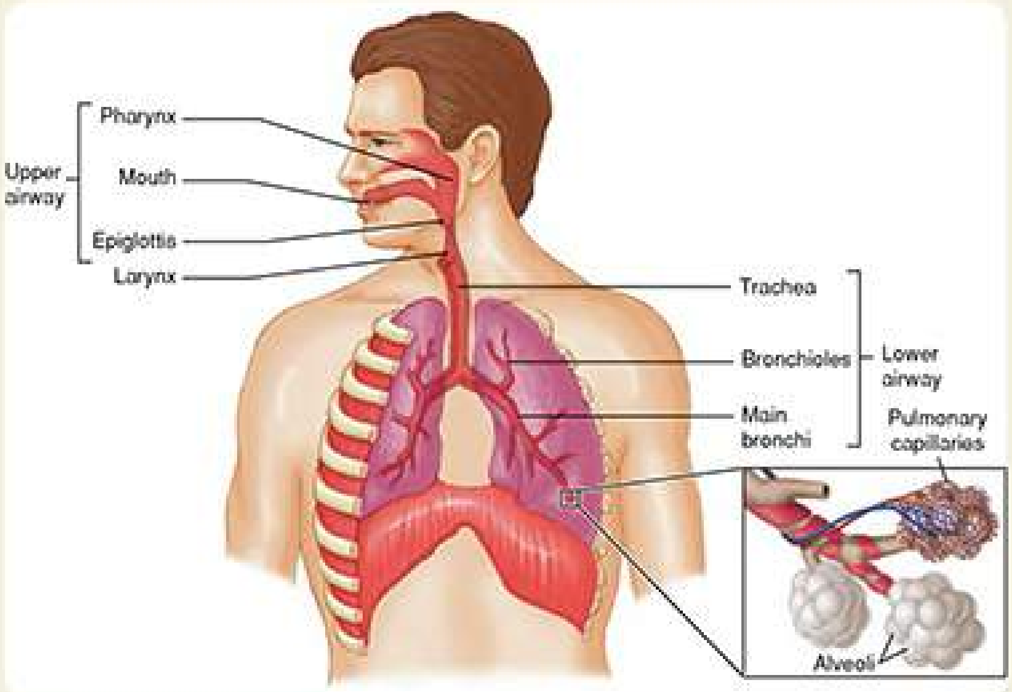

Figure 15-1 The upper airway includes the nose, mouth, jaw, oral cavity, pharynx, and larynx. The lower airway includes the trachea, bronchi, bronchioles, and alveoli surrounded by the pulmonary capillaries.

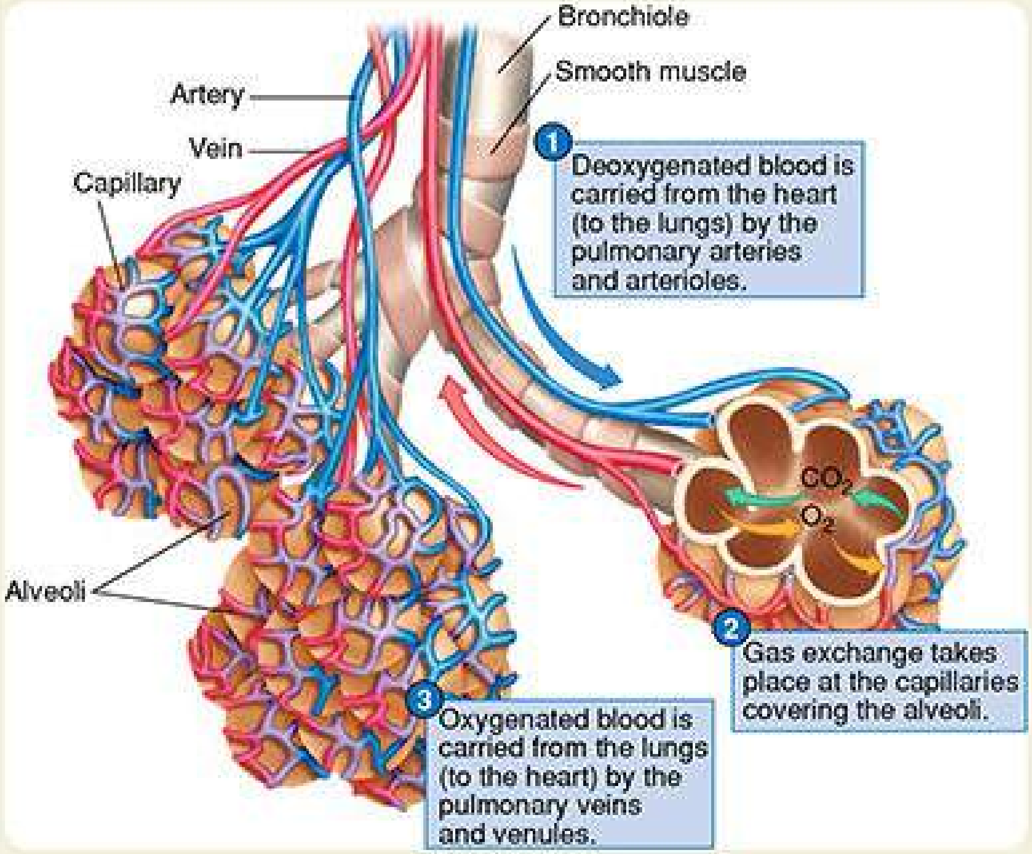

Figure 15-2 An enlarged view of a single alveolus (air sac) showing where the exchange of oxygen and carbon dioxide between air in the sac and blood in the pulmonary capillaries takes place.

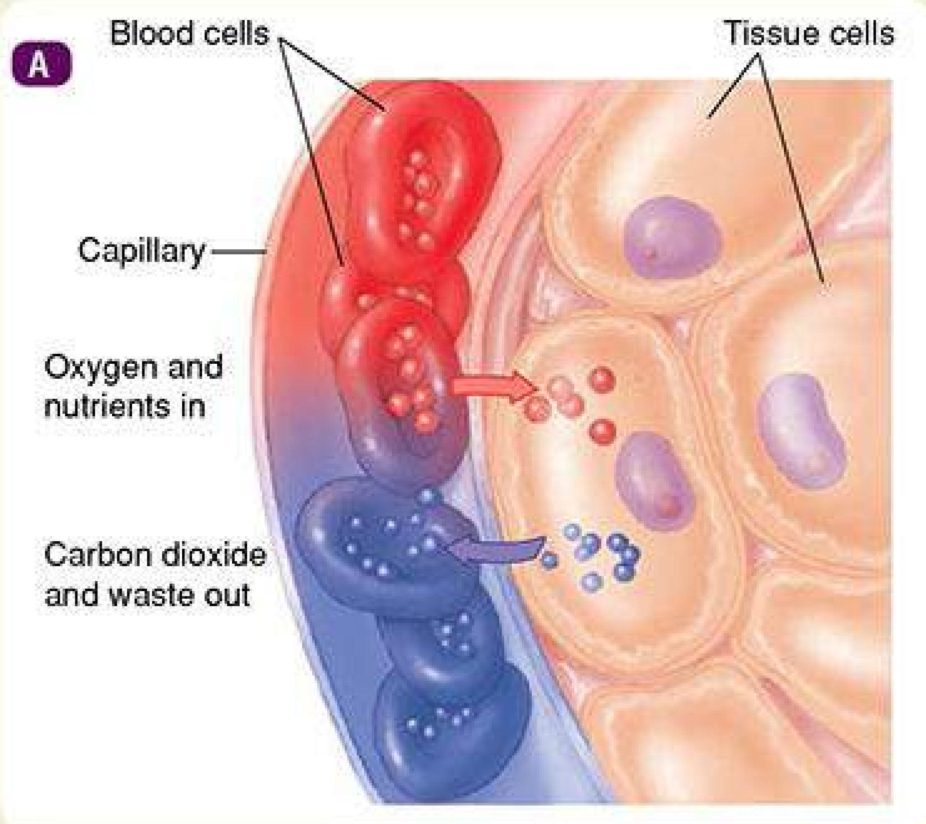

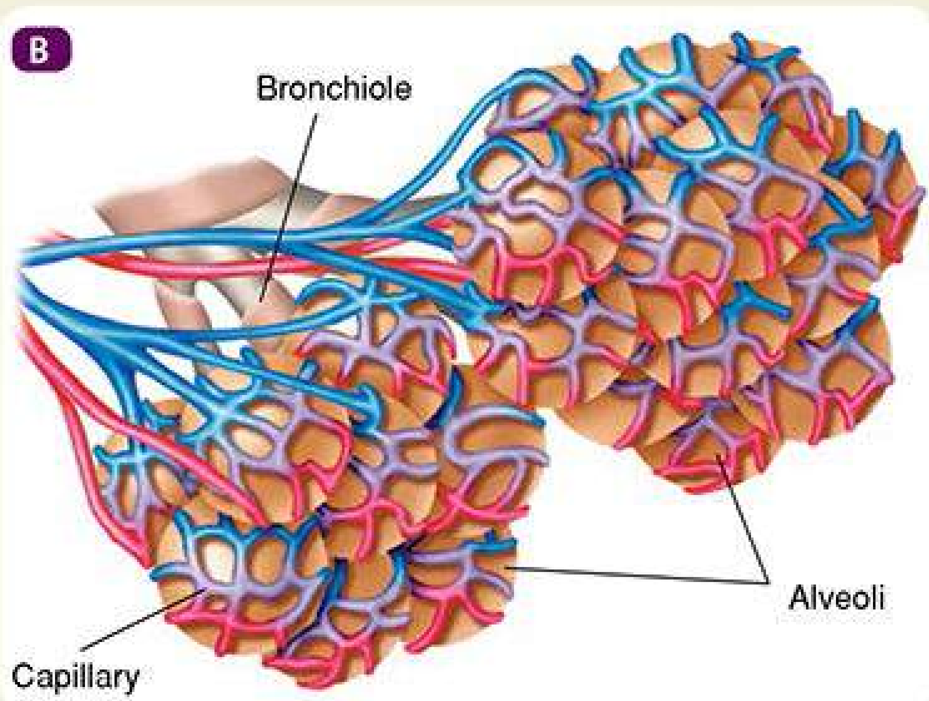

Figure 15-3 The exchange of oxygen and carbon dioxide in respiration. **A.** Oxygen passes from the blood through capillaries to tissue cells. Carbon dioxide passes from tissue cells through capillaries to the blood. **B.** In the lungs, oxygen is picked up by the blood, and carbon dioxide is given off.

Pathophysiology

The pathophysiology of respiration refers to conditions under which body processes are not working as they should and, as a result, interfere with normal respiration. Abnormal or pathologic conditions in the anatomy of the airway, disease processes, and traumatic conditions can prevent the proper exchange of oxygen and carbon dioxide. In addition, the pulmonary blood vessels themselves may have abnormalities that interfere with blood flow and thus with the transfer of gases.

Regardless of the reason for breathing difficulty, it is important that you are able to immediately recognize the signs and symptoms of inadequate breathing and know what to do about it. Table 15-1 gives the signs of normal (adequate) breathing, which is measured by rate, rhythm, and quality.

Table 15-2 lists the clues that will help you determine if your patient is having difficulty breathing.

Table 15-3 provides key signs and symptoms to help you recognize and differentiate between various respiratory-related complaints.

Carbon Dioxide Retention and Hypoxic Drive

You will sometimes encounter patients who have an elevated level of carbon dioxide in their arterial blood. The level can rise for a number of reasons. The exhalation process may be impaired by various types of lung disease. The body may also produce too much carbon dioxide, either temporarily or chronically, depending on the disease or abnormality. If, for a period of years, arterial carbon dioxide levels rise to an abnormally high level and remain there, the respiratory centers in the brain, which sense the carbon dioxide level and control breathing, may work less efficiently.

The failure of these centers to respond normally to a rise in arterial levels of carbon dioxide is due to chronic **carbon dioxide retention**. Recall from Chapter 10, *Airway Management,* that normally, the brain senses the levels of carbon dioxide (based on the pH) in the blood and cerebrospinal fluid. When carbon dioxide levels become elevated, the respiratory centers in the brain adjust the rate and depth of **ventilation** accordingly. However, patients with chronic lung diseases have difficulty eliminating carbon dioxide through exhalation; thus, they always have higher levels of carbon dioxide. This condition potentially alters their drive for breathing. The theory is that the brain gradually accommodates high levels of carbon dioxide and then uses a "backup system" to control breathing based on low levels of oxygen, rather than high levels of carbon dioxide. This condition is called **hypoxic drive**.

Table 15-1 Signs of Normal Breathing

- A normal rate (adult: 12 to 20 breaths/min; child: 15 to 30 breaths/min; infant: 25 to 50 breaths/min)
- A regular pattern of inhalation and exhalation
- Clear and equal breath sounds on both sides of the chest
- Regular and equal chest rise (chest expansion) and fall
- Adequate depth (tidal volume)
- Unlabored; without adventitious (abnormal) breath sounds (wheezing, stridor)

Note: Respiratory ranges are per the NHTSA 2009 EMT National EMS Education Standards. Ranges presented in other sources may vary.

Table 15-2 Signs and Symptoms of Inadequate Breathing

- The patient reports difficulty breathing or shortness of breath.
- The patient has an altered mental status associated with shallow or slow breathing.
- The adult patient appears anxious or restless; the pediatric patient appears sleepy or listless.
- The respiratory rate is too fast or too slow (see Table 15-1).
- The breathing rhythm is irregular.
- The skin is pale, cool, clammy, or cyanotic.
- Adventitious breath sounds are heard, including wheezing, gurgling, snoring, crowing, or stridor (harsh, high-pitched, barking sounds).
- Decreased or noisy breath sounds are heard on one or both sides of the chest.
- The patient cannot speak more than few words between breaths. Ask the patient "How are you doing?" If the patient cannot speak at all, he or she most likely has a respiratory emergency.
- You observe accessory muscle use, retractions, or labored breathing.
- The patient has unequal or inadequate chest expansion.
- The patient is coughing excessively.
- The patient is sitting up, leaning forward with his or her palms flat on the bed or the arms of the chair. This is called the tripod position because the patient's back and both arms are working together to support the upper body.
- The patient has pursed lips (pursed lip breathing) or nasal flaring.

Table 15-3 Signs and Symptoms Seen in Various Respiratory Conditions

Condition	Signs and Symptoms
Asthma	▪ Wheezing on inspiration/expiration ▪ Bronchospasm
Anaphylaxis	▪ Flushed skin or hives (urticaria) ▪ Generalized edema ▪ Decreased blood pressure (hypotension) ▪ Laryngeal edema with dyspnea ▪ Wheezing or stridor
Bronchiolitis	▪ Shortness of breath ▪ Wheezing ▪ Coughing ▪ Fever ▪ Dehydration ▪ Tachypnea ▪ Tachycardia
Bronchitis	▪ Chronic cough (with sputum production) ▪ Wheezing ▪ Cyanosis ▪ Tachypnea (increased breathing rate)
Congestive heart failure	▪ Dependent edema ▪ Crackles (pulmonary edema) ▪ Orthopnea ▪ Paroxysmal nocturnal dyspnea
Common cold	▪ Cough ▪ Runny or stuffy nose ▪ Sore throat
Croup	▪ Fever ▪ Barking cough ▪ Stridor ▪ Mostly seen in pediatric patients
Diphtheria	▪ Difficulty breathing and swallowing ▪ Sore throat ▪ Thick, gray buildup in throat or nose ▪ Fever
Emphysema	▪ Barrel chest ▪ Pursed lip breathing ▪ Dyspnea on exertion ▪ Cyanosis ▪ Wheezing/decreased breath sounds
Epiglottitis	▪ Dyspnea ▪ High fever ▪ Stridor ▪ Drooling ▪ Difficulty swallowing ▪ Severe sore throat ▪ Tripod or sniffing position

Influenza type A (flu)	▪ Cough ▪ Fever ▪ Sore throat ▪ Fatigue
Pertussis (whooping cough)	▪ Coughing spells ▪ "Whooping" sound ▪ Fever
Pneumonia	▪ Dyspnea ▪ Chills, fever ▪ Cough ▪ Green, red, or rust-colored sputum ▪ Localized wheezing or crackles
Pneumothorax	▪ Sudden chest pain with dyspnea ▪ Decreased breath sounds (affected side) ▪ Subcutaneous emphysema
Pulmonary embolus	▪ Sharp chest pain ▪ Sudden onset ▪ Dyspnea ▪ Tachycardia ▪ Clear breath sounds initially
Tension pneumothorax	▪ Severe shortness of breath ▪ Decreased/altered level of consciousness ▪ Neck vein distention ▪ Tracheal deviation (late sign) ▪ Hypotension; signs of shock (late sign)
Respiratory syncytial virus (RSV)	▪ Cough ▪ Wheezing ▪ Fever ▪ Dehydration
Tuberculosis (TB)	▪ Cough ▪ Fever ▪ Fatigue ▪ Productive/bloody sputum

Hypoxic drive is frequently found in end-stage chronic obstructive pulmonary disease (COPD). Some experts advocate for withholding high concentrations of oxygen from patients with chronic lung diseases for fear that the increased oxygen level in the blood could depress, or completely stop, the patient's respiratory drive. Regardless of the current research, use caution when providing high concentrations of oxygen on a long-term basis to patients with chronic lung disease, but *never* withhold oxygen therapy from a patient who needs it. Closely monitor patients who are experiencing respiratory distress, and be prepared to assist with ventilations if needed.

Special Populations

As a result of the normal aging process, geriatric patients have greater difficulties with the exchange of carbon dioxide and oxygen. In respiratory emergencies, begin oxygen therapy early in the assessment and treatment process.

Words of Wisdom

It is important for you to properly ventilate a patient; both underventilation and overventilation can cause harmful alterations in the level of carbon dioxide in the blood. Avoid hyperventilation when performing bag-valve mask (BVM) ventilation during CPR. This is a common pitfall that detracts from the overall quality of CPR and can cause serious alterations in pH, increased intrathoracic pressure, impaired venous return, and hypotension.

Causes of Dyspnea

Many medical problems may cause dyspnea. Be aware that if the patient's problem is severe and the brain is deprived of oxygen, he or she may not be alert enough to report shortness of breath. Altered mental status may be a sign that the brain is dysfunctional because of severe **hypoxia**, a condition in which the body's cells and tissues do not get enough oxygen.

In addition to the conditions discussed in Table 15-3, patients often have breathing difficulty and/or hypoxia with the following medical conditions:

- Pulmonary edema
- Hay fever
- Pleural effusion

- Obstruction of the airway
- Hyperventilation syndrome
- Environmental/industrial exposure
- Carbon monoxide poisoning
- Drug overdose

As you treat patients with disorders of the lung, be aware that one or more of the following situations most likely exists:

- Gas exchange between the alveoli and pulmonary circulation is obstructed by fluid in the lung, infection, or collapsed alveoli (**atelectasis**).
- The alveoli are damaged and cannot transport gases properly across their own walls.
- The air passages are obstructed by muscle spasm, mucus, or weakened airway walls.
- Blood flow to the lungs is obstructed by blood clots.
- The pleural space is filled with air or excess fluid, so the lungs cannot properly expand.

All of these conditions prevent the proper exchange of oxygen and carbon dioxide. In addition, the pulmonary blood vessels themselves may have abnormalities that interfere with blood flow and thus with the transfer of gases.

Besides shortness of breath, a patient with dyspnea may also report the sensation of chest tightness and air hunger. Air hunger is when a person reports the feeling of "not getting enough air" and has a strong need to breathe. Chest tightness is described as an uncomfortable feeling in the chest, and it is commonly reported by patients with asthma.

Dyspnea is also a common complaint in patients with cardiopulmonary diseases. In some cases, it may be caused by physical exertion that has been made difficult because the patient's heart is damaged. Congestive heart failure is a troublesome cause of breathlessness because the heart is not pumping efficiently and, therefore, the body does not have adequate oxygen. Another condition commonly associated with congestive heart failure is pulmonary edema, in which the alveoli are filled with fluid.

Severe pain can cause a patient to experience rapid, shallow breathing without the presence of a primary pulmonary dysfunction. In some patients, breathing deeply causes pain because it causes expansion of the chest wall.

When you assess your patient for complaints of dyspnea, ask about chest pain; conversely, when you are evaluating your patient for chest pain, ask about dyspnea.

Upper or Lower Airway Infection

Infectious diseases causing dyspnea may affect all parts of the airway. Some cause mild discomfort; others require aggressive respiratory support. Infections that impair airflow through the airways are problems of respiration. Inadequate oxygen delivery to the tissues is a problem of **oxygenation**. Infections may cause dyspnea by obstructing airflow in the larger airways due to production of mucus and secretions (colds, diphtheria) or by causing swelling of soft tissues located in the larger, upper airways (epiglottitis, croup). Infections may also impair exchange of gases between the alveoli and the capillaries (pneumonia). In patients with infectious diseases, you will be in close contact, so be diligent about your personal use of appropriate personal protective equipment (PPE). Recall from Chapter 2, *Workforce Safety and Wellness*, that immunizations, protective techniques, and handwashing can dramatically minimize your risk of contracting an infectious disease. Follow your local protocols, and stay up to date on the latest Centers for Disease Control and Prevention (CDC) recommendations. A minimum of gloves, eye protection, and a surgical mask or a high-efficiency air particulate (N-95) respirator should be mandatory. Gowns can be considered in some situations. Place a surgical mask on patients with suspected or confirmed respiratory disease. Remember to completely disinfect your unit prior to returning to service.

The following section discusses some of the infectious diseases that may be associated with complaints of dyspnea.

Croup

Croup is caused by inflammation and swelling of the pharynx, larynx, and trachea **Figure 15-4**. This disease is often secondary to an acute viral infection of the upper respiratory tract and is typically seen in children between ages 6 months and 3 years. It is easily passed between children. Peak seasonal outbreaks of this disease occur in the late fall and during the winter.

The disease starts with a cold, cough, and a low-grade fever that develops over 2 days. The hallmark signs of croup are stridor and a seal-bark cough, which signal a narrowing of the air passage of the trachea that may progress to significant obstruction.

Croup is rarely seen in adults because their breathing passages are larger and can accommodate the inflammation and mucus production without producing symptoms. The airways of adults are wider, and the supporting tissue is firmer than in children.

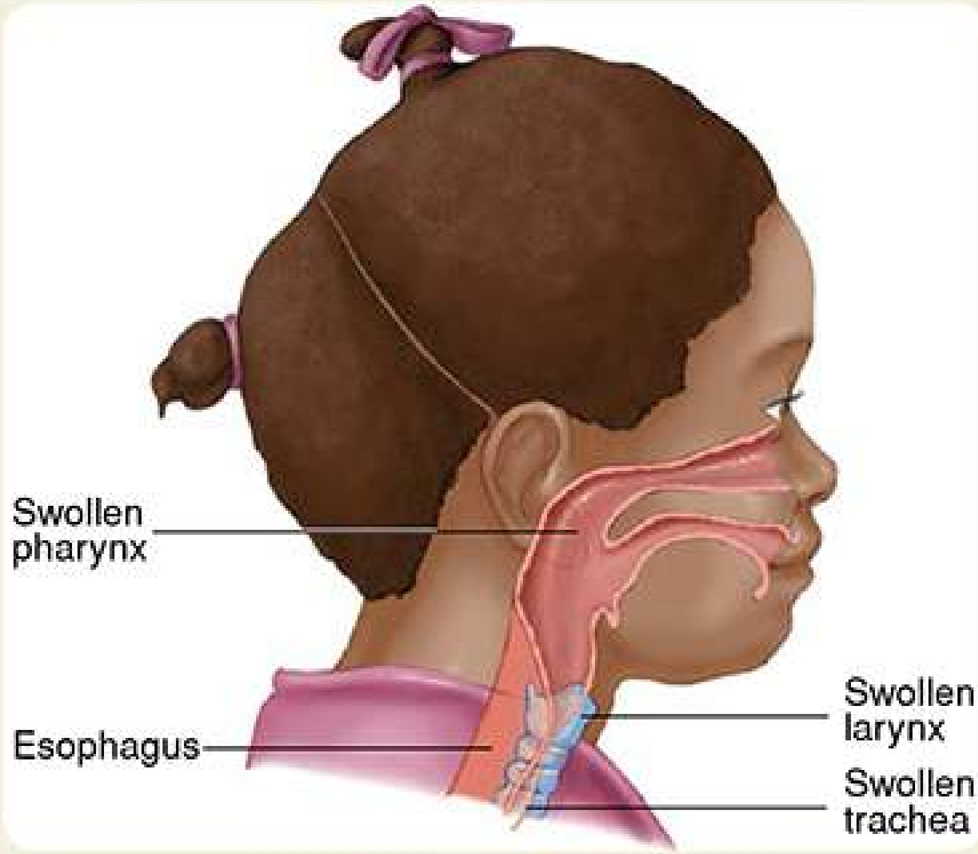

Figure 15-4 Croup results in swelling of the whole airway: pharynx, larynx, and trachea.

Croup often responds well to the administration of humidified oxygen. Note that bronchodilators are not indicated for croup and can worsen a patient's symptoms.

Epiglottitis

Epiglottitis is a life-threatening inflammatory disease of the epiglottis, the small flap of tissue at the back of the throat that protects the larynx and trachea during swallowing. Bacterial infection is the most common cause **Figure 15-5**. In the past, epiglottitis was most often seen in infants and children. In some cases, it occurs in adults. The development of a childhood vaccine against *Haemophilus influenzae* has dramatically decreased the incidence of this disease.

In preschool and school-aged children especially, the epiglottis can swell to two to three times its normal size. This puts the airway at risk of complete obstruction. The condition usually develops in otherwise healthy children, and symptoms are sudden in onset. Children with this infection look ill, report a very sore throat, and have a high fever. They will often be found in the tripod position and drooling. Stridor is a late sign in the development of airway obstruction.

Treat children with suspected epiglottitis gently and try not to do anything that will cause them to cry. Keep them in a position of comfort, and give them high-flow oxygen. *Do not* put anything in their mouths, as this could trigger a complete airway obstruction.

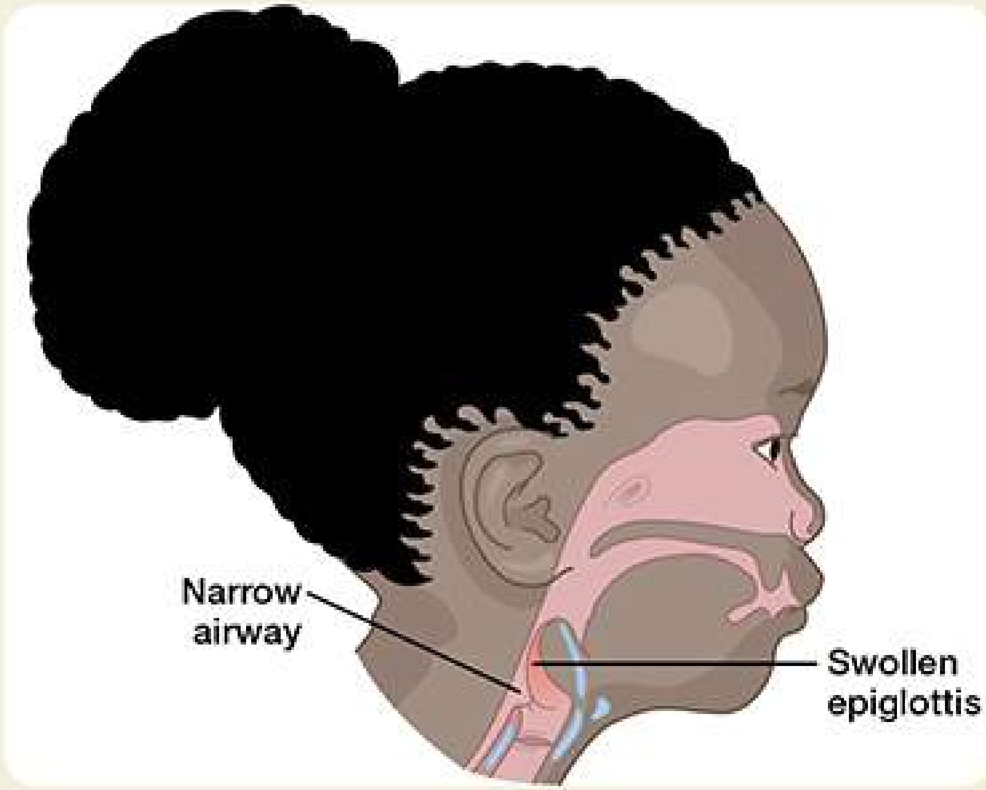

Figure 15-5 Acute epiglottitis is caused by a bacterial infection that results in severe swelling of the epiglottis, which could obstruct the airway.

Deterioration can occur quickly in adults with acute epiglottitis. You should be concerned if your adult patient presents with stridor or any other sign of airway obstruction without an obvious mechanical cause. Focus your patient management on maintaining a patent (adequate) airway, and provide prompt transport to the emergency department (ED).

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is a common cause of illness in young children. It causes an infection in the lungs and breathing passages, and can lead to other serious illnesses such as bronchiolitis and pneumonia, as well as serious heart and lung problems in premature infants and in children who have depressed immune systems.

RSV is highly contagious and can be spread through droplets when the patient coughs or sneezes. The virus can also survive on surfaces, including hands and clothing. Therefore, the infection tends to spread rapidly through schools and child care centers.

When you assess a child with suspected RSV, look for signs of dehydration. Infants with RSV often refuse liquids. Treat airway and breathing problems as appropriate. Humidified oxygen is helpful if available.

Bronchiolitis

Bronchiolitis is a respiratory illness that often occurs due to respiratory syncytial virus (RSV) infection and results in severe inflammation of the bronchioles. Bronchioles, the tiny airways that lead from the larger airways (bronchi) to the alveoli in the lungs, become inflamed, swell, and fill with mucus. It occurs most frequently in newborns and toddlers, especially boys, whose airways can easily become blocked. Infections are common during the winter and spring. Young children who require hospitalization for bronchiolitis are at increased risk for developing childhood asthma.

The treatment for a child suffering from bronchiolitis is mainly supportive. While many of these patients do well, there is still a risk for significant respiratory compromise. You should provide appropriate oxygen therapy and allow the patient to remain in a position of comfort. Reassess frequently for signs of worsening respiratory distress. Be prepared to provide airway management and positive-pressure ventilation should the patient develop respiratory failure.

Pneumonia

According to the World Health Organization, pneumonia is a significant cause of morbidity worldwide. **Pneumonia** is a general term that refers to an infection of the lungs. The infection collects in the surrounding normal lung tissues, impairing the lung's ability to exchange oxygen and carbon dioxide.

Pneumonia is often a secondary infection, meaning it begins after an upper respiratory tract infection such as a cold or sore throat. It can be caused by a virus or bacterium, or by a chemical injury after an accidental ingestion or a direct lung injury from a submersion incident. Interventions such as intubation and tracheostomy can increase the risk of developing pneumonia. Pneumonia commonly affects people who are chronically and terminally ill. The factors that predispose patients to pneumonia include:

- Institutional residence (nursing home or long-term care facilities)
- Recent hospitalization
- Chronic disease processes (such as renal failure requiring dialysis)
- Immune system compromise (patient receiving chemotherapy or diseases such as HIV)
- History of COPD

Symptoms of pneumonia vary, depending on the age of the person and the cause of the illness. Children often present with unusually rapid or labored breathing or breathing characterized by grunting or wheezing sounds. In severe cases where oxygen exchange at the alveoli is markedly impaired, the lips and fingernails may be blue or gray. If the pneumonia is in the lower part of the lungs near the abdomen, there may be fever, abdominal pain, and vomiting rather than dyspnea.

Bacterial pneumonia results in severe symptoms more quickly including high fevers, which put the child at risk for febrile seizures. A viral pneumonia presents more gradually and is less severe.

Other signs and symptoms include dry skin, decreased skin turgor, exertional dyspnea, a productive cough, chest discomfort and pain that vary with inspiration and expiration, headache, nausea and vomiting, musculoskeletal pain, weight loss, and confusion. The patient may be febrile, tachycardic, or even hypotensive. Assessment of the lungs may reveal diminished breath sounds with sounds of wheezing, crackles, or rhonchi. You will need to evaluate the patient's history for possible risk factors. If possible, assess temperature to determine the presence of fever. Pulse oximetry readings, if available, may be low.

Regardless of the cause, treatment includes airway support and providing supplemental oxygen. Use oxygen with appropriate adjuncts, and provide supportive measures if needed. Evaluate patient treatment through reassessment and prepare for possible deterioration in the patient's condition.

Pertussis

Pertussis (whooping cough) is an airborne bacterial infection that primarily affects children younger than 6 years. It is highly contagious and is passed through droplet infection.

A patient with pertussis will be feverish and exhibit a "whoop" sound on inspiration after a coughing attack. Symptoms are generally similar to colds, but coughing spells can last for more than a minute during which the child may turn red or purple. This may frighten the parents or caregivers into calling 9-1-1.

Some infants and younger children with pertussis should be treated in a hospital because they are at greater risk for complications like pneumonia, which occurs mostly in children younger than 1 year. In infants younger than 6 months, pertussis can be life threatening.

Children with pertussis may vomit or not want to eat or drink. Watch for signs of dehydration. You may have to suction thick secretions to clear the airway. Give oxygen by the most appropriate means.

Pertussis in adults does not cause the typical whooping illness that it does in infants and toddlers. However, it can cause a severe upper respiratory infection, which can lead to pneumonia in geriatric patients or people with compromised immune systems. The infection can cause coughing spells that last for weeks and can be so severe that patients find it hard to breathe, eat, or sleep. In the worst cases of infection in geriatric patients, coughing can lead to cracked ribs. For patients who are already weak from other chronic conditions, pertussis can lead to hospitalization. According to the CDC, the disease has become a serious issue and physicians are becoming more aggressive about immunizing adults with the pertussis vaccine.

Influenza Type A

Influenza type A is an animal respiratory disease that has mutated to infect humans. In 2009, the H1N1 strain of influenza type A became **pandemic** (an outbreak that occurred on a global scale). Like seasonal flu, it may make chronic medical conditions worse. All strains of influenza type A are transmitted by direct contact with nasal secretions and aerosolized droplets from coughing and sneezing by infected people. Influenza type A viruses cause fever, cough, sore throat, muscle aches, headache, and fatigue and may lead to pneumonia or dehydration.

Tuberculosis

Tuberculosis (TB) is a bacterial infection caused by *Mycobacterium tuberculosis*. TB spreads by cough and is dangerous because many strains are resistant to antibiotics. TB most commonly affects the lungs but can also be found in almost any organ of the body, particularly the kidneys, spine, and lining of the brain and spinal cord (meninges). In some cases, TB can remain dormant (inactive) for years without causing symptoms or being infectious to other people. However, when the person is in a state of weakened immunity, TB can become active again. The patient may not even be aware he or she has the disease.

Patients with active TB involving the lungs will report fever, coughing, fatigue, night sweats, and weight loss. If the lung infection becomes severe, the patient will experience shortness of breath, coughing, productive sputum, bloody sputum, and chest pain.

TB has a higher prevalence among people who live in close contact, such as prison inmates, nursing home residents, and people in homeless shelters. TB is also found in people who abuse intravenous drugs or alcohol and people whose immune systems are compromised by an infection such as HIV. Anyone who comes into close contact with people who have active TB, or is in contact with people from countries that have a high prevalence of TB, is at risk for contracting the disease. As an EMT, you are also at risk.

If you suspect your patient may have active TB, you need to wear (at a minimum) your gloves, eye protection, and an N-95 respirator. These respirators are fit-tested to the individual to ensure no contaminated air can pass through.

Acute Pulmonary Edema

Sometimes, the heart muscle is so injured after a heart attack or other illness that it cannot circulate blood properly. In these cases, the left side of the heart cannot remove blood from the lung as fast as the right side delivers it. As a result, fluid builds up within the alveoli and in the lung tissue between the alveoli and the pulmonary capillaries. This accumulation of fluid is referred to as **pulmonary edema**, and it is usually a result of congestive heart failure. By physically separating the alveoli from the pulmonary capillary vessels, the edema interferes with the exchange of carbon dioxide and oxygen **Figure 15-6**. Not enough space is left in the lung to allow for slow, deep breaths. High blood pressure and low cardiac output often trigger this "flash" (sudden) pulmonary edema. These patients are among the most sick, frightened, and worrisome patients you will encounter. They are literally drowning in their own fluid. The patient usually experiences dyspnea with rapid, shallow respirations. In the most severe cases, you will see frothy pink sputum at the nose and mouth.

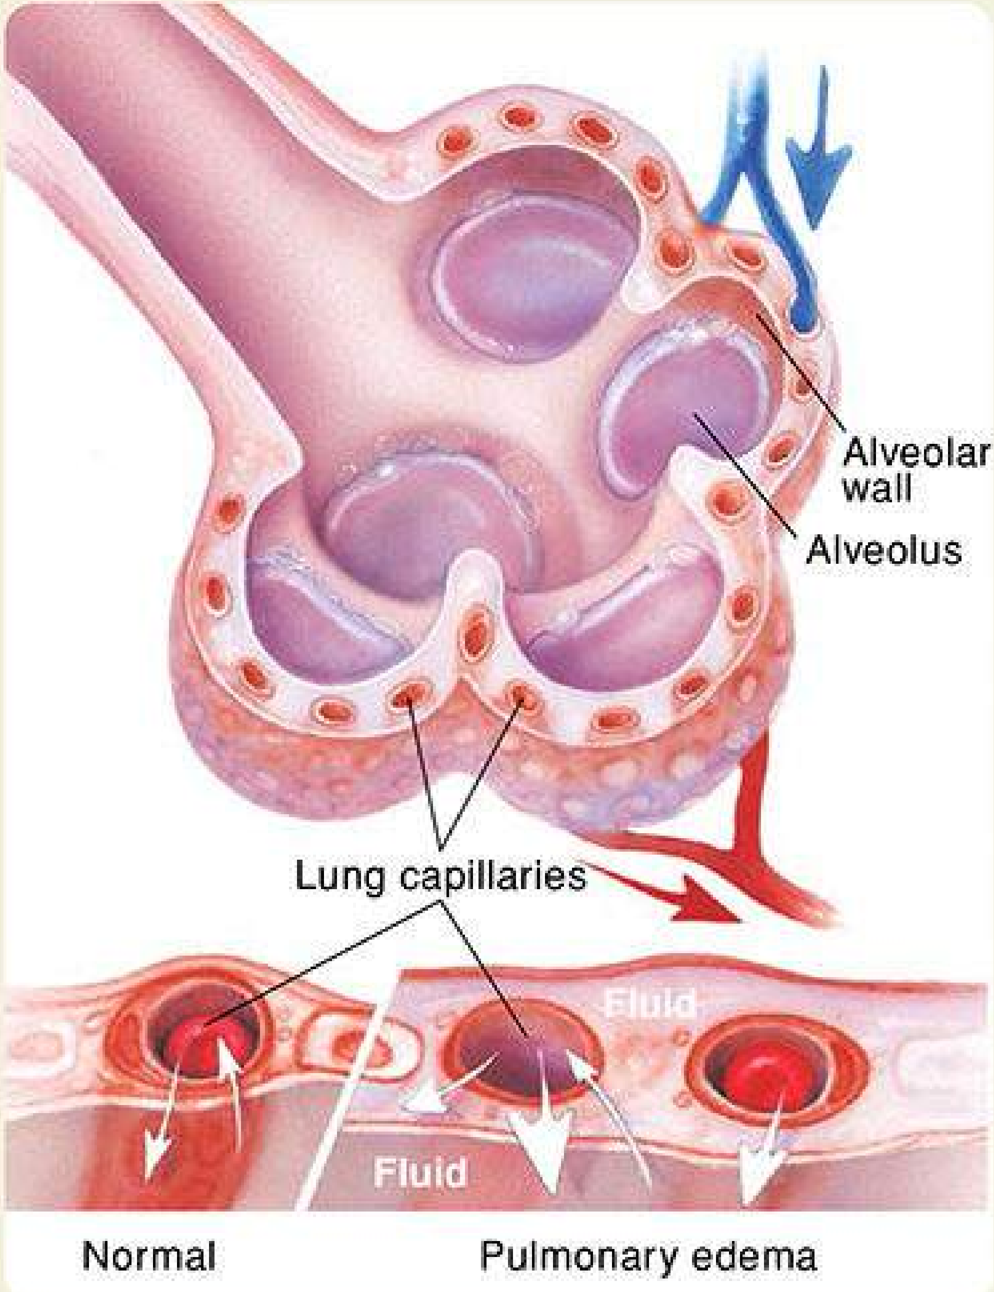

Figure 15-6 In pulmonary edema, fluid fills the alveoli and separates the capillaries from the alveolar wall, interfering with the exchange of oxygen and carbon dioxide.

Patient risk factors for congestive heart failure include hypertension and a history of coronary artery disease and/or atrial fibrillation, a condition in which the atria no longer contract, but instead quiver.

According to the Agency for Healthcare Research and Quality, congestive heart failure (which can lead to pulmonary edema) is one of the most common causes of hospital admission in the United States. It is not uncommon for a patient to have repeated bouts. In most cases, patients have a long-standing history of chronic congestive heart failure that can be kept under control with medication. However, an acute onset may occur if the patient stops taking the medication, eats food that is too salty, or has a stressful illness, a new heart attack, or an abnormal heart rhythm.

However, not all patients with pulmonary edema have heart disease. Poisonings from inhaling large amounts of smoke or toxic chemical fumes can produce pulmonary edema, as can traumatic injuries of the chest and exposure to high altitudes. In these cases, fluid collects in the alveoli and lung tissue in response to damage of the tissues of the lung or the bronchi.

Signs and symptoms of congestive heart failure include difficulty breathing with exertion because the heart cannot keep up with the body's need for oxygen. Patients may also report a sudden attack of respiratory distress that wakes them at night when they are in a reclining position. This is caused by fluid accumulation in the lungs. Patients also report coughing, feeling suffocated, cold sweats, and tachycardia.

In your primary assessment, you might find the patient has cool, diaphoretic, cyanotic skin and you will hear adventitious breath sounds like crackles or wheezing. The patient's pulse will be tachycardic. The patient may have hypertension early, followed by deterioration to hypotension as a late finding.

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is a slow process of dilation and disruption of the airways and alveoli caused by chronic bronchial obstruction. According to the US Department of Health and Human Services, an estimated 12 million people are diagnosed with COPD, and an additional 12 million people may have COPD and not know it. According to the CDC, it is the third leading cause of death in the United States. COPD is an umbrella term used to describe a few lung diseases including emphysema and **chronic bronchitis**, an ongoing irritation of the trachea and bronchi.

COPD may be a result of direct lung and airway damage from repeated infections or inhalation of toxic gases and particles, but most often it results from cigarette smoking. Although it is well known that cigarettes are a direct cause of lung cancer, their role in the development of COPD is far more significant and less publicized.

Tobacco smoke is a bronchial irritant and can create chronic bronchitis. With bronchitis, excess mucus is constantly produced, obstructing small airways and alveoli. Protective cells and lung mechanisms that remove foreign particles are destroyed, further weakening the airways. Chronic oxygenation problems can also lead to right-sided heart failure and fluid retention, such as edema in the legs.

Pneumonia develops easily when the air passages are persistently obstructed. Ultimately, repeated episodes of irritation and pneumonia cause scarring in the lungs and some dilation of the obstructed alveoli, leading to COPD **Figure 15-7**.

The most common form of COPD is **emphysema**. Emphysema is a loss of the elastic material in the lungs that occurs when the alveolar air spaces are chronically stretched due to inflamed airways and obstruction of airflow out of the lungs. Smoking can also directly destroy the elasticity of the lung tissue. Normally, the lungs act like spongy balloons that are inflated; once they are inflated, they will naturally recoil because of their elastic nature, expelling gas rapidly. However, when they are constantly obstructed or when the elasticity is diminished, air is no longer expelled rapidly, and the walls of the alveoli eventually fall apart, leaving large "holes" in the lung that resemble large air pockets or cavities.

Most patients with COPD have elements of both chronic bronchitis and emphysema. Some patients will have more elements of one condition than the other; few patients will have only emphysema or bronchitis. Therefore, most patients with COPD will chronically produce sputum, have a chronic cough, and have difficulty expelling air from their lungs, with long expiration phases and wheezing. Patients may present with adventitious breath sounds such as crackles, rhonchi, and wheezes, or may have severely diminished breath sounds due to poor air movement.

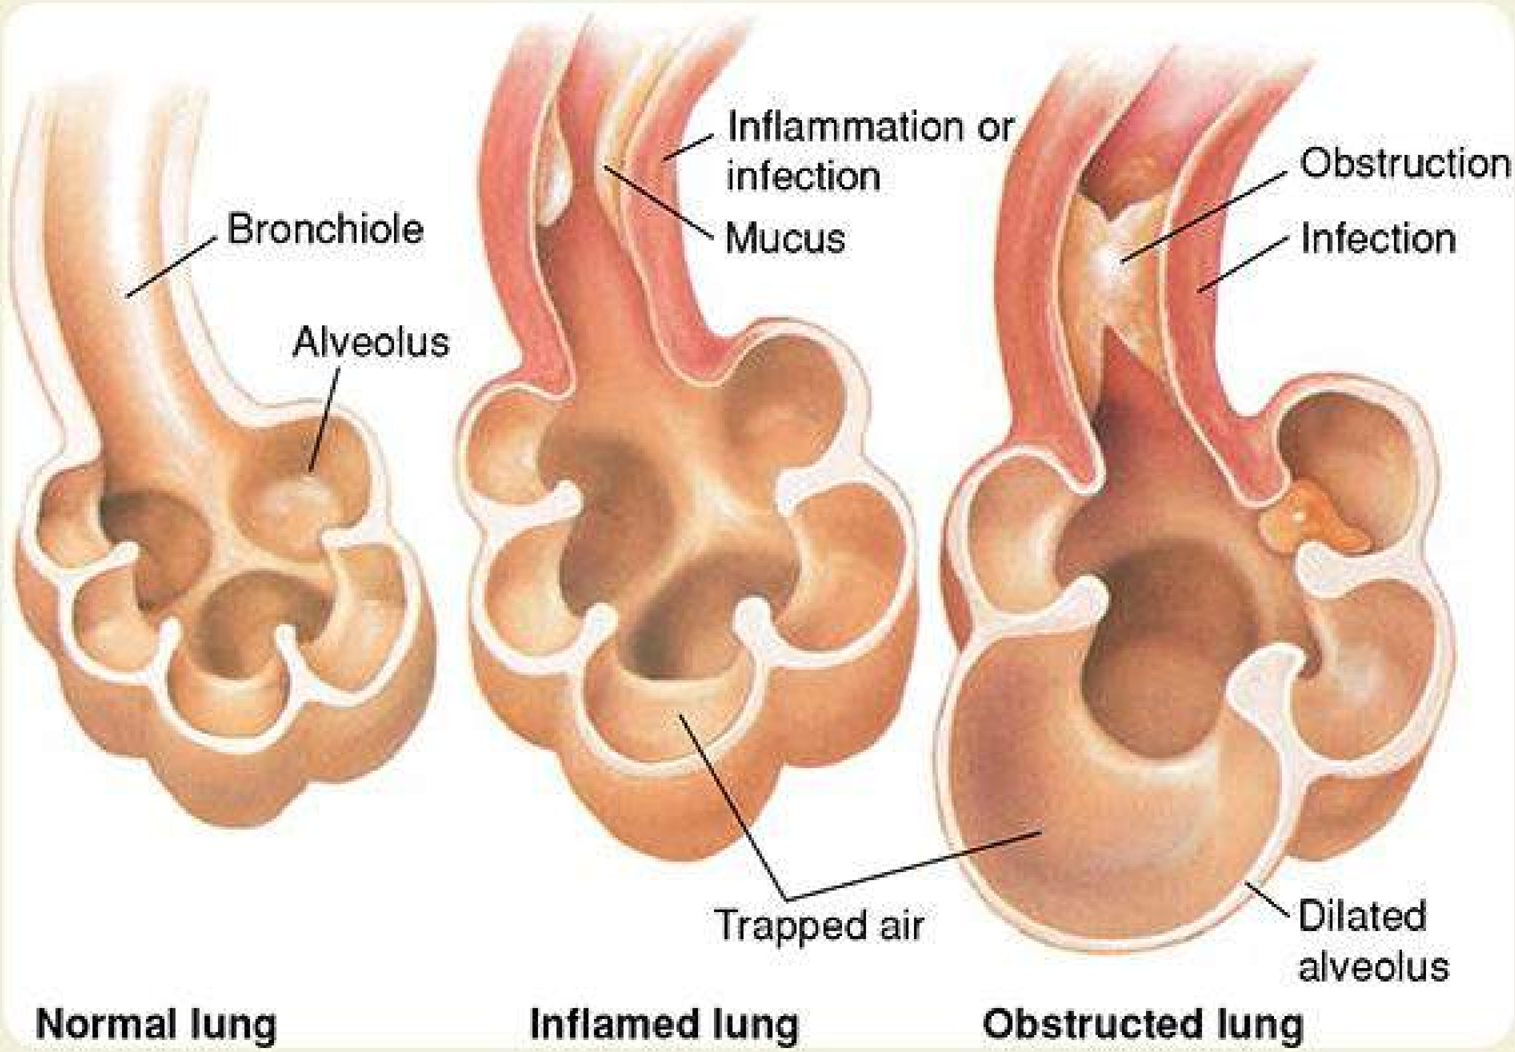

Figure 15-7 Repeated episodes of irritation and inflammation in the alveoli result in the obstruction, scarring, and some dilation of the alveolar sac characteristic of COPD.

Wet Lungs Versus Dry Lungs and "Cardiac Asthma"

Be aware that the signs and symptoms of COPD and congestive heart failure significantly overlap. Many patients suffer from both diseases, and it is often difficult to determine which disease is causing the patient's shortness of breath; often these patients are treated for both diseases after arrival to the hospital. Lung sounds (discussed later in the chapter) are one way to help you tell the difference. Patients with pulmonary edema caused most often by congestive heart failure will often have "wet" lung sounds (rhonchi, crackles), and patients with COPD will often have "dry" lung sounds (wheezes). However, do not assume *all* COPD patients have wheezes and *all* congestive heart failure patients have crackles. Table 15-4 compares COPD and congestive heart failure.

Suppose you are called to assist an 80-year-old man who has had shortness of breath for 45 minutes. Physical examination reveals that his pulse and respirations are elevated, and you observe pedal edema (swollen legs and feet) and jugular vein distention. His lung sound check reveals wheezing. He has a history of hypertension, congestive heart failure, and myocardial infarction; however, he has no history of smoking, asthma, or COPD. What is your initial general impression?

This patient's elevated blood pressure, pedal edema, jugular vein distention, and history of congestive heart failure should lead you in the direction of congestive heart failure. Unlike a typical patient with COPD, he has no history of smoking and takes diuretics and medication for hypertension. In this case, the alveoli are so full of fluid that bubbles (the condition that gives the sound of crackles) cannot form. The bronchi also become constricted, which produces wheezing. The wheezing this patient is experiencing is called cardiac asthma, which is not a form of asthma, but rather a type of coughing or wheezing that occurs with left-sided heart failure.

Patients with COPD wheeze because of bronchial constriction and present with shortness of breath. Their breathing gets progressively worse, and they have the most trouble breathing on exertion. Patients with COPD have chronic coughing and thick sputum. They are usually long-term smokers with a thin, barrel chest appearance. Their medications would include home oxygen, bronchodilators, and corticosteroids.

Patients with COPD often have a slower onset of symptoms because their disease is worsened by infection and other stressors. Patients with congestive heart failure experience a fluid overload in the lung, which may develop quickly from a failing pump.

As you try to discern between COPD and congestive heart failure, keep an open mind so that you do not miss important differences. The best advice is to treat the patient, not the lung sounds.

Asthma, Hay Fever, and Anaphylaxis

Asthma, hay fever, and anaphylaxis are the result of an allergic reaction to an inhaled, ingested, or injected substance. The substance itself (**allergen**) is not the cause of the allergic reaction; rather, it is an exaggerated response of the body's immune system to that substance that causes it. In some cases, however, there is no identifiable allergen that triggers the body's immune system.

Asthma

Asthma is an acute spasm of the bronchioles associated with excessive mucus production and with swelling of the mucous lining of the respiratory passages **Figure 15-8**. According to the CDC, approximately 25 million Americans have asthma. Asthma affects people of all ages, but the highest prevalence rate is seen in children 5 to 17 years of age.

Table 15-4 Comparison of COPD and Congestive Heart Failure

	COPD	Congestive Heart Failure
Description	▪ A slow process of dilation and disruption of the airways and alveoli caused by chronic bronchial obstruction. ▪ Usually in long-term smokers	▪ A disease of the heart characterized by shortness of breath, edema, and weakness ▪ Patient may or may not smoke
Pathophysiology	Emphysema: ▪ Destruction of the airways distal to the bronchiole ▪ Destruction of the pulmonary capillary bed ▪ Decreased ability to oxygenate the blood ▪ Lower cardiac output and hyperventilation ▪ Development of muscle wasting and weight loss Chronic bronchitis: ▪ Excessive mucus production with airway obstruction ▪ Pulmonary capillary bed undamaged ▪ Compensation by decreasing ventilation and increasing cardiac output ▪ Poorly ventilated lungs, leading to hypoxemia ▪ Increased carbon dioxide retention	▪ Damaged ventricles and failure of heart as a pump ▪ Attempt by heart to compensate with increased rate ▪ Enlarged left ventricle ▪ Backup of fluid into the body as the heart fails to pump adequately
Signs/symptoms	▪ Use of accessory muscles Emphysema: ▪ Thin appearance with barrel chest ▪ "Puffing" (pursed lip) style of breathing ▪ Tripod position Chronic bronchitis: ▪ May be obese ▪ Difficulty with expiration	▪ Abdominal distention ▪ Dependent edema (sacral or pedal) ▪ Tachycardia ▪ Increased respiratory rate ▪ Anxiety ▪ Inability to lie flat ▪ Ashen or cyanotic
Level of consciousness	Normal or altered	Confusion
Neck veins	▪ Flat ▪ Distended when heart failure also present	Distended
Skin color	▪ In emphysema, pink ▪ In chronic bronchitis, blue, often cyanotic	Blue
Lung condition	▪ In emphysema, dry ▪ In chronic bronchitis, wet when heart failure also present	Wet
Breathing	▪ Shortness of breath (mostly on exertion) ▪ Breathing worsens over time (progressive)	▪ Shortness of breath all the time ▪ Sudden onset of shortness of breath
Breath sounds	Rhonchi, wheezing	Crackles, wheezing
Circulation	No dependent edema	Dependent edema
Cough	▪ In emphysema, little or none ▪ In chronic bronchitis, frequent or chronic cough	Coughing may be present; increases when supine
Sputum	▪ In emphysema, no mucus ▪ In chronic bronchitis, excessive, thick mucus	Pink, frothy sputum
Medications	Home oxygen, bronchodilators, and steroids help open the airways	Diuretics and antihypertensives help promote cardiac function and reduce fluid loads on the heart

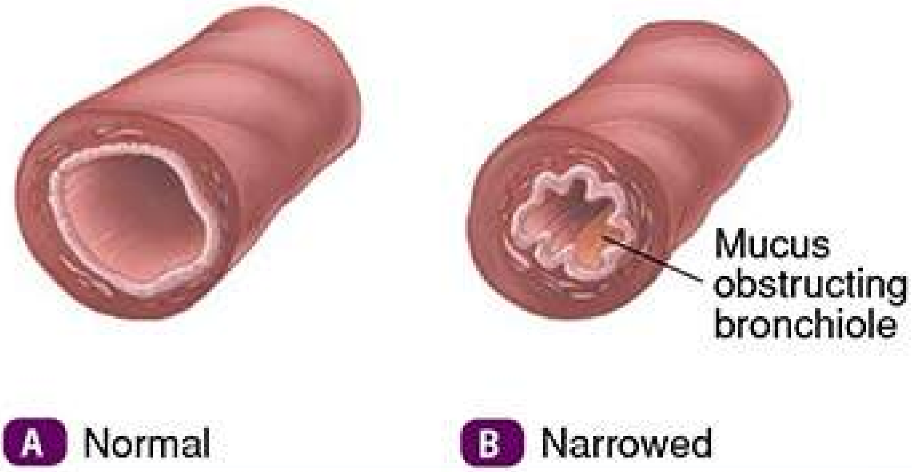

Figure 15-8 Asthma is an inflammation of the lungs associated with excessive mucus production and swelling of the bronchioles. **A.** Cross section of a normal bronchiole. **B.** The bronchiole in spasm; a mucous plug has formed and partially obstructed the bronchiole.

Asthma produces a characteristic wheezing as the patient attempts to exhale through partially obstructed air passages; wheezing is indicative of a partial lower airway obstruction. These same air passages open easily during inspiration. The wheezing may be so loud that you can hear it without a stethoscope. In other cases, the airways are so blocked that no air movement is heard. In severe cases, the actual work of exhaling is tiring, and cyanosis and/or respiratory arrest may quickly develop. Cyanosis is the body's attempt to divert blood to the core to help keep the vital organs functioning. It can be seen first in the lips and mucous membranes.

An acute asthma attack may be caused by an allergic response to specific foods or some other allergen. Between attacks, patients may breathe normally. Asthma attacks may also be triggered by severe emotional stress, exercise, and respiratory infections. In its most severe form, an allergic reaction can produce anaphylaxis. This, in turn, may cause respiratory distress that is severe enough to result in coma and death.

Most patients with asthma are familiar with their symptoms and know when an attack is imminent. Typically, they will have appropriate medication with them. Depending on your local protocols, you may be allowed to assist an asthma patient with an inhaler or nebulizer. Listen carefully to what a patient with asthma tells you; they often know exactly what they need.

YOU are the Provider — PART 2

After arriving at the scene and entering the patient's house, you smell cigarette smoke. There are numerous full ashtrays in the living room. The patient is sitting on the edge of her couch; she is wearing a nasal cannula attached to home oxygen, is smoking a cigarette, and is experiencing obvious breathing difficulty. She tells you, in two-word sentences, that her shortness of breath has worsened. You perform a primary assessment as your partner prepares to begin treatment.

Recording Time: 0 Minutes	
Appearance	Obvious breathing difficulty; breathing through pursed lips
Level of consciousness	Conscious and alert

Airway	Open; no secretions or foreign bodies
Breathing	Rapid and labored
Circulation	Radial pulse, rapid and weak; skin pink, warm, and dry

3. What should be your *most* immediate action?
4. How does emphysema differ from chronic bronchitis?

Hay Fever (Allergic Rhinitis)

Hay fever, or allergic rhinitis, causes coldlike symptoms, including a runny nose, sneezing, congestion, and sinus pressure. The symptoms are caused by an allergic response, usually to outdoor airborne allergens such as pollen or sometimes indoor allergens such as dust mites and pet dander. For many people, hay fever is at its worst in the spring and summer, but others may have hay fever symptoms year-round. People do not generally call 9-1-1 or request an ambulance for simple hay fever symptoms, but hay fever is included in this discussion of allergic conditions because it affects so many people. People with hay fever tend to be atopic, meaning that they are more likely to have other allergies, and they may also have a higher incidence of severe reactions, including anaphylaxis.

Anaphylactic Reactions

Anaphylaxis (anaphylactic shock) is a severe allergic reaction characterized by airway swelling and dilation of blood vessels all over the body, which may significantly lower blood pressure **Figure 15-9**. Anaphylaxis may be associated with widespread hives (urticaria), itching, signs of shock, and signs and symptoms similar to asthma. The airway may swell so much that breathing problems can progress to total airway obstruction in a matter of minutes. Most anaphylactic reactions occur within 30 minutes of exposure to the allergen, which can be anything from food (such as peanuts) to medication (such as penicillin). For some patients, the episode of anaphylaxis may be their first; therefore, they may not know what caused the reaction. In other cases, the patient may be aware of what substance he or she is sensitive to but is unaware that an exposure has occurred, such as eating food that was not supposed to contain nuts. In most cases, epinephrine (adrenalin) is the treatment of choice. Patients may have their own prescribed automatic epinephrine injector, or EpiPen. Oxygen and antihistamines are also useful. As always, medical direction should guide appropriate therapy. For more information about anaphylaxis and the EpiPen, see Chapter 20, *Immunologic Emergencies*.

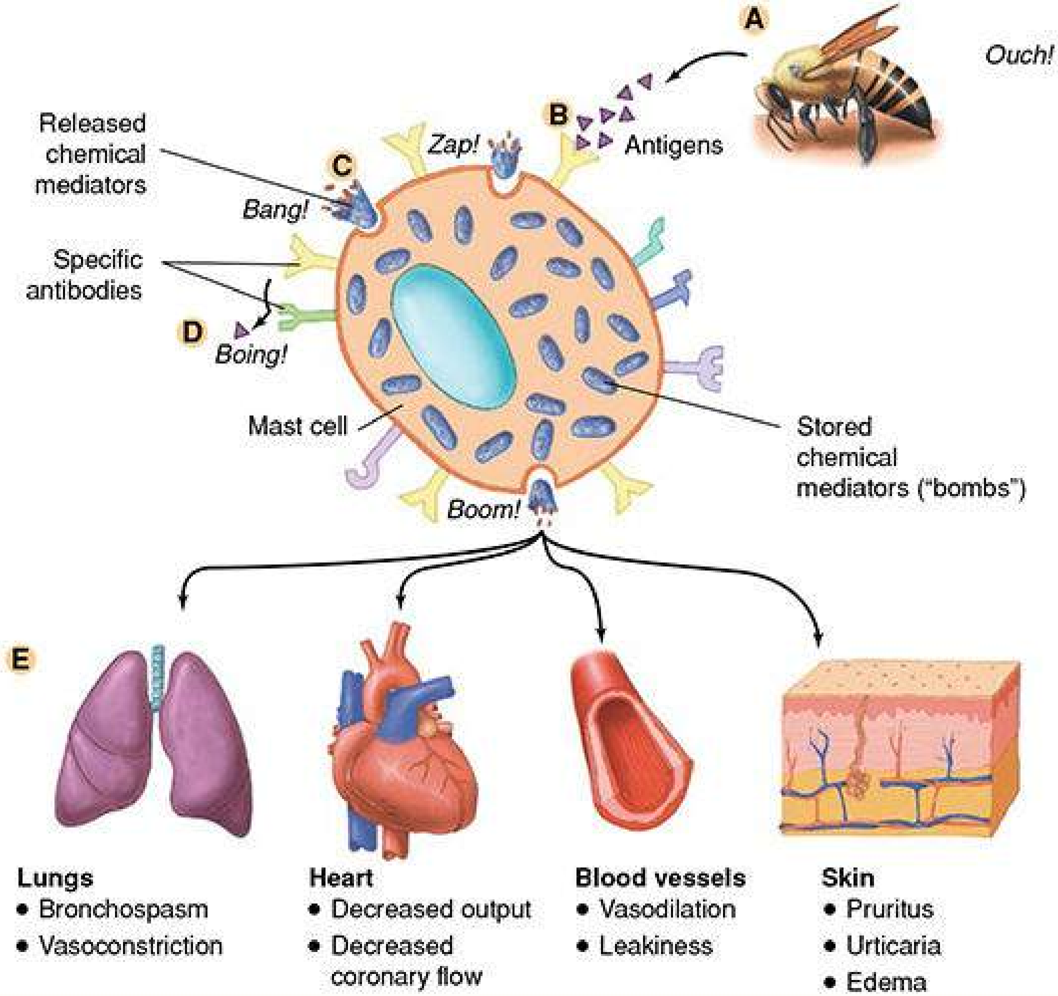

Figure 15-9 The sequence of events in anaphylaxis. **A.** The antigen is introduced into the body. **B.** The antigen-antibody reaction at the surface of a mast cell. **C.** The release of mast cell chemical mediators. **D.** Specific antibody reacts with its corresponding antigen. **E.** Chemical mediators exert their effects on end organs.

▶ Spontaneous Pneumothorax

Pneumothorax is a partial or complete accumulation of air in the pleural space. Pneumothorax is most often caused by trauma, but it can also be caused by some medical conditions. In these cases, the condition is called a "spontaneous" pneumothorax.

Normally, the "vacuum" pressure in the pleural space keeps the lung inflated. When the surface of the lung is disrupted, however, air escapes into the pleural cavity and results in a loss of negative vacuum pressure. The natural elasticity of the lung tissue causes the lung to collapse. The accumulation of air in the pleural space may be mild or severe **Figure 15-10**.

Spontaneous pneumothorax may occur in patients with certain chronic lung infections or in young people born with weak areas of the lung. Patients with emphysema and asthma are at high risk for spontaneous pneumothorax when a weakened portion of lung ruptures, often during severe coughing. Tall, thin men are also more susceptible than the rest of the population to development of spontaneous pneumothorax, particularly while performing strenuous activities, such as heavy lifting.

A patient with a spontaneous pneumothorax has dyspnea and might report **pleuritic chest pain**, a sharp, stabbing pain on one side that is worse during inspiration and expiration or with certain movement of the chest wall. By listening to the chest with a stethoscope, you can sometimes detect that breath sounds are absent or decreased on the affected side. However, altered breath sounds are very difficult to detect in a patient with severe emphysema. Spontaneous pneumothorax may be the cause of sudden dyspnea in a patient with underlying emphysema. A spontaneous pneumothorax has the potential to evolve into a life-threatening pneumothorax. Continually reassess for anxiety, increased dyspnea, hypotension, absent or severely decreased breath sounds on one side, the presence of jugular vein distention, and cyanosis.

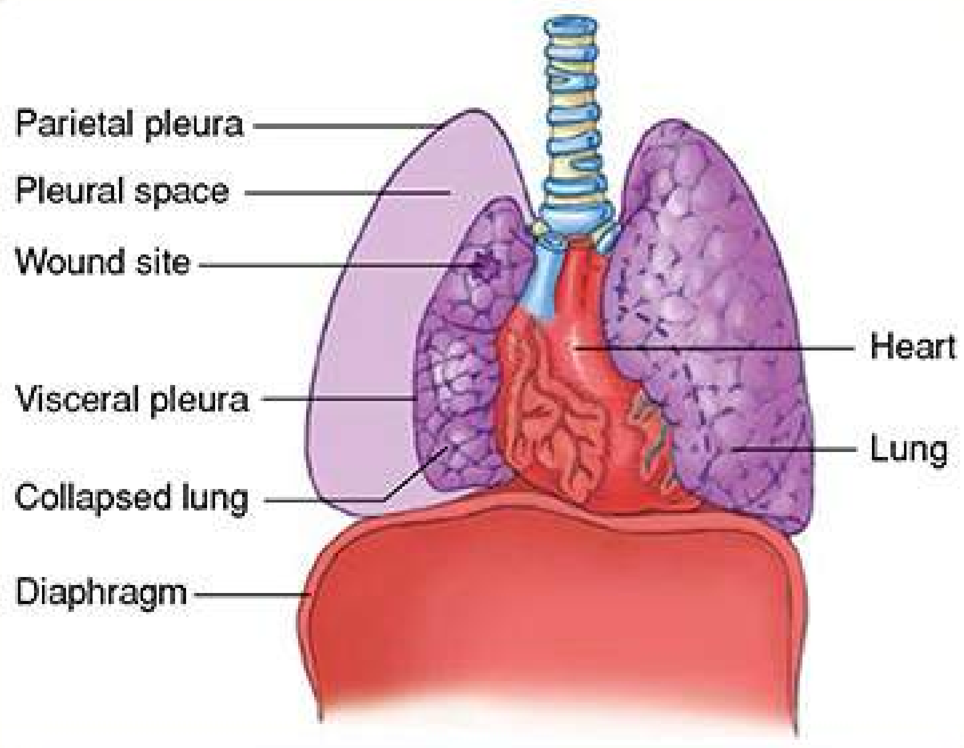

Figure 15-10 A pneumothorax occurs when air leaks into the pleural space from an opening in the chest wall or the surface of the lung. The lung collapses as air fills the pleural space and the two pleural surfaces are no longer in contact.

Pleural Effusion

A **pleural effusion** is a collection of fluid outside the lung on one or both sides of the chest. It compresses the lung or lungs and causes dyspnea **Figure 15-11**. This fluid may collect in large volumes in response to any irritation, infection, congestive heart failure, or cancer. Though it can build up gradually, over days or even weeks, patients often report that their dyspnea came on suddenly. Pleural effusions may also contribute to shortness of breath in a patient with lung cancer.

When you listen with a stethoscope to the chest of a patient with dyspnea resulting from pleural effusion, you will hear decreased breath sounds over the region of the chest where fluid has moved the lung away from the chest wall. These patients frequently feel better if they are sitting upright. Nothing will completely relieve their symptoms, however, except removal of the fluid, which must be done by a physician in the hospital.

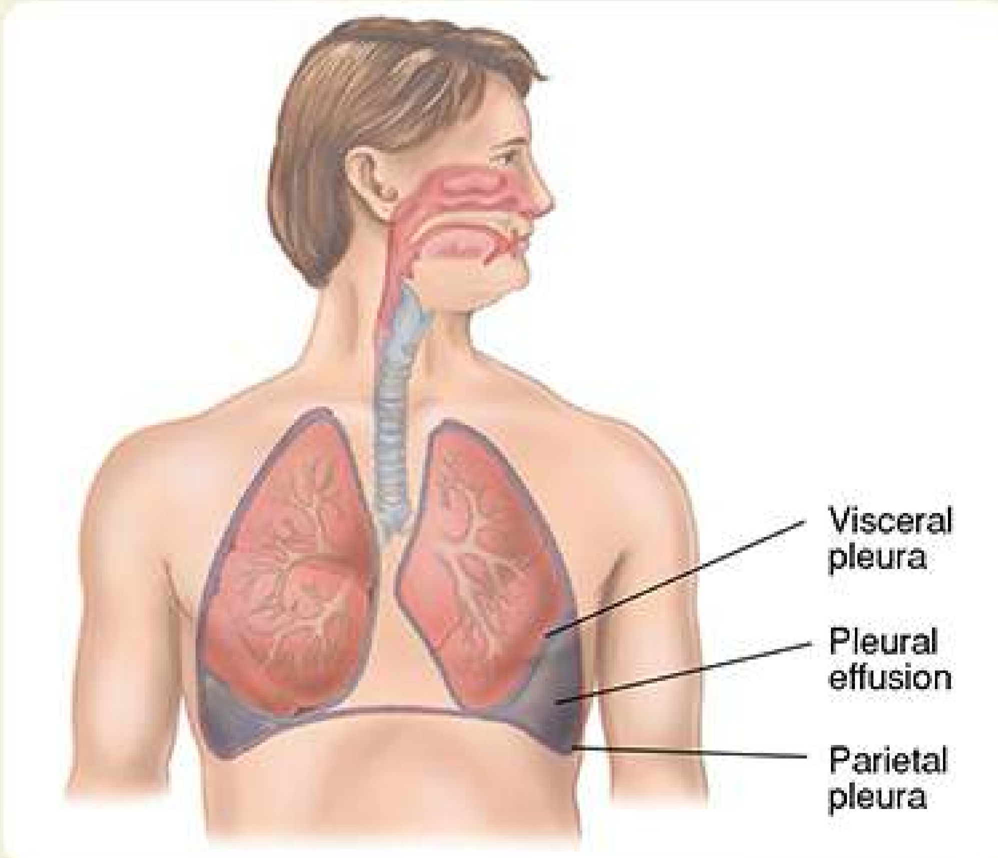

Figure 15-11 With a pleural effusion, fluid may accumulate in large volumes on one or both sides, compressing the lungs and causing dyspnea.

Obstruction of the Airway

As an EMT, always be aware of the possibility that a patient with dyspnea may have a mechanical obstruction of the airway and be prepared to treat it quickly. In semiconscious and unconscious patients, the obstruction may be the result of aspiration of vomitus or a foreign object **Figure 15-12A** or improper positioning of the head so that the tongue is blocking the airway **Figure 15-12B**.

Always consider upper airway obstruction from a foreign body first in patients who were eating just before becoming short of breath.

Pulmonary Embolism

An embolus is anything in the circulatory system that moves from its point of origin to a distant site and lodges there, obstructing subsequent blood flow in that area. Beyond the point of obstruction, circulation can be significantly decreased or completely blocked, which can result in a life-threatening condition. Emboli can be fragments of blood clots in an artery or vein that break off and travel through the bloodstream, or foreign bodies that enter the circulation, such as a bubble of air.

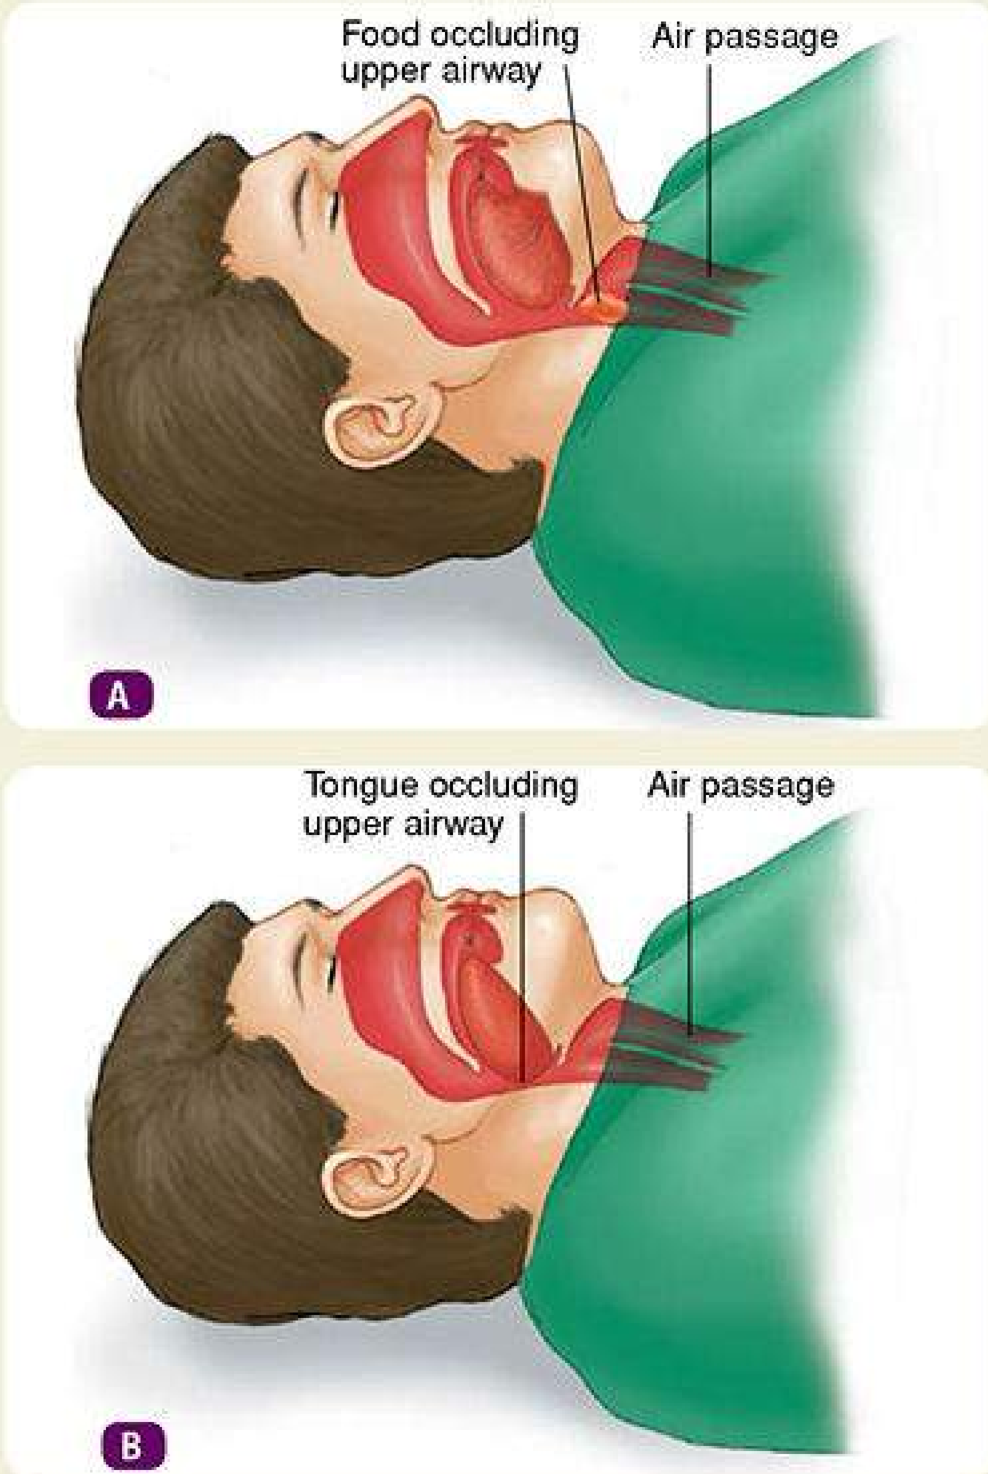

Figure 15-12 **A.** Foreign body obstruction occurs when an object, such as food, is lodged in the airway. **B.** Mechanical obstruction also occurs when the head is not properly positioned, causing the tongue to fall back into the throat.

A **pulmonary embolism** is a blood clot formed in a vein, usually in the legs or pelvis, that breaks off and circulates through the venous system. The embolus can also come from the right atrium in a patient with atrial fibrillation. The clot moves through the right side of the heart and into the pulmonary artery, where it becomes lodged, significantly decreasing or blocking blood flow Figure 15-13. Even though the lung itself can continue the process of inhalation and exhalation, no exchange of oxygen or carbon dioxide takes place in the areas of blocked blood flow because there is no effective circulation. In this circumstance, oxygen levels in the bloodstream may drop enough to cause cyanosis. The severity of cyanosis and dyspnea is directly related to the size of the embolism and the amount of tissue affected.

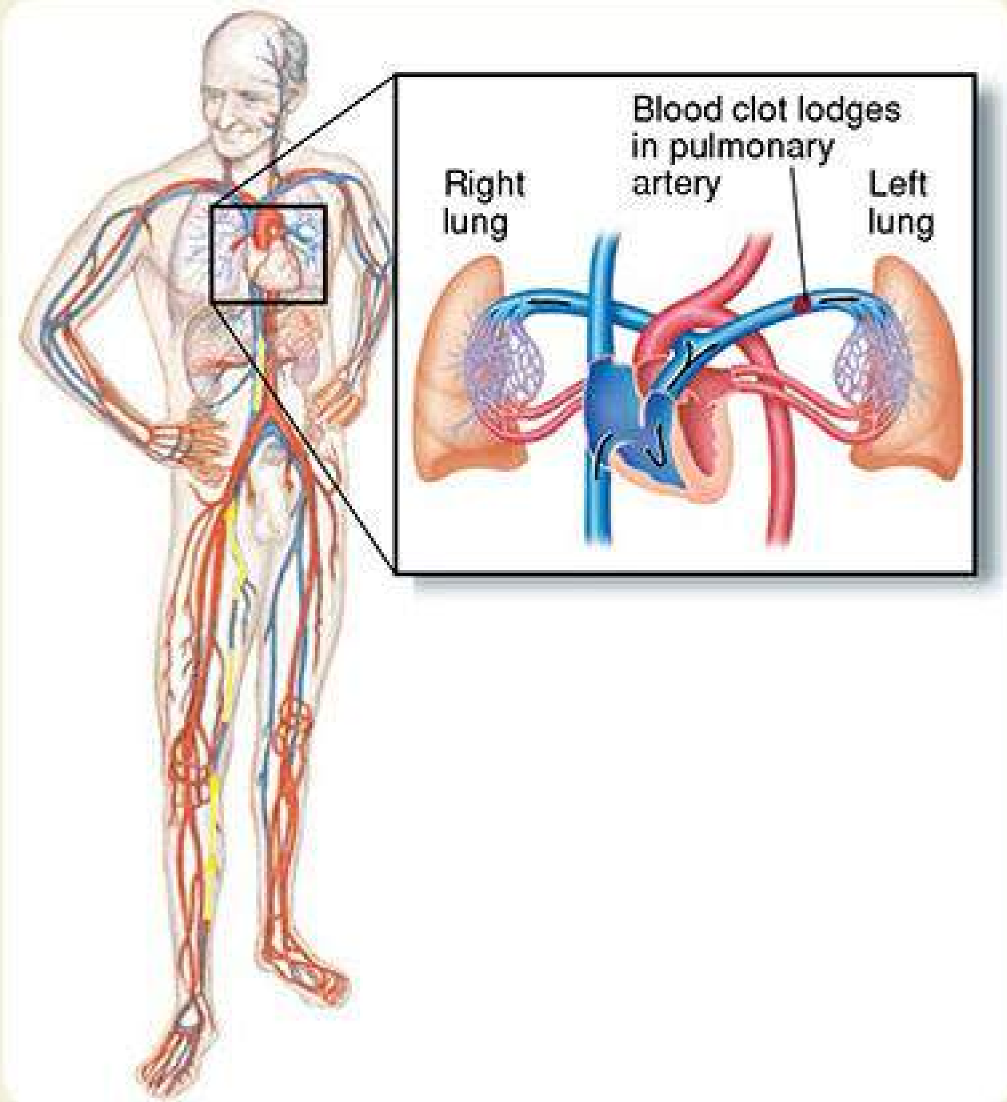

Figure 15-13 A pulmonary embolus is a blood clot from a vein that breaks off, circulates through the venous system, and moves through the right side of the heart into the pulmonary artery. Here, it can become lodged and significantly obstruct blood flow.

Pulmonary emboli may occur as a result of damage to the lining of vessels, a tendency for blood to clot unusually fast, or, most often, slow blood flow in a lower extremity. Slow blood flow in the legs is usually caused by long-term bed rest, which can lead to the collapse of veins. Patients whose legs are immobilized following a fracture or recent surgery are at risk for pulmonary emboli for days or weeks after the incident. Pregnancy, active cancer, and bed rest are other risk factors. Only rarely do pulmonary emboli occur in active, healthy people.

Although they are fairly common, pulmonary emboli are difficult to diagnose. According to the US Department of Health and Human Services, 100,000 cases of pulmonary embolism occur each year in the United States. Symptoms and signs of pulmonary emboli include the following:

- Dyspnea
- Tachycardia
- Tachypnea
- Varying degrees of hypoxia
- Cyanosis
- Acute chest pain
- Hemoptysis (coughing up blood)

With a large enough embolus, complete, sudden obstruction of the output of blood flow from the right side of the heart can result in sudden death.

Hyperventilation

Hyperventilation is defined as overbreathing to the point that the level of arterial carbon dioxide falls below normal. This may be an indicator of a life-threatening illness. For example, a patient with diabetes who has a high blood glucose level, a patient who has taken an overdose of aspirin, or a patient with a severe infection is likely to hyperventilate. In these cases, rapid, deep breathing is the body's attempt to stay alive. The body is trying to compensate for **acidosis**, the buildup of excess acid in the blood or body tissues that results from the primary illness. Because carbon dioxide, mixed with water in the bloodstream, can add to the blood's acidity, lowering the level of carbon dioxide helps to compensate for the other acids.

Similarly, in an otherwise healthy person, blood acidity can be diminished by excessive breathing because it "blows off" too much carbon dioxide. The result is a relative lack of acids. The resulting condition, **alkalosis**, is the buildup of excess base (lack of acids) in the body fluids.

Alkalosis is the cause of many of the symptoms associated with **hyperventilation syndrome (panic attack)**, including anxiety, dizziness, numbness, tingling of the hands and feet, and painful spasms of the hands and/or feet (carpopedal spasms). Patients often feel they cannot catch their breath despite the rapid breathing. Although hyperventilation can be the response to illness and a buildup of acids, hyperventilation syndrome is not the same thing. Instead, this syndrome occurs in the absence of other physical problems. It commonly occurs when a person is experiencing psychological stress and affects some 10% of the population at one time or another. The respirations of an individual who is experiencing hyperventilation syndrome may be as high as 40 shallow breaths/min or as low as only 20 deep breaths/min.

The decision whether hyperventilation is being caused by a life-threatening illness or a panic attack should not be made outside the hospital. Initially, you can verbally instruct the patient to slow his or her breathing; however, if that does not work, give supplemental oxygen and provide transport to the hospital where physicians will determine the cause of the hyperventilation.

Environmental/Industrial Exposure

Many accidental exposures that cause inhalation injury and dyspnea occur at industrial sites. Pesticides, cleaning solutions, chemicals, chlorine, and other gases can be accidentally released and inhaled by employees. Sometimes chemicals like ammonia and chlorine bleach are mixed and create a hazardous by-product.

In many cases, industrial sites have their own medical, fire, and/or hazardous materials (HazMat) teams that are familiar with all the chemicals used at their site and know what to do in case of an exposure. They will begin immediate decontamination and medical care. In these cases, the patient needs to be decontaminated by trained responders before you take responsibility.

Once the patient is decontaminated, gather information from the first responders about the substance and the cause of dyspnea. Assess the patient, paying special attention to breath sounds. Inhalation injuries can cause aspiration pneumonia that can result in eventual pulmonary edema. The inhaled substance can also cause lung damage. Blood coming from the airway is an ominous sign. Chapter 39, *Incident Management*, discusses HazMat in more detail.

Carbon Monoxide Poisoning

Toxic gases can also affect people outside the industrial setting. One common type of exposure is **carbon monoxide**, a colorless, odorless, tasteless, and highly poisonous gas known as “the silent killer.” Carbon monoxide is the leading cause of accidental poisoning deaths in the United States, according to the CDC. People who survive carbon monoxide poisoning can have permanent brain damage.

Carbon monoxide is produced by fuel-burning household appliances such as gas water heaters, space heaters, grills, and generators; it is also present in smoke from fire or cigarettes. The onset of cold weather commonly leads to an increase in carbon monoxide poisonings as people turn on heaters for the first time. The combined effects of incomplete combustion and a poorly ventilated building can cause a buildup of carbon monoxide. Another common source of carbon monoxide poisoning is motor vehicle exhaust. Some people will attempt suicide by running the engine inside a closed garage and inhaling the fumes.

People who are exposed to carbon monoxide may think they have the flu. They initially report headache, dizziness, fatigue, and nausea and vomiting. They may report dyspnea on exertion and chest pain and display nervous system symptoms like impaired judgment, confusion, or even hallucinations. The worst exposures may result in syncope or seizure. Carbon monoxide has a much stronger bond with hemoglobin than does oxygen; therefore, oxygen is not being delivered to the tissues of the body. This can lead to cellular death and organ failure if uncorrected.

When you assess the scene, do not put yourself at risk of exposure **Figure 15-14**. Consider toxic gas exposure if more than one patient in the same environment is experiencing the same signs and symptoms. The symptoms of patients will start to improve as soon as they are removed from the toxic environment. High-flow oxygen by nonrebreathing mask is the best treatment for conscious patients. Patients who are unconscious or have an altered level of consciousness may need full airway control with insertion of an airway adjunct and BVM ventilation. In the worst cases, patients may be treated with hyperbaric or pressurized oxygen therapy.

Patient Assessment

Your assessment of patients in respiratory distress should be a calm and systematic process. The patients are usually anxious, and they may be some of the most ill and challenging patients you will encounter.

Scene Size-up

As always, first consider standard precautions and use of PPE. The patient may have a respiratory infection that could be passed to you through sputum and/or air droplets. Follow local protocols.

Figure 15-14 A portable carbon monoxide alarm can be attached to your medical bag to alert you to its presence at potential toxic scenes.

Next, consider whether the respiratory emergency may have been caused by a toxic substance that was inhaled, absorbed, or ingested.

Once you have determined the scene is safe, determine how many patients there are and whether you need additional or specialized resources. If there are multiple people with dyspnea, consider the possibility of an airborne hazardous material release.

If the nature of illness (NOI) is in question, ask why 9-1-1 was activated. By questioning the patient, family, and/or bystanders, you should be able to determine the NOI.

Primary Assessment

Perform a rapid examination to identify immediate life threats, which includes problems with the ABCs: airway, breathing, and circulation (discussed next). If any major problem is identified, treat it immediately. If you find life-threatening issues, provide rapid transport.

Note your general impression of the patient. What is his or her age and position? A patient in significant respiratory distress will want to sit up. In a worst-case scenario, you will arrive to see the patient in the tripod position.

Does the patient appear calm? Is he or she anxious and restless, or listless and tired? How severe is his or her breathing complaint? This initial impression will help you decide whether the patient's condition is stable or unstable.

Use the AVPU scale to check for responsiveness. If the patient is alert or responding to verbal stimuli, you know that the brain is still receiving oxygen. Ask the patient about his or her chief complaint. If the patient is responsive only to painful stimuli or unresponsive, the brain may not be oxygenating well and the potential for an airway or breathing problem is more likely. If there is no gag or cough reflex, you need to immediately assess the patient's airway status. Within seconds you will be able to determine if there are any immediate threats to life.

Assessing ABCs in Respiratory Patients

Assess the airway; air must flow in and out of the chest easily for the airway to be considered patent. If there is any question about airway patency, immediately open the airway using the head tilt–chin lift maneuver in nontrauma patients and the jaw-thrust maneuver for patients with suspected spinal trauma.

If the airway is patent, next evaluate whether the patient's breathing is adequate. What are the rate, rhythm, and quality of the respirations? Is the rate within normal limits for the patient's age? Is the patient using accessory muscles to assist the respiratory effort, and can you see retractions? Is there abdominal breathing? What is the depth of breathing, and is the tidal volume adequate? Is there adequate rise and fall of the chest? What are the color, temperature, and condition of the patient's skin? Are the patient's respirations labored? If the patient can speak only one or two words at a time before gasping for a breath, ventilations are considered labored. If the respiratory effort is inadequate, you must provide the necessary intervention. If the patient is in respiratory distress, place him or her in a position that best facilitates breathing (generally sitting upright in a full or semi-Fowler position) and begin administering oxygen at 15 L/min via nonrebreathing mask, unless contraindicated because of preexisting medical conditions. If the patient's breathing has inadequate depth or the rate is too slow, ventilations may need to be assisted with a BVM.

Ask yourself the following questions:

1. Is the air going in?
2. Does the chest rise and fall with each breath?
3. Is the rate adequate for the age of the patient?

If the answer to any of these questions is "no," something is wrong. Try to reposition the patient and insert an oral airway to keep the tongue from blocking the airway. Refer to Chapter 10, *Airway Management*, for a review of airway management and ventilation techniques. Continue to monitor the airway for fluid, secretions, and other problems as you move on to assess the adequacy of your patient's breathing.

The next step in assessing breathing in a patient with a respiratory emergency is to assess breath sounds. Techniques for this assessment are described at the end of this section.

YOU are the Provider — PART 3

Your partner obtains the patient's vital signs as you continue your assessment. You notice she is breathing through pursed lips and has a prolonged exhalation phase, and cyanosis is present in her fingernail beds. You auscultate her breath sounds and hear scattered wheezing in all lung fields. When you talk to her, you note she is now confused, is slow to answer your questions, and appears fatigued.

Recording Time: 3 Minutes	
Respirations	28 breaths/min, labored; prolonged exhalation phase
Pulse	110 beats/min; weak
Skin	Cyanotic, cool, clammy
Blood pressure	116/54 mm Hg
Oxygen saturation (Spo_2)	88% (on oxygen)

5. Why do patients with emphysema breathe through pursed lips?
6. What does a prolonged exhalation phase indicate in patients with obstructive lung disease?
7. What treatment is indicated for the patient at this point?

After assessing breath sounds, assess circulation—the pulse rate, quality, and rhythm. If the pulse rate is too fast or too slow, the patient may not be getting enough oxygen. Determine the quality of the pulse. Is it strong, bounding, or weak? Also determine whether the rhythm is regular or irregular. Irregular beats could indicate a cardiac problem.

Assessing a patient's circulation includes an evaluation for the presence of shock and bleeding. Respiratory distress in a patient could be caused by an insufficient number of red blood cells to transport the oxygen. Assess capillary refill in infants and children. Normal capillary refill is less than 2 seconds; abnormal capillary refill is greater than 2 seconds. Capillary refill is not considered a reliable assessment tool in the adult patient.

Assess the patient's perfusion by evaluating skin color, temperature, and condition. A loss of perfusion may be caused by chronic anemia, a wound, internal bleeding, or simply shock overwhelming the body's ability to compensate for the illness.

You now know enough to be able to identify any life threats in your patient. They would include any of the following signs or symptoms:

- Problems with the ABCs
- Poor initial general impression
- Unresponsiveness
- Potential hypoperfusion or shock
- Chest pain associated with a low blood pressure
- Severe pain anywhere
- Excessive bleeding

If the patient's condition is unstable and there is a possible life threat, address the life threat and proceed with rapid transport. This means you will keep your scene time short, providing only lifesaving interventions. Perform a secondary assessment en route to the hospital. If the patient's condition is stable and there are no life threats, you may decide to perform a thorough secondary assessment on scene, after obtaining the patient history.

Assessing Breath Sounds

Obtaining breath sounds, or lung sounds, is an important step when you assess a patient who is experiencing respiratory distress. Listen over the bare chest. Trying to listen over clothing or chest hair may give you inaccurate information. The diaphragm of the stethoscope must be in firm contact with the skin. If your patient is lying down, bring him or her to a sitting position, which is a better position for assessing breath sounds.

You need to determine whether your patient's breath sounds are normal (**vesicular breath sounds**, **bronchial breath sounds**) or decreased, absent, or abnormal (**adventitious breath sounds**). With your stethoscope, check breath sounds on the right and left sides of the chest, and compare each side **Figure 15-15**. When listening on the patient's back, place the stethoscope head between and below the scapulae, not over them, or you will have an inaccurate assessment.

Figure 15-15 Auscultation of breath sounds.

Make sure you listen for a full respiratory cycle so you can detect the adventitious sounds that may be heard at the end of the inspiratory or expiratory phase. When you assess for fluid collection, pay special attention to the lower lung fields. Start from the bottom up and determine at which level you start hearing clear breath sounds.

You want to hear clear flow of air in both lungs. Not hearing the flow of air is considered an absent lung sound. The lack of air movement in the lung is a significant finding. Listen carefully and do not confuse absent breath sounds with clear breath sounds. See Table 15-5 for examples of breath sounds, the diseases that may be associated with them, and important signs and symptoms.

Snoring sounds are indicative of a partial upper airway obstruction, usually in the oropharynx. **Wheezing** indicates constriction and/or inflammation in the bronchus. Wheezing is generally heard on exhalation as a high-pitched, almost musical or whistling sound. This sound is commonly heard in patients with asthma and sometimes in patients with COPD.

Crackles (formerly called rales) are the sounds of air trying to pass through fluid in the alveoli. It is a crackling or bubbling sound typically heard on inspiration. High-pitched sounds are called "fine" crackles, and low-pitched sounds are called "coarse" crackles. These sounds are often a result of congestive heart failure or pulmonary edema.

Rhonchi are low-pitched rattling sounds caused by secretions or mucus in the larger airway. Rhonchi are sometimes referred to as "junky" lung sounds and can be heard with infections such as pneumonia and bronchitis or in cases of aspiration.

Table 15-5 Signs, Symptoms, and Adventitious Breath Sounds Associated With Specific Respiratory Diseases

Breath Sounds	Disease	Signs and Symptoms
Wheezes	Asthma COPD Congestive heart failure/pulmonary edema Pneumonia Bronchitis Anaphylaxis	Dyspnea Productive or nonproductive cough Dependent edema, pink frothy sputum Fever, pleuritic chest pain Clear or white sputum Hives, facial swelling, stridor, nonproductive cough
Rhonchi	COPD Pneumonia Bronchitis	Productive cough Fever, pleuritic chest pain Clear or white sputum
Crackles	Congestive heart failure/pulmonary edema Pneumonia	Dependent edema, pink frothy sputum Fever, pleuritic chest pain
Stridor	Croup Epiglottitis	Fever, barking cough Fever, sore throat, drooling
Decreased or absent breath sounds	Asthma COPD Pneumonia Hemothorax Pneumothorax Atelectasis	Nonproductive cough, dyspnea Productive cough Fever, pleuritic chest pain Shock, respiratory distress Dyspnea, pleuritic chest pain Fever, decreased oxygen saturation

Stridor is the high-pitched sound heard on inspiration as air tries to pass through an obstruction in the upper airway. This sound indicates a partial obstruction of the trachea and occurs in patients with anatomic or foreign body airway obstruction.

Words of Wisdom

Adventitious breath sounds are sounds heard by auscultation of abnormal lungs. These sounds can include wheezing, crackles, rhonchi, gurgling, snoring, crowing, and stridor. The ability to hear and distinguish different kinds of breath sounds can give you important clues as to what is wrong with your patient. The only way to develop your ability to identify breath sounds is through practice. Ask your instructor if you can accompany a physician, nurse, or respiratory therapist in the hospital to help you develop this ability.

History Taking

The next step of your assessment will provide more information specific to the patient's chief complaint (history of present illness) through history taking. The information you obtain during history taking will be subjective (what the patient expresses, or symptoms) and objective (what you observe, or signs). Both sets of information are important in building a general assessment. Rule out any findings that warrant no care or intervention. Report pertinent negatives to health care providers or ED staff members. Recall that a pertinent negative is any sign or symptom that commonly accompanies a particular condition, but is absent. Examples of pertinent negatives would be a patient in respiratory distress who denies chest pain, or a patient with severe chest pain who denies shortness of breath.

Find out what the patient has done for the breathing problem. Does the patient have home oxygen? Does the patient use a prescribed inhaler or a small-volume nebulizer? If so, when was it used last? How many doses have been taken? Does the patient use more than one inhaler or treatment? Be sure to record the name of each device and when it was used.

Chronic Respiratory Conditions

Different respiratory complaints offer different clues and different challenges. Patients with chronic conditions may have long periods in which they are able to live relatively normal lives but then sometimes experience acute worsening of their conditions. That is when you are called, and it is important for you to be able to determine your patient's baseline status; in other words, his or her normal condition (and what is different this time that made the patient call you). For example, patients with COPD do not cope well with pulmonary infections because the existing airway damage makes them unable to cough up the mucus or sputum produced by the infection. The chronic lower airway obstruction makes it difficult for the patient to breathe deeply enough to clear the lungs. Gradually, the arterial oxygen level falls, and the carbon dioxide level rises. If a new infection of the lung occurs in a patient with COPD, the arterial oxygen level may fall rapidly. In a few patients, the carbon dioxide level may become high enough to cause sleepiness. In these cases, patients require respiratory support and careful administration of oxygen.

Recall that the patient with COPD usually has a long history of dyspnea with a sudden increase in shortness of breath. There is rarely a history of chest pain. More often, the patient will remember having had a recent "chest cold" with fever and either an inability to cough up mucus or a sudden increase in thick green or yellow sputum. The blood pressure of patients with COPD is often normal; however, the pulse may be rapid and occasionally irregular. Pay particular attention to the respirations. They may be rapid, or they may be very slow.

Patients with asthma may have different "triggers," including allergens, cold, exercise, stress, infection, and noncompliance with medication prescriptions. It is important to try to determine what may have triggered the attack so that it can be treated appropriately. For example, an asthma attack that occurred while your patient was jogging in the cold will probably not respond to antihistamines, whereas one brought on by a reaction to pollen might.

Patients with congestive heart failure often walk a fine line between compensating for their diminished cardiac capacity and decompensating. Many take several medications, most often including diuretics ("water pills") and blood pressure medications. Obtain a list of all medications and ask about the events leading up to the present problem.

Questioning a Patient With Difficulty Breathing

With patients in respiratory distress, many of the SAMPLE questions can be answered by the family or bystanders if they are present. Limit the number of questions to pertinent ones—a patient who is in respiratory distress does not need to be using any additional air to answer questions.

Ask the following questions about a patient in respiratory distress:

- What is the patient's general state of health?
- Has the patient had any childhood or adult diseases?
- Have there been any recent surgical procedures or hospitalizations?
- Have there been any traumatic injuries?

To help determine the cause of your patient's problem, be a detective. Look for medications, medical alert bracelets, environmental conditions, and other clues to what may be causing the problem. Each part of the SAMPLE history may give you clues, so be thorough. For example, you forget to ask about allergies, only to find out later that your patient has a severe allergy to cat dander and that her 8-year-old son had been playing with a cat shortly before the onset of her problem. You would have missed important and possibly lifesaving information.

The OPQRST assessment, generally used for determining the specifics of pain, can also be modified to obtain more specific information about the breathing problem. Begin by asking the patient to describe the problem. Pay close attention to OPQRST and include the following open-ended questions:

- When did the breathing problem begin (Onset)?
- What makes the breathing difficulty worse (Provocation or palliation)?
- How does the breathing feel (Quality)?
- Does the discomfort move (Radiation/region)?
- How much of a problem is the patient having (Severity)?
- Is the problem continuous or intermittent? If it is intermittent, how frequently does it occur and how long does it last (Timing)?

An additional assessment for a complaint of shortness of breath or difficulty breathing uses the mnemonic PASTE:

P *Progression*. Similar to the O in OPQRST, you want to know if the problem started suddenly or has worsened over time.
A *Associated chest pain.* Dyspnea can be a significant symptom of a cardiac problem.
S *Sputum*. Has the patient been coughing up sputum? Mucus-like sputum could indicate a respiratory infection, pink frothy sputum is indicative of fluid in the lungs, and a problem like a pulmonary embolus may not result in any sputum at all.
T *Talking tiredness.* This is an indicator of how much distress the patient is in. Ask the patient to repeat a sentence and see how many words he or she can speak without needing to take a breath. The assessment results would be reported as the patient "speaks in full sentences" or, perhaps, "speaks in two-to-three-word sentences."
E *Exercise tolerance*. Ask the patient a question about what he or she was able to do before this problem started, like walk across the room, and then ask if the patient could do it now. If the answer is "no," then it is another indicator that your patient is in distress. Exercise tolerance will decrease as the breathing problem and hypoxia incease.

Secondary Assessment

During the secondary assessment, further investigate the specific chief complaint (for example, dyspnea) by performing a physical examination and taking vital signs.

In respiratory emergencies, as in all other emergencies, only proceed to history taking and the secondary assessment once all life threats have been identified and treated during the primary assessment. If you are busy treating airway or breathing problems, you may not have the opportunity to proceed to a physical examination prior to arriving at the ED. Never compromise the assessment and treatment of airway and breathing problems to conduct a physical examination.

Sometimes it is not possible to quickly and definitively determine what is causing your patient's respiratory distress. If your patient is a 20-year-old woman at a picnic who rapidly develops difficulty breathing and hives after being stung by a bee, you have a clearcut diagnostic picture. Conversely, if your patient is an older woman in a nursing home who is receiving 12 medications and has a cough and increasing shortness of breath that developed during the past week, this is more perplexing. Keep an open mind, gather as complete a history as possible, and perform a secondary assessment.

Conduct an in-depth assessment when a patient reports shortness of breath. In addition to the signs of air hunger present in all patients with respiratory distress, such as the tripod position, rapid breathing, and use of accessory muscles, restriction of the small lower airways in patients with asthma often causes wheezing. Patients may have a prolonged expiratory phase of breathing as they attempt to exhale trapped air from the lungs. In severe cases, you may actually not hear wheezing because of insufficient airflow. Remember that the brain needs a constant, adequate supply of oxygen to function normally. As your patient tires from the effort of breathing and oxygen levels drop, the respiratory and heart rates may drop, and you will notice an altered level of consciousness. This may manifest itself as confusion, lack of coordination, bizarre behavior, or even combativeness. Your patient may seem to relax or fall asleep. A change in affect or level of consciousness is one of the early warning signs of respiratory inadequacy, and you must act immediately.

When you perform a secondary assessment on the respiratory system, look for overall symmetry of the chest, adequate rise and fall of the chest, and evidence of retractions or accessory muscle use. Are the patient's respirations labored or unlabored? Assess breath sounds, and do a physical assessment if warranted.

A secondary assessment of the cardiovascular system, especially when there is associated chest pain, should include checking and comparing distal pulses, reassessing the skin condition, and being alert for bradycardia and tachycardia.

Feel for the skin temperature, and look for color changes in the extremities and in the core of the body. Cyanosis is an ominous sign that requires immediate, aggressive intervention.

Blood pressure should be auscultated (by listening) when possible to obtain the systolic and diastolic numbers. If you are in an environment where you cannot hear well enough to auscultate the blood pressure, then palpation (by feeling) is an alternative.

Words of Wisdom

Never delay the assessment and treatment of airway and breathing problems to conduct a physical examination.

It is important to assess the neurologic system because the level of consciousness can change. Check the patient's mental status, and determine if the patient's activity can be described as anxious or restless. If so, that would be an indicator of hypoxia. Does the patient have clear thought processes? Disorientation may be another indicator of hypoxia.

Use monitoring devices if you have them available, including, but not limited to, a pulse oximeter. Pulse oximetry is an effective diagnostic tool when used in conjunction with experience, good assessment skills, and clinical judgment. Pulse oximeters measure the percentage of hemoglobin that is saturated by oxygen. In patients with normal levels of hemoglobin, pulse oximetry can be an important tool in evaluating oxygenation. To use pulse oximetry properly, it is important for you to be able to evaluate the quality of the reading and correlate it with the patient's condition. For example, it is doubtful a patient with congestive heart failure in severe respiratory distress will have a pulse oximetry reading of 98% or that a pulse oximetry reading of 80% is reliable in a conscious, alert, active patient with good skin color.

If you get a good reading consistent with your patient's condition, the pulse oximeter can help you determine the severity of the respiratory component of the patient's problem. Also, if the reading goes steadily up or down, it can give you an indication of improvement or deterioration of the patient's oxygenation status, often even prior to changes in the patient's appearance or vital signs.

Words of Wisdom

Be aware of conditions that can skew pulse oximeter results. Bright light, darkly pigmented skin, and nail polish can cause errors in the readings. Remember that it only measures the percentage of hemoglobin that is saturated with oxygen. Therefore, a patient with a low hemoglobin level, such as a patient with anemia or hypovolemia, may have 100% oxygen saturation. This means that the hemoglobin is saturated, but the reading does not tell you that the hemoglobin level in the bloodstream is insufficient to sustain organ function. Other conditions that may cause false readings are sickle cell disease and carbon monoxide poisoning.

Secondary Assessment of COPD Versus Congestive Heart Failure

Additional pieces to the assessment and treatment puzzle may be revealed during the physical examination. For example, you are treating a patient in acute respiratory distress who is breathing at a rate of 40 breaths/min and has audible wheezing. On the basis of this information, you may be unsure as to whether the patient is in congestive heart failure or is having an asthma attack. The secondary assessment may provide you with some clues, such as a consistently elevated blood pressure and swollen legs and feet (pedal edema) that would lead you in the direction of congestive heart failure.

Assume you are assessing a patient with COPD. What would you notice? Patients with COPD are usually older than 50 years. They will often have a history of recurring lung problems and are almost always long-term active or former cigarette smokers. Patients may report tightness in the chest and constant fatigue. Because air has been gradually and continuously trapped in their lungs in increasing amounts, their chests often have a barrel-like appearance. Patients with COPD often use accessory muscles to breathe **Figure 15-16**. If you listen to the patient's chest with a stethoscope, you will hear abnormal breath sounds. Patients with COPD will often exhale through pursed lips as a strategy to keep airways open longer. Digital clubbing (abnormal enlargement of the ends of the fingers) is also a sign of COPD.

Reassessment

Once the assessment and treatment have been completed, you need to reassess the patient and closely watch patients with shortness of breath. Repeat the primary assessment, and maintain an open airway. Monitor the patient's breathing, and reassess circulation.

Determine if there have been changes in the patient's condition. Confirm the adequacy of interventions and patient status. Is the current treatment improving the patient's condition? Has an already identified problem improved? Has an already identified problem gotten worse? What is the nature of any newly identified problems?

If the changes you find are improvements, simply continue the treatments; however, if your patient's condition deteriorates, prepare to modify treatments. Be prepared to assist ventilations with a BVM. Monitor the skin color and temperature. Reassess and record vital signs at least every 5 minutes for a patient in unstable condition and/or after the patient uses an inhaler. If the patient's condition is stable and no life threat exists, vital signs should be obtained at least every 15 minutes.

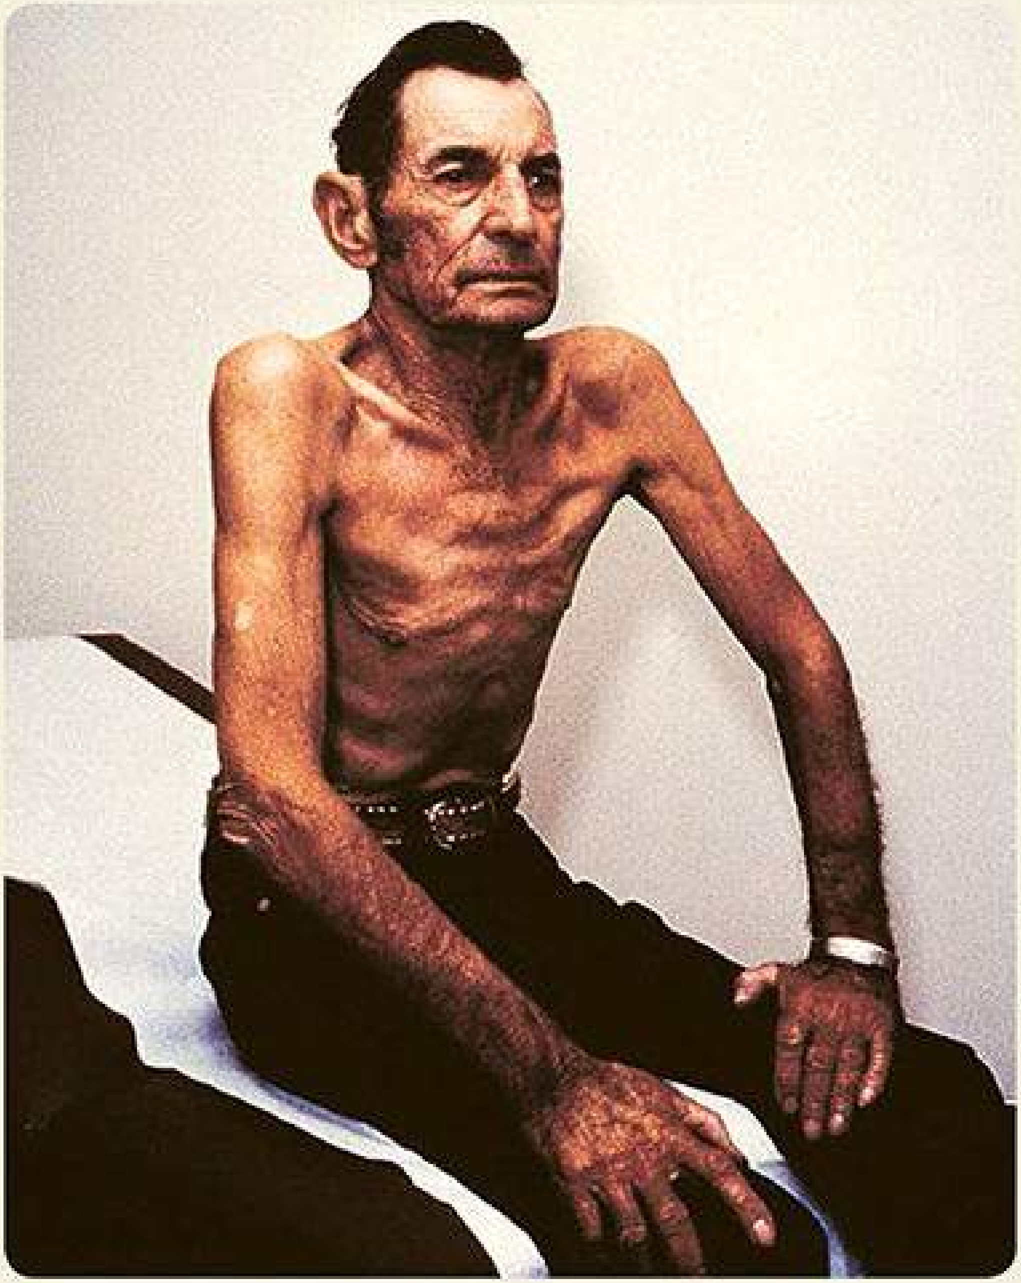

Figure 15-16 Patients with COPD often use accessory muscles and pursed lips for breathing. The increased work of breathing leads to decreased food intake (malnutrition) and muscle wasting. Notice, also, that this patient is sitting in the tripod position.

Now that you have completed the secondary assessment and have gathered information about your patient with difficulty breathing, it is time to provide interventions for the problems that are not immediate life threats. Your interventions may be based on standing orders, or contact the hospital and ask for specific directions. Remember, interventions for immediate life threats should be been completed during the primary assessment and should not require contacting the hospital first. Interventions for respiratory problems may include the following:

- Providing oxygen via a nonrebreathing mask at 15 L/min
- Providing positive-pressure ventilations using a BVM, pocket mask, or a flow-restricted oxygen-powered ventilation device
- Using airway management techniques such as an oropharyngeal (oral) airway, a nasopharyngeal (nasal) airway, suctioning, or airway positioning
- Providing noninvasive ventilatory support with continuous positive airway pressure (CPAP)
- Positioning the patient in a high-Fowler's position or a position of choice to facilitate breathing
- Assisting with respiratory medications found in a patient-prescribed metered-dose inhaler or a small-volume nebulizer

Some of these interventions were performed in the primary assessment to address life threats. Others are used to support breathing problems until definitive care can be provided at the hospital. Some of your interventions may even correct the problem.

Contact medical control with any change in level of consciousness or difficulty breathing. Depending on local protocols, contact medical control prior to assisting with any prescribed medications. Be sure to document any changes (and at what time) and any orders given by medical control.

Emergency Medical Care

Management of respiratory distress involves continuing awareness of scene safety and the use of standard precautions. Management of ABCs and positioning are primary treatments along with oxygen and suction.

You will usually administer oxygen. If a patient reports breathing difficulty, administer supplemental oxygen immediately. Adult patients breathing more than 20 breaths/min or fewer than 12 breaths/min should receive high-flow oxygen (defined as 15 L/min). Depending on the level of distress, some patients may benefit from CPAP (discussed later in the chapter). In addition, patients may require ventilatory support with a BVM, particularly if their mental status is declining or if they are in moderate to severe respiratory distress.

Take great care in monitoring the patient's respirations as you provide oxygen. Reevaluate the respirations and the patient's response to oxygen repeatedly, at least every 5 minutes, until you reach the ED. In a person with a chronically high carbon dioxide level (eg, certain patients with COPD), this is critical, because the supplemental oxygen may cause a rapid rise in the arterial oxygen level. This, in turn, may depress the patient's hypoxic drive and cause respiratory arrest.

In patients who have long-standing COPD and probable carbon dioxide retention, administration of low-flow oxygen (2 L/min) is a good place to start, with adjustments to 3 L/min, then 4 L/min, and so on, until symptoms have improved (for example, the patient's breathing becomes easier or he or she becomes more responsive). Pulse oximetry will help you understand the degree of oxygen deprivation and adjust oxygen therapy accordingly. When in doubt, err on the side of more oxygen, and monitor the patient closely.

Remember, do *not* withhold oxygen for fear of depressing or stopping breathing in a patient with COPD who needs oxygen. A decreased respiratory rate after administration of oxygen does not necessarily mean that the patient no longer needs the oxygen; he or she may need it even more. If respirations slow and the patient becomes unconscious, assist breathing with a BVM.

Always provide emotional support to the patient who is anxious. Always speak with assurance and assume a concerned, professional approach to reassure the patient, who is probably very frightened.

Words of Wisdom

Some states allow EMTs to administer inhalers or assist patients in the administration of their own inhalers. With this increased scope of practice comes an increased responsibility to know the names, doses, indications, contraindications, side effects, and precautions of the numerous inhalers available for a variety of conditions. Patients sometimes do not know the difference between their "rescue" inhalers (immediately effective medication, such as albuterol) and their "maintenance" inhalers (such as corticosteroids, which have no immediate effect). It is essential, then, that you know the difference!

Metered-Dose Inhaler and Small-Volume Nebulizer

Patients who call for help because of difficulty breathing are likely to have had the same problem before. They probably have prescribed medications to use that are delivered by an inhaler or small-volume nebulizer. If so, you may be able to help them use these devices depending on local protocols. Some of the most common medications used for shortness of breath are inhaled beta-agonists, which dilate breathing passages. The following medications may be administered via a **metered-dose inhaler (MDI)**, which is a miniature spray canister used to direct such substances through the mouth and into the lungs, such as the following: albuterol (Proventil, Ventolin), albuterol/ipratropium (Combivent), metaproterenol (Alupent, Metaprel), and terbutaline (Brethine).

Medications typically administered by small-volume nebulizer include, but are not limited to, albuterol, metaproterenol, and epinephrine. The **small-volume nebulizer** works by providing a means for a fine mist of aerosolized medicine to get deep into the patient's lungs and start to work quickly. The patient inhales the mist through a mouthpiece. When the medicine is breathed in correctly, it goes directly into the lungs.

Medical Control

Consult medical control (online), or follow standing orders (off-line). Remember to report what the medication is, when the patient last self-administered a treatment, how much medication was used at that time, and what the label states regarding dosage. If medical control or standing orders permit, you may assist the patient to self-administer the medication. Be certain that the inhaler belongs to the patient, it contains the correct medication, the expiration date has not passed, and the correct dose is being administered. There may be times in which the prescribed dose is not explicitly listed on the inhaler. In this situation, ask the patient how many inhalations of the medication he or she takes. Administer repeated doses of the medication if the maximum dose has not been exceeded and the patient is still experiencing shortness of breath.

Unlike an MDI, a small-volume nebulizer must be assembled prior to use. An oxygen tank is also required to administer the aerosolized medication. The patient may have a tank available, or you will need to use your own tank.

Indications and Contraindications

Before helping a patient to self-administer any MDI or small-volume nebulizer medication, make sure that the medication is indicated—that is, the patient has signs and symptoms of shortness of breath. The most common use for an MDI is asthma, and a small-volume nebulizer is used in asthma, bronchiolitis, COPD, and anaphylaxis. Check that there are no contraindications for its use, such as the following:

- The patient is unable to help coordinate inhalation with depression of the trigger on an MDI or is too confused to effectively administer medication through a small-volume nebulizer. These devices will be only minimally effective when patients are in respiratory failure and have only minimal air movement.
- The MDI or small-volume nebulizer is not prescribed for this patient.
- You did not obtain permission from medical control and/or it is not permissible by local protocol.
- The patient has already met the maximum prescribed dose before your arrival.
- The medication is expired.
- There are other contraindications specific to the medication.

Actions

Most respiratory inhalation medications used relax the muscles that surround the air passages in the lungs, leading to enlargement (dilation) of the airways and easier movement of air. See Table 15-6 for a list of respiratory inhalation medications. The medications used for acute symptoms are designed to give the patient rapid relief from symptoms if the condition is reversible. Medications used for chronic symptoms are administered for preventive measures or as maintenance doses. The medications for long-term use will provide little relief of acute symptoms.

Table 15-6 Respiratory Inhalation Medications

Medication			Indications			Use: Acute Versus Chronic Disease	
Generic Drug Name	Trade Names	Action	Asthma	Bronchitis	COPD	Acute	Chronic
Albuterol	Proventil, Ventolin, Volmax	Dilates bronchioles	Yes	Yes	Yes	Yes	No
Beclomethasone	Beclovent, Beconase, Qvar, Vanceril	Anti-inflammatory, reduces swelling	Yes	No	No	No	Yes
Cromolyn	Intal	Decreases release of histamines	Yes	No	No	No	Yes
Fluticasone	Flovent Diskus	Anti-inflammatory, reduces swelling	Yes	No	No	No	Yes
Fluticasone, salmeterol	Advair Diskus	Decreases secretions	Yes	No	No	No	Yes
Ipratropium bromide	Atrovent	Dilates bronchioles	Yes	Yes	Yes	Yes	No
Levalbuterol	Xopenex	Dilates bronchioles	Yes	Yes	Yes	Yes	No
Metaproterenol sulfate	Alupent, Metaprel	Dilates bronchioles	Yes	Yes	Yes	Yes	No
Montelukast	Singulair	Anti-inflammatory, reduces swelling	Yes	No	Yes	No	Yes
Salmeterol	Serevent Diskus	Dilates bronchioles	Yes	Yes	Yes	No	Yes

Side Effects

Common side effects of inhalers used for acute shortness of breath include increased pulse rate, nervousness, and muscle tremors. Often, a patient will begin coughing *after* administration of an inhaler as the airways are opened and secretions start to loosen and clear.

If the patient has a prescribed MDI or small-volume nebulizer, read the label carefully to make sure that the medication is to be used for shortness of breath and that it has, in fact, been prescribed by a physician **Figure 15-17**. When in doubt, consult medical control.

Dose and Route

Medication from an inhaler is delivered through the respiratory tract to the lung. The dose is one puff for an MDI and continuation of the small-volume nebulizer until all the medication has been administered or the patient no longer feels the need for the medication.

Figure 15-17 Some inhalers have spacer devices to better control the medication delivery to the patient.

Administration of a Metered-Dose Inhaler

To help a patient self-administer medication from an inhaler, follow the steps in **Skill Drill 15-1**:

1. Follow standard precautions.
2. Obtain an order from medical control or local protocol.
3. Check that you have the right medication, right patient, right dose, and right route and that the medication is not expired.
4. Make sure that the patient is alert enough to use the inhaler.
5. Check to see whether the patient has already taken any doses.
6. Make sure the inhaler is at room temperature or warmer **Step 1**.
7. Shake the inhaler vigorously several times.
8. Stop administering supplemental oxygen, and remove any mask from the patient's face.
9. Ask the patient to exhale deeply and, before inhaling, to put his or her lips around the opening of the inhaler **Step 2**.
10. Have the patient depress the hand-held inhaler as he or she begins to inhale deeply.
11. Instruct the patient to hold his or her breath for as long as is comfortable to help the body absorb the medication **Step 3**.
12. Continue to administer supplemental oxygen.
13. Allow the patient to breathe a few times, then repeat a second dose per direction from medical control or local protocol **Step 4**.

YOU are the Provider — PART 4

After initiating the appropriate treatment, you place the patient onto the stretcher, load her into the ambulance, and begin transport to the hospital. You reassess her and note that her condition has acutely deteriorated.

You insert a nasopharyngeal airway and begin assisting her ventilations with a BVM and high-flow oxygen.

Recording Time: 9 Minutes	
Level of consciousness	Responsive only to pain
Respirations	8 breaths/min; shallow
Pulse	124 beats/min; weak
Skin	Cool and dry; cyanosis of the nail beds and around the lips
Blood pressure	108/50 mm Hg
Spo_2	82% (on oxygen)

8. Why is cyanosis a later sign of hypoxemia in patients with emphysema?

9. Why does tachycardia develop in hypoxemic patients?

Skill Drill 15-1 Assisting a Patient With a Metered-Dose Inhaler

Step 1

Check to make sure you have the correct medication for the correct patient. Check the expiration date. Ensure inhaler is at room temperature or warmer.

Step 2

Remove oxygen mask. Hand inhaler to patient. Instruct about breathing and lip seal.

Step 3

Instruct patient to press inhaler and inhale one puff. Instruct about breath holding.

Step 4

Reapply oxygen. After a few breaths, have patient repeat dose if order or protocol allows.

▶ Administration of Small-Volume Nebulizer

To help a patient self-administer medication from a small-volume nebulizer, follow the steps in **Skill Drill 15-2**:

1. Follow standard precautions.
2. Obtain an order from medical control or local protocol.
3. Check that you have the right medication, right patient, right dose, and right route and that the medication is not expired. Ensure there are no issues with contamination, discoloration, or clarity of the medication **Step 1**.

4. Make sure that the patient is alert enough to use the device.

Skill Drill 15-2 Assisting a Patient With a Small-Volume Nebulizer

Step 1

Check to make sure you have the correct medication for the correct patient. Check the expiration date. Confirm you have the correct patient.

Step 2

Insert the medication into the container on the nebulizer. In some cases, sterile saline may be added (about 3 mL) to achieve the optimum volume of fluid for the nebulized application.

Step 3

Attach the medication container to the nebulizer, mouthpiece, and tubing. Attach oxygen tubing to the oxygen tank. Set the flowmeter at 6 L/min.

Step 4

Instruct the patient on how to breathe.

5. Check to see whether the patient has already taken any treatments.
6. If assisting to assemble the device, maintain aseptic technique.
7. Open the medication container on the nebulizer, and insert the medication (generally the whole volume of the medication). In some cases, sterile saline may be added (about 3 mL) to achieve the optimum volume of fluid for the nebulized application **Step 2**.
8. Attach the medication container to the nebulizer, mouthpiece, and tubing. Attach oxygen tubing to the oxygen tank.
9. Adjust oxygen flow to 6 L/min to establish misting effect **Step 3**.

10. Stop administering supplemental oxygen, and remove nonrebreathing mask from the patient's face.
11. Ask the patient to put his or her lips around the mouthpiece of the device, inhale the mist, and hold it for 3 to 5 seconds before exhaling Step 4.
12. When the mist dissipates and the medication has been used or the patient is no longer experiencing shortness of breath, discontinue use of the device.
13. Place the nonrebreathing mask back on the patient if the patient continues to report shortness of breath.
14. Reassess vital signs, and document your actions and the patient's response.
15. Consult with medical control and/or follow local policy if repeated doses are necessary.

Treatment of Specific Conditions

Upper or Lower Airway Infection

Dyspnea associated with acute infections is common. Except in the patient with pneumonia, acute bronchitis, or epiglottitis, it is rarely serious. The acute congestion and stuffiness of a common cold hardly ever require emergency care. Indeed, most people with colds treat themselves with over-the-counter medications. However, people with a common cold who have underlying problems such as asthma or heart failure may experience a worsening of their condition as a result of the additional stress of the infection. In addition, medications for colds may also have stressful side effects, such as agitation, increased heart rate, and increased blood pressure.

For patients with upper airway infections and dyspnea, administer humidified oxygen (if available). Do not attempt to suction the airway or place an oropharyngeal airway in a patient with suspected epiglottitis. These maneuvers may cause a spasm and complete airway obstruction. Transport the patient promptly to the hospital. Allow the patient to sit in the position that is most comfortable. For someone with epiglottitis, this is usually sitting upright and leaning forward in the "sniffing position" Figure 15-18. To force a patient with epiglottitis to lie supine may cause upper airway obstruction that could result in death.

Figure 15-18 A child with epiglottitis may be more comfortable sitting up and leaning forward.

Acute Pulmonary Edema

Dyspnea caused by acute pulmonary edema may be associated with cardiac disease or direct lung damage. In either case, administer 100% oxygen, and, if necessary, carefully suction any secretions from the airway. The best position for a conscious patient who has a myocardial infarction or direct lung injury is the position in which it is easiest to breathe. Usually, this is sitting up. An unconscious patient with acute pulmonary edema may require full ventilatory support, including placement of an airway adjunct, positive pressure ventilation with oxygen, and suctioning.

Continuous positive airway pressure (CPAP) is a noninvasive means of providing ventilatory support for patients experiencing respiratory distress associated with obstructive pulmonary disease and acute pulmonary edema. As discussed in Chapter 10, *Airway Management*, CPAP increases pressure in the lungs, opens collapsed alveoli, pushes more oxygen across the alveolar membrane, and forces interstitial fluid back into the pulmonary circulation. CPAP systems use oxygen to deliver the positive ventilatory pressure to the patient. Many patients show dramatic improvement with the use of CPAP. CPAP can be used for patients who have moderate to severe respiratory distress from an underlying disease, such as pulmonary edema or obstructive pulmonary disease, are alert and able to follow commands, have tachypnea, or have a pulse oximetry reading of less than 90%. One potential contraindication to the use of CPAP is low blood pressure. Because of the increased pressure inside the chest, blood flow returning to the heart is diminished. CPAP is also not used in patients in respiratory arrest or who have signs and symptoms of a pneumothorax or chest trauma, a tracheostomy, have a decreased level of consciousness, inability to follow commands, or have active gastrointestinal bleeding.

If you are authorized to apply CPAP for acute pulmonary edema according to your local protocols, do so. Otherwise, provide prompt transport to the nearest appropriate ED. Continue to reassess patients using CPAP for signs of deterioration and/or respiratory failure.

▶ Chronic Obstructive Pulmonary Disease

Patients with COPD may have an altered level of consciousness or may be unresponsive from hypoxia or carbon dioxide retention. Patients with COPD often find breathing difficult when lying down. Assist with the patient's prescribed inhaler if there is one. Oftentimes a patient with COPD will overuse an inhaler, so watch for side effects. Promptly transport patients with COPD to the ED, allowing them to sit upright if this is most comfortable.

▶ Asthma, Hay Fever, and Anaphylaxis

Many lung problems are incorrectly labeled "asthma"; therefore, you must critically assess the patient. Asthma is often a recurring pathologic condition. Confirm whether the patient is able to breathe normally at other times. If possible, ask family members to describe the patient's asthma. Even if they only identify wheezing as a problem, be aware that some forms of heart failure, foreign body aspiration, toxic fumes inhalation, or allergic reactions may cause wheezing.

As you assess the patient's vital signs, note that the pulse rate will be normal or elevated, the blood pressure may be slightly elevated, and respirations will be increased. Ask questions about how and when the symptoms began.

As you care for the patient, be prepared to suction large amounts of mucus from the mouth and to administer oxygen. If you do suction, do not withhold oxygen for more than 15 seconds for adult patients, 10 seconds for a child, and 5 seconds for an infant. Allow some time for oxygenation between suction attempts. If the patient is unconscious, you may have to provide airway management.

If the patient has medication, such as an inhaler for an asthma attack, you may help with its administration, as directed by local protocol. Even patients who use their inhaler may continue to get worse. Reassess breathing frequently and be prepared to assist ventilations with a BVM in severe cases. If you must assist ventilations in a patient who is having an asthma attack, use slow, gentle breaths. Remember, the problem in asthma is getting the air out of the lungs, not into them. Resist the temptation to squeeze the bag hard and fast. Always assist with ventilations as a last resort, and then provide only about 10 to 12 shallow breaths/min.

A prolonged asthma attack that is unrelieved may progress into a condition known as *status asthmaticus*. The patient is likely to be frightened, frantically trying to breathe, and using all the accessory muscles. Status asthmaticus is a true emergency. Give oxygen and promptly transport to the ED.

The effort to breathe during an asthma attack is very tiring, and the patient may be exhausted by the time you arrive at the hospital. An exhausted patient may have stopped feeling anxious or even struggling to breathe. This patient is not recovering; he or she is at a very critical stage and is likely to stop breathing. Aggressive airway management, oxygen administration, and prompt transport are essential in this situation. Advanced life support (ALS) should be considered. Follow local protocol.

The patient with hay fever is unlikely to need emergency treatment unless the condition has worsened from generalized cold symptoms. Manage the airway, and give oxygen according to the level of distress.

An anaphylactic reaction is a life-threatening emergency. The first step should be to remove the offending agent. For example, if the patient has a stinger from a bee sting still in place, you may need to remove the stinger. Remember to scrape the stinger off because you can inject more venom into the patient if you pinch or squeeze the stinger.

Maintain the airway—the airway is always a priority regardless of the situation. If the patient is still awake, allow him or her to assume a position that does not compromise breathing. Use an appropriate oxygen device for supplemental oxygen administration. Be prepared to assist breathing as needed. Rapid transport and the early administration of epinephrine, if allowed by protocol, should be a priority. Because epinephrine has immediate action, it can rapidly reverse the effects of anaphylaxis.

▶ Spontaneous Pneumothorax

Patients with spontaneous pneumothorax may have severe respiratory distress, or they may have no distress at all and report only pleuritic chest pain. Provide supplemental oxygen, and provide prompt transport to the hospital. Like most dyspneic patients, those with spontaneous pneumothorax are usually more comfortable sitting up. Monitor the patient carefully, watching for any sudden deterioration in the respiratory status. Be ready to support the airway, assist respirations, and provide CPR if it becomes necessary.

▶ Pleural Effusion

Treatment of pleural effusion consists of removal of fluid collected outside the lung, which must be done by a physician in a hospital setting. However, you should provide oxygen and other routine support measures to these patients.

▶ Obstruction of the Airway

If the patient is a small child or someone who was eating just before dyspnea developed, you may assume that the problem is an inhaled or aspirated foreign body. If the patient is old enough to talk but cannot make any noise, upper airway obstruction is the likely cause.

Upper airway obstruction may be either partial or complete. If your patient is able to talk and breathe, the wisest course may be to provide supplemental oxygen and transport carefully in a position of comfort to the hospital. As long as the patient is able to obtain sufficient oxygen, avoid doing anything that might turn a partial airway obstruction into a complete airway obstruction.

There is no condition more immediately life threatening than a complete airway obstruction. The obstructing body must be removed before any other actions will be effective. Clear the patient's upper airway according to basic life support guidelines. Opening the airway with the head tilt–chin lift maneuver (or the jaw-thrust maneuver for patients with suspected spinal trauma) may solve the problem. You should perform this maneuver only after you have ruled out a head or neck injury. If simply opening the airway does not correct the breathing problem, you will have to assess the upper airway for the obstruction. Then, whether or not you are successful in clearing the airway, administer supplemental oxygen and transport the patient promptly to the ED.

▶ Pulmonary Embolism

Because a considerable amount of lung tissue may not be functioning, supplemental oxygen is mandatory in a patient with a pulmonary embolism. Place the patient in a comfortable position, usually sitting, and assist breathing as necessary. Hemoptysis, if present, is usually not severe, but any blood that has been coughed up should be cleared from the airway. The patient may have an unusually rapid and possibly irregular heartbeat. Transport the patient to the ED promptly. Be aware that large pulmonary emboli may cause cardiac arrest.

▶ Hyperventilation

When you respond to a patient who is hyperventilating, complete a primary assessment and gather a history of the event. Is the patient having chest pain? Is there a history of cardiac problems or diabetes? You must always assume a serious underlying problem even if you suspect that the underlying problem is stress. Do not have the patient breathe into a paper bag, even though it was once thought to be the technique for managing hyperventilation syndrome. In theory, breathing into a paper bag causes the patient to rebreathe exhaled carbon dioxide, allowing the level of carbon dioxide in the blood to return to normal. In fact, if the patient is hyperventilating because of a serious medical problem, this maneuver could make things worse. A patient with underlying pulmonary disease who breathes into a bag may become severely hypoxic. Treatment should instead consist of reassuring the patient in a calm, professional manner; supplying supplemental oxygen; and providing prompt transport to the ED. Patients who hyperventilate need to be evaluated in the hospital.

▶ Environmental/Industrial Exposure

The commonality in these kinds of respiratory problems is the inhalation of a toxic chemical. There are many different types of chemicals, different types of presentations, and certainly different levels of severity. Ensure that all patients are decontaminated prior to treatment. Treat with oxygen, adjuncts, and suction on the basis of presentation, level of consciousness, and level of distress that is observed in your patient.

Foreign Body Aspiration

Upper airway obstruction is common in young children, who put objects in their mouths as a way to learn about them. If you have evidence of a partial or complete airway obstruction in a young child, especially a crawling baby, consider that the child may have swallowed and choked on a small object. Perform the appropriate airway clearing technique specific to the age of the child.

Another scenario to consider is that an object passed through the airway and has been aspirated (inhaled) into the lung. This problem will not be as obvious as an airway obstruction.

Most deaths from foreign body aspiration occur in patients who are younger than 5 years, and most of them are infants. Typical items aspirated include balloons, small balls, and small parts of toys. Toddlers may aspirate pieces of food like hot dogs or peanuts.

One sign of aspiration in a child may be an abnormality in the voice. The aspirated object will most likely go down the right mainstem bronchus. If the bronchus is fully obstructed, the lung could collapse. Aspiration pneumonia may also develop.

Provide oxygen, and transport any child with a suspected aspiration. An X-ray will be needed to confirm the aspiration, its location, and the treatment.

For an older person, the normal process of aging creates conditions that contribute to breathing problems. For example, weakening of the airway musculature can cause decreased breathing capacity. Decreased cough and gag reflexes cause a decreased ability to clear secretions. Difficulty in swallowing means the risk for aspiration is markedly increased. Older people can aspirate food or oral secretions that, in many cases, can develop into a potentially life-threatening aspiration pneumonia.

Tracheostomy Dysfunction

Children with chronic pulmonary medical conditions may use a home ventilator that is connected by a tracheostomy tube. This tube is placed in an opening in the neck (stoma) and can sometimes become obstructed by secretions, mucus, or foreign bodies. Other tracheostomy tube complications include bleeding, leaking, dislodgement, and infection. Your main goal is to establish a patent airway. Place the patient in a position of comfort and provide suctioning to clear the obstruction. If you are unable to clear the airway, consider ALS intervention. Once the obstruction is clear, oxygenate the patient and treat based on the patient's presentation.

Geriatric patients may have a tracheostomy tube in place because of airway obstruction, laryngeal cancer, severe infection, trauma, or the inability to manage secretions. As with children, the tube can become obstructed by secretions, foreign bodies, or airway swelling. The stoma itself can become infected. Your immediate goal is to establish airway patency.

Asthma

Asthma is a common childhood illness. When you assess a pediatric patient, look for retractions of the skin above the sternum and between the ribs. Retractions are typically easier to see in children than in adults. Cyanosis is a late finding in children.

Keep in mind that a cough is not always a symptom of a cold; it could signal pneumonia or asthma. Even if you do not hear much wheezing, the presence of a cough can indicate that some degree of reactive airway disease or an acute asthma attack may be taking place.

Figure 15-19 Because children may refuse to wear an oxygen mask, you may have to hold the mask in front of the child's face or ask the parents or caregivers for help.

The emergency care of a child with shortness of breath is the same as it is for an adult, including the use of supplemental oxygen. However, many small children will not tolerate (or may refuse to wear) a face mask. Rather than fighting with the child, provide blow-by oxygen by holding the oxygen mask in front of the child's face or ask the parent or caregiver to hold the mask **Figure 15-19**.

Many children with asthma also will have prescribed hand-held MDIs. Use these inhalers just as you would with an adult. Pediatric patients and some geriatric patients are more likely to use spacers to assist in inhaler use. Treat as in adult asthma.

Asthma in an older patient causes bronchospasm, swelling of the lining of the airways, and an accumulation of secretions. Attacks are easily triggered by air pollutants, viral infections, allergens, and sometimes something as simple as exposure to cold air. Asthma, as with any chronic disease, can become life threatening in older people, especially in patients who have problems with airway control. The condition is made worse by anxiety and dehydration, which is typical in older people. Geriatric patients with asthma tend to have both inspiratory and expiratory wheezes.

Cystic Fibrosis

Cystic fibrosis (CF) is a genetic disorder that affects the lungs and digestive system. CF disrupts the normal function of cells that make up the sweat glands in the skin and that also line the lungs and the digestive and reproductive systems. The disease predisposes the child to repeated lung infections.

The disease process in CF disrupts the essential balance of salt and water necessary to maintain a normal coating of fluid and mucus inside the lungs and other organs. The end result is that the mucus becomes thick, sticky, and hard to move. The mucus holds germs, causing the lungs to become infected.

In CF, the child's symptoms range from sinus congestion to wheezing and asthma-like complaints. A chronic cough that produces thick, heavy, discolored mucus may develop in the child. As lung function decreases, so does the ability to breathe effectively. The child often has dyspnea; this generally results in the parents or caregivers calling EMS. Treat the child with suction and oxygen using age-appropriate adjuncts.

Cystic fibrosis often causes death in childhood because of chronic pneumonia secondary to the very thick, pathologic mucus in the airway. It also causes malabsorption of nutrients in the intestines. Because of advances in treatment, the life expectancy for CF patients becomes better each year. Adults with CF are predisposed to other medical conditions, including arthritis, osteoporosis, diabetes, and liver problems.

Special Populations

Most geriatric patients take medications, sometimes many, to treat various ailments that are part of the aging process. Some of these medications will blunt the body's normal reactions to stress and the mechanisms the body uses to compensate for respiratory compromise and hypoxia. For example, beta-blockers, used for a variety of conditions, prevent the heart from speeding up to compensate for when the blood pressure drops. Keep this in mind when you evaluate vital signs in geriatric patients.

YOU are the Provider — PART 5

With an estimated time of arrival at the hospital of 8 minutes, you ask your partner to radio in the patient report. The patient's level of consciousness has not changed; however, the cyanosis around her mouth and in her nail beds has resolved and her oxygen saturation has improved. You complete your reassessment and continue treatment.

Recording Time: 15 Minutes	
Level of consciousness	Responsive to pain only
Respirations	12 breaths/min; shallow
Pulse	118 beats/min; weak
Skin	Cool and dry; cyanosis has resolved
Blood pressure	112/70 mm Hg
Spo_2	90% (on oxygen)

You deliver the patient to the ED staff and give your verbal report to the nurse. Because of the patient's decreased level of consciousness and the need for ongoing ventilation assistance, the physician elects to intubate her. She is diagnosed with acute exacerbation of her emphysema and is admitted to the intensive care unit.

10. How can positive-pressure ventilation cause a decrease in a patient's blood pressure?

11. What does *exacerbation* mean?

YOU are the Provider — SUMMARY

1. What is emphysema? What is the typical cause?

Emphysema, a form of COPD, is a disease of the respiratory system in which airways develop chronic inflammation, excessive mucus is produced and narrows the airways, and destruction of alveoli and small airways leads to a loss of lung elasticity. As a result, the expiratory phase of respiration becomes difficult and gas exchange in the lungs becomes impaired. Although emphysema is an irreversible condition, its symptoms can be reduced and the disease progression slowed with lifestyle changes (eg, quitting smoking) and certain medications.

The single most common cause of emphysema is heavy, long-term cigarette smoking. Other causes include frequent pulmonary infections and long-term exposure to toxic agents, such as by working in an industrial setting for a long period.

2. Why is it especially significant that this patient called 9-1-1?

Patients with chronic diseases call 9-1-1 when something is different or has gotten worse. The patient could be experiencing an acute flare of her emphysema, a secondary respiratory illness to which she is predisposed (ie, pneumonia), or complete respiratory failure. Just because she has refused EMS transport in the past does not mean that she will this time; she has a known respiratory illness, which you should assume has gotten worse, and she should be treated no differently from any other patient with a respiratory emergency.

3. What should be your *most* immediate action?

Oxygen and lit cigarettes—or any other source of fire—do not go together! Ask the patient to immediately extinguish her cigarette and then continue your assessment. Although oxygen is not flammable or explosive, it does support the process of combustion. A small spark or lit cigarette can become a flame in an oxygen-rich atmosphere. Oxygen will cause a fire to burn more vigorously, as well as hotter. The patient could literally light her face on fire; you and your partner could be injured as well.

4. How does emphysema differ from chronic bronchitis?

As previously discussed, emphysema is a disease in which small airways and the inner walls of alveoli are progressively destroyed, resulting in a loss of lung elasticity. Chronic bronchitis is caused by persistent inflammation in larger airways. With chronic bronchitis, excess mucus is constantly produced, which obstructs the bronchioles and alveoli. As a result, pulmonary gas exchange is less efficient. Many patients with chronic bronchitis have a chronic productive cough. In some patients, however, the cough reflex is weakened; this causes sputum to settle in the lungs and become infected, resulting in pneumonia. Emphysema and chronic bronchitis are both forms of COPD and are both usually caused by heavy, long-term cigarette smoking.

5. Why do patients with emphysema breathe through pursed lips?

With emphysema, the force of exhalation increases intrathoracic pressure and causes premature closure of the small airways, causing air to be trapped in the alveoli. The harder the patient tries to push air out, the more air gets trapped in the alveoli. Chronic air trapping in the lungs explains why many patients with long-term emphysema have a characteristic barrel-shape appearance to their chest. Over time, patients with emphysema learn that if they push air out slowly at a higher residual airway pressure, they can exhale more air than if they try to push it out faster because their airways will remain open for longer. One of the ways they do this is by breathing through pursed lips during exhalation. Pursed lip breathing allows the patient to push air out slowly under controlled pressure.

6. What does a prolonged exhalation phase indicate in patients with obstructive lung disease?

A prolonged exhalation phase indicates that the patient is experiencing difficulty exhaling air from the lungs, which, as a result, causes chronic air trapping in the lungs. The inhalation-to-exhalation ratio in healthy people during normal breathing is typically 1:2. In other words, it takes about twice as long to exhale as it does to inhale. Depending on the severity of their disease process, patients with obstructive lung disease may have an I:E ratio of 1:4, 1:5, or longer. Because the patient's bronchioles significantly narrow when he or she exhales, wheezing—a whistling sound—is often heard during the exhalation phase while auscultating the lungs.

7. What treatment is indicated for the patient at this point?

Compared with the patient's condition during your initial assessment, it has deteriorated. She is now confused and slow to answer your questions, which indicates decreased oxygen delivery to the brain. Her oxygen saturation level of 88% indicates significant hypoxemia, and the fatigue indicates that she is less able to compensate for her condition. She clearly needs a higher concentration of oxygen than what her nasal cannula is supplying. Apply a nonrebreathing mask, set the flow rate at 12 to 15 L/min, and reassess her condition. If it does not improve, assisted ventilation with a BVM may be necessary. If you must assist the patient's breathing, however, ensure that you allow complete exhalation between positive-pressure breaths. Remember, patients with emphysema have a lot of air trapped in the alveoli.

8. Why is cyanosis a later sign of hypoxemia in patients with emphysema?

Patients with emphysema maintain chronically low blood oxygen levels and chronically elevated carbon dioxide levels. In many patients, this leads to excessive red blood cell production (polycythemia), which is why the patients tend to maintain a pink skin color, even in the presence of hypoxemia. This, and the fact that many patients with emphysema breathe through pursed lips, is why they are often referred to as "pink puffers." Unlike otherwise healthy people, patients with emphysema often do not develop cyanosis until significantly more hemoglobin is desaturated (not carrying oxygen). The absence of cyanosis does not rule out hypoxemia in any patient, especially a patient with emphysema.

9. Why does tachycardia develop in hypoxemic patients?

Whenever the body's demand for oxygen increases and its supply decreases (eg, hypoxemia), the nervous system increases the production of epinephrine from the adrenal glands. Epinephrine is a hormone that causes tachycardia (rapid heart rate) and an increase in the strength of cardiac contraction. Tachycardia is a critical physiologic compensatory mechanism that circulates oxygenated blood faster, thus helping to maintain adequate perfusion of the body's vital organs. However, if the underlying cause of the patient's hypoxemia is not corrected, the nervous system, which also requires oxygen, will no longer be able to compensate and the patient's heart rate will begin to fall.

10. How can positive-pressure ventilation cause a decrease in a patient's blood pressure?
